Dr. James Bull said that he thought pulmonary schistosomiasis should be considered in the differential diagnosis of small multiple calcified lesions in the lungs. He had seen a case about six years ago, a British soldier who had served in Egypt and had bathed in the Nile, who was suffering from a brain-stem lesion thought to be granulomatous in type. There was no evidence of syphilis or tuberculosis and an X-ray of the lungs showed a bizarre picture of multiple minute densely calcified foci. The case was never confirmed by autopsy and no calcified foci were seen in the bladder or rectum. Dr. Bull was very struck by the similarity of the X-ray appearances to the lung specimens illustrated in Shaw and Ghareeb's paper (1938). They had performed 282 autopsies on cases of schistosomiasis and at least 33% had pulmonary involvement and many of the lesions were calcified. *S. hæmatobium* was twice as common as *S. mansoni* and 11% showed mixed infection.

Dr. Bull suggested that this lesion might be seen in this country in the next few years as so many residents of these islands had served in the Nile Valley during the war. It was also possible that *S. japonicum* behaved in the same way although Dr. Bull knew of no reference confirming it.

first for surface applications, and subsequently worked out by them for interstitial therapy, remains the simplest, the most useful and generally accepted method. As regards the total dose it has varied in our cases from 6,000 r to 9,000 r delivered in 168 hours; the dosage rate showed an equally wide range from 30-75 r/hr. For interstitial treatment an average of six days is now used.

As regards teleradium, a vast amount of clinical, physical and biological research has been done in the past fifteen years. The magnitude of the task can be illustrated by the problems which the treatment presents: total dose, dosage rate, time of individual treatment, interval between treatments, over-all time of treatment. From the physicist's point of view in the use of beam therapy—the direction of the beam, the combination of multiple ports of entry, and the spatial distribution of radiation are some of the problems. Limitations imposed by the maximum tolerance of the skin, the anatomical configuration of the part traversed by the beam and the position of the lesion are so many added difficulties. To overcome these practical difficulties and to ensure an optimum arrangement for the fields in each individual case, H. T. Flint and C. W. Wilson have constructed suitable frameworks or "jigs" for the various parts of the neck which provide the position of the fields and the direction of the beam. Wilson has thus contributed the principle and provided the facilities for *placing the patient within a known field of radiation in preference to providing unknown fields within the patient.*

Using the present model of the 4 gramme radium unit at Westminster Hospital it takes four to six weeks to treat a lesion in the pharyngeal portion of the tongue; two treatments of fifty minutes each are given daily five days a week. The average tissue dosage is between 5,000-6,000 r; the skin reactions are still at times severe, in degree up to desquamation and moist peeling.

Treatment of cervical lymph nodes.—No method of irradiation can so far compare in adequacy with the surgical removal of the cervical lymph nodes. The wide dissection or "block" dissection associated with the names of Butlin, Crile and, later, Roux-Berger still remains the most certain method of treatment.

The operation should consist in the removal of the deep cervical fascia from the level of the mandible to the clavicle; the sternomastoid muscle, the internal jugular vein, the anterior belly of the omohyoid and often the posterior belly of the digastric are removed, together with the glands in the anterior and submaxillary triangles. It is an operation for the skilled surgeon, and in such hands presents no great risk. The indications for this operation are quite clear-cut: (1) The primary lesion in the tongue should be healed and there must be a reasonable prospect of permanent regression. (2) The glands although palpable and clinically malignant should be mobile or only slightly adherent; they must be not only "removable" but strictly operable. (3) The general health of the patient should not be such as to preclude a major operation. It is necessary to emphasize that the operation should not be undertaken unless these conditions prevail. Incomplete removal is doomed to failure.

If a block dissection is deemed unsuitable, irradiation by teleradium and X-rays is the second-best available. In a few cases additional local needling of a gland or mass is indicated. Regression of cervical lymph nodes for periods of two or three years has been obtained by radiation.

I would have liked to finish this introductory paper with up-to-date statistical tables showing results, but my absence on war service for six and a half years has left a gap in the statistics. The following tables show a record of cases treated before 1939 and a minimum of a five-year survival.

Conclusion.—It is clear that treatment of cancer of the tongue to-day is manifold: radiotherapist, surgeon, physicist, all three are of paramount importance. Adequate treatment needs expensive apparatus, facilities for all types of radiation —beam, needles, seeds, X-rays, laboratories and workshops for the physicists.

that multiplicity of apparently separate primary growths is no bar to radiotherapy; that the actual site influences the technique but not the principles guiding the treatment.

Technique of surgical treatment.—It is the topographically extralingual spread of the disease in certain definite directions which requires extensive and complex treatment. The principles underlying the surgical treatment of such cases are as follows: (1) Control of bleeding should be obtained by preliminary ligation of the lingual arteries or external carotids. Bilateral ligation is sometimes indicated. (2) All intra-oral ablation should be carried out with the diathermy needle, slowly and bloodlessly. (3) Access to the mandible and floor of the mouth should be by reflexion of a flap consisting of the lower lip and the skin of the chin down to the submental area, and extending to the posterior edge of the masseter. (4) The mucosa and the skin should be sutured separately, and drained adequately. With modern methods of anæsthesia, attention to surgical detail and the help of chemotherapy, these operations of considerable magnitude can be carried out with a negligible operative mortality, remarkably little post-operative inconvenience and a speedy recovery.

Age is no contra-indication for such operations. My oldest patient was 76 years of age and has, so far, survived three years without a recurrence.

Cases suitable for surgical treatment are few, no more than 6-7% of cases seen. In the past three years I have had the opportunity of carrying out these operations ten times. There has been so far no operative mortality. 8 of the 10 patients remain free from disease, and 2 died of recurrence; 3 patients were women.

I have come to the conclusion that palliative irradiation of carcinoma of the tongue in cases unsuitable for irradiation is not worth doing as it does not prolong life and rarely increases the patient's comfort. Much better palliation can be obtained by diathermy coagulation.

Radium therapy.—Two methods of radium therapy are employed at Westminster Hospital for cancer of the tongue. Their choice depends solely on the site of the lesion.

For lesions of the anterior part of the tongue insertion of *radium needles* is the method of choice. In lesions of the vallecula, epiglottis, glosso-palatine folds, or in the posterolateral group spreading to the alveolar mucosa or palate, *teleradium* is used. X-ray therapy as the sole method of treatment in cancer of the tongue is disappointing although as an additional source of radiation in cases treated by teleradium, it has proved useful. In both types of cases and in superficial lesions of the floor of the mouth or palate, intra-oral plaques (moulds) are occasionally used to supplement needling or teleradium; especially in cases where, at the junction of the tongue and upper or lower alveolus or the palate, uniform distribution of radiation and an adequate dose are difficult or impossible to achieve by other means.

Distribution of radiation and dosage.—To obtain a homogeneous distribution of radiation in the lesion and surrounding tissue, to assess the quantity of radium needed, and to determine the dose from a given arrangement of needles, the co-operation of a clinically trained physicist is a primary essential. Without such co-operation radium therapy is empirical and there is no control over the efficacy of the radiation. The dosage rate, the total time of treatment, and the estimation of degree of reaction are the clinician's responsibility, and as in other branches of medicine, experience can only be gained by constant practice. The actual insertion of needles or seeds and their retention in the tissues for the desired time require a certain degree of surgical skill. The treatment must be planned and systematic. The lesion in the tongue is of course carefully examined and its extent, position, shape and volume ascertained. The spatial distribution of the needles must fulfil certain physical desiderata and the dosage system devised by Paterson and Parker

case to carry out a careful pre-calculation of any proposed implant so as to bring treatment time as near as possible to the desired over-all time. Even so, however, measurement of exact dimensions on the operating table is far from accurate, so each case is radiographed after implantation. From these radiographs the final estimation of dimensions is made, and hence of the time to give a desired dose. The ring shown on some of the figures is used as a magnification index.

A really poor implant should be dismantled at once and reinserted at a later date. It is indeed one of the defects of permanent radon seed implant that dose cannot be adjusted by alteration of time as with needle implant. Seeds thus call for a much higher degree of accuracy of technique than the needle implant.

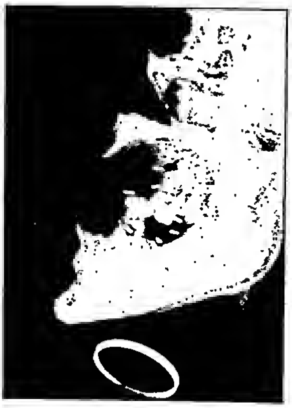

FIG. 4.—Gold seed implant—extensive implant of side of tongue.

It is remarkable how little disturbance most patients suffer even after extensive implants, apart from a rather miserable first post-operative day. Penicillin as irrigation or in lozenges has certainly proved a very great asset in the nursing of mouth cases.

One most important factor requiring further study in relation to satisfactory application of this method of treatment is the dose to be given. There is very little margin between optimum and either insufficient dose or overdosage. In Manchester we have for some time adopted as the standard dose for moderate sized

Dr. Ralston Paterson: There are four practical methods of treatment for cancer of the tongue: (1) Radical operations, such as glossectomy and hemi-glossectomy. (2) Electro-coagulation. (3) Radium beam therapy. (4) Radium implant.

The main theme of my contribution is the superiority of radium implant over any of the other methods. This presumes, however, its use as a well thought out technique using a dosage system with post-implantation check by radiograph.

In making such a claim for implant there is no intention of suggesting that the other three methods cannot give results. All of them can yield a percentage of cure; but it is my firm belief that the patient's chance of survival is greatest when implant is the first treatment used. I would place second, radium beam therapy, third, systematic radical operations whose main defect is the mutilation produced, and well down the scale, diathermy, which often proves little more than a snare and a delusion.

It is essential to keep in mind, however, that where irradiation methods fail, as they do in a fraction of cases, the patient can often be given the best second chance by well conceived and well carried out radical surgery.

The first principle of radium implantation is that the implant must approximate to some simple geometrical form to allow measurable dosage. In practice one finds that the available implants fall fairly clearly into four main groups: Single Plane, Two-Plane, Volume, Radon Seeds.

The *single plane* (fig. 1 A and B) may be considered as a palisade of radium which irradiates a slab of tissue from 1-1½ cm. thick. Ideally both ends of this palisade should be crossed, but in practice only the upper end can usually be crossed and allowance is made in the calculation for the open lower end.

The *two-plane* (fig. 2 A and B) consists of two such palisades, parallel to each other, and so planned as to irradiate a somewhat thicker slab of tissue. The irradiated block of tissue, however, is still relatively flat.

Perhaps the most generally applicable implant in tongue is that known as the *volume implant* (fig. 3) in which any roughly spherical tumour can be included within a cylindrical volume of tissue.

There are, however, in the tongue a few sites which do not lend themselves easily to systematic needle implantation—for example lesions of the tip or of the edge of the tongue. For such cases *radon seed implant* (fig. 4) often offers the ideal solution. In a sense this may be regarded as a curved single plane.

Following the general principles first set out by Regaud at the Fondation Curie, these implants should be left in for seven to eight days. It is essential in

TABLE III.—CARCINOMA MOUTH—TONGUE.
Treated by Radium 1932-1938.

	Number treated	5-year survival
Stages I and II—i.e. node-free when first seen	291	41%
Stages III and IV—i.e. nodes present when first seen ..	174	8%
Evaluation of primary treatment taken alone	138	63%

Mr. W. R. Douglas: In this discussion, as a surgeon, I am concerned solely with the treatment of the metastatic cervical field. The emphasis is on the eradication by surgical dissection of the area of the neck likely to be involved and accessible to surgery—in other words, block dissection of the neck.

I shall confine myself to a consideration of block dissection giving the end-results of a series of blocks carried out for tongue primaries. Out of a series of 500 blocks carried out during the last twenty years for varying primaries I have taken from the years 1935 to 1940 a group of 44 cases. This group consists of block dissections carried out for tongue primaries only. Only cases have been included in which both the primary and the glands were proved positive. All others have been eliminated, for, in order to obtain a true estimate of the value of the block in tongue cases, no questionable cases should be included.

The background of the work is important. At the Christie Hospital and Holt Radium Institute in Manchester (a single hospital) we have been able to centralize tongue cases from the peripheral hospitals. This makes for numbers and efficiency. Also all cases are considered by a team, and this combination of surgeon and therapist is, in my opinion, essential. The two are interdependent. Further, there is an intensive annotation and follow-up system, which makes the notes of the cases accurate as far as possible, and invaluable.

In considering the surgical operation of "block neck" one must think in terms of lymphatic field rather than of glands. Metastatic deposits of carcinoma are present not only in the glands, but also in permeated lymphatics spreading from gland to gland. The conception of removal of glands is wrong, it must be a conception of the quadrate sheet of lymphatic tissue carrying the glands.

This lymphatic sheet, with its focal glands, offers marked resistance to systemic spread. No stronger barrier exists in the rest of the body. Systemic invasion is found in only 25% of cases. On this fact, so long as the primary is under control, depends the success of the block operation.

Embolism is erratic, probably dependent on the histological type of the primary, the position in the tongue, the traumatism and movements of the tongue muscles in the region of the growth. Some emboli are notoriously slow in growth in glands, and some rapid—in fact, even with the closest follow-up, they occasionally overtake one. Sometimes emboli, like the afferent lymphatics to a gland, bypass the regional glands and affect glands at a distance. Very occasionally the contralateral glands are involved first.

This erratic distribution stresses the importance of a wide removal.

In considering the cervical field there are four distinct clinical groups:

Group I.—An early primary with no palpable glands. A group which is likely to be controlled easily, and where only about 10% develop glands subsequently. A close follow-up is necessary.

Group II.—An infiltrating growth, with no palpable glands; but where glands develop to the extent of 35% after the primary has been controlled. The vexed question arises as to whether these cases should be blocked, though no glands are palpable—in other words, should a prophylactic block (so-called) be done? From 1932 to 1934 I carried out a series of prophylactic blocks. 18% contained metastatic glands. In the rest, i.e. 82%, no metastatic tissue was found after careful pathological search. I was therefore blocking 4 out of 5 cases needlessly, and subjecting them to a mortality rate of 3%. Moreover, in the 18% which were implants in good tissue 7,000 r over seven days. This dose has to be adjusted downwards with rather larger volumes or where time is found to come appreciably under seven days. It should correspondingly be increased for very small volumes or for relatively extended times. There is some suggestive evidence in an analysis of the treated cases that slight prolongation of the over-all time—for the standard dose of 7,000 r—might be of real value.

If the tongue is to be treated by intra-oral radium, an implant technique is almost always called for. It seems, therefore, desirable to remind you that in the rather wider field of mouth cancer as a whole, a greater variety of techniques is available. Of these the best—ideal where applicable—is the intra-oral radium applicator, so-called dental mould. In the old days we attempted the use of moulds, even for tongue lesions, but it is too mobile an organ and the experiment was a failure. For lesions of the very posterior part of the mouth, including the real base of the tongue just above the vallecula, some method of external radiotherapy, either by radium beam or beam-directed X-rays, is often the treatment of choice.

I have confined myself here to the question of treatment of the primary growth. The secondary gland involvement is important but is a separate theme. It is not too much to say that systematic radical block dissection is an essential part of any mouth cancer treatment policy. Radiotherapeutic methods of dealing with secondary lymph nodes are largely palliative, and do not compete with block dissection.

In matters of this kind results of treatment are inevitably of interest. We can most usefully take as starting point the first table in the Bradshaw lecture given by Sir Alfred Webb-Johnson, *see Brit. med. J.*, 1941 (i), 1 and 39. In this table he contrasts Butlin's original results with those of the Christie Hospital, Manchester, on a group of 1932-1933 cases. He arrives, from these figures, at a decision just slightly in favour of implant.

The figures for the work done after 1933 are, therefore, of interest (*see* Second Statistical Report from the Holt Radium Institute, Manchester, 1934-1938, Livingstone). Table I shows figures for the summated results of the whole period 1932-1938 for cases of cancer of the tongue only, assessed at five years. Of these years, however, 1938 proved itself clearly superior to the others. It is impossible to say whether this improvement, which was considerable, was due to improving technique or was just a vintage year by chance. In the stresses and strains of war organization, we have not been able to repeat these figures although the 1932-1938 over-all standards have been easily maintained. The results of the 1938 work are shown in Table II. The *over-all* inclusive figure of 39% can reasonably be compared with Butlin's figure for *treated cases only* of 27·9%.

Over-all figures, however, only give the one aspect of the picture, so in Table III an effort is made to arrive at some evaluation of the results of treatment of the mouth lesion, as such, disentangled from the effect of lymph-node invasion. The last group of cases includes all cases in the total sample in which the end-result was not determined in any way by the question of secondary node involvement. 63% five-year survival probably does genuinely represent the real value of tongue implant.

TABLE I.—
CARCINOMA MOUTH—TONGUE.
Treated by Radium 1932-1938.

Stage	Number treated	5-year survival
I	146	51%
II	145	31%
III	122	11%
IV	52	2%
Total	465	28%

III	10	20%
IV	6	17%
Total	51	39%

moment, provided both ends are found and ligatured. There appears to be an efficient collateral lymphatic circulation.

Patients are shocked for twenty-four hours, but quickly recover. They are up within a week, and go out in ten to fourteen days. Some brawny œdema of the face and neck remains for three to six months. Lip movements at the angle of the mouth are interfered with, usually because of damage to the mandibular branch of the facial nerve. Also, arm movements are somewhat limited, because of trapezius loss, but quite a number of patients go back to work.

Bilateral blocks are carried out with an interval gap between the two sides of not less than three weeks, leaving the second internal jugular. Both internal jugulars can be safely taken if there is a three-months' interval. Cases have been done with a shorter interval, but it is wiser to allow a venous collateral circulation to be properly established.

End-results.—In estimating the results of block necks for tongue primaries, no attempt has been made to differentiate between anterior and posterior lesions, or between early and borderline cases. All are included. The five-year survival rate, in which cases are well, with no clinical sign of secondaries, is 30% of all the cases blocked for tongue carcinoma.

Lieut.-Colonel W. L. Harnett (*Medical Secretary to the Clinical Cancer Research Committee of the British Empire Campaign*) said that he had the permission of the Committee to bring forward statistics of 287 cases of cancer of the tongue collected from all the London hospitals between April 1, 1938, and September 3, 1939. These cases constituted 1·9% of all the cancer cases registered, corresponding closely to the Registrar-General's figure of 1·7% for England and Wales in 1937. There were 247 males and 40 females, a ratio of 6 to 1.

The cases were grouped as follows:

	Number		%
Stage I—Confined to organ of origin	101		35·2
Stage II—Adjacent tissues invaded, but lymph nodes not involved ..	21		7·3
Stage III—Lymph nodes involved :			
(*a*) Adjacent tissues not invaded	95	162	56·4
(*b*) Adjacent tissues invaded	67		
Stage IV—Remote metastases present	3		1·0

There were also 65 cases of carcinoma of the vallecula and epiglottis, which had been included with growths of the pharynx.

blocked, the results were little, if any, better than if we had waited for glands to appear. We now adopt a "watch technique" and wait for glands to be palpable. Then a block is carried out, the optimum time being at least six weeks after the primary has settled, so as to avoid the reaction phase. 60% of cancer clinics throughout the world adopt the "watch technique" but it is dangerous unless a close intensive follow-up is observed. If the patient is likely to live abroad, or is non-co-operative, it is better to carry out a prophylactic block; if the lesion is unilateral, then a unilateral block; if a mid-line lesion, then a bilateral block, with an interval of at least three weeks between the two sides.

Group III.—An infiltrating growth, often advanced, with palpable glands. The majority of cases present themselves in this stage for the first time. If the glands are early and are blockable, wait until the primary has been treated and has reacted before carrying out the block. If glands are fixing and are borderline, then fine judgment is required as to whether and when to block. Fixation does not necessarily mean extracapsular spread. It may be only inflammatory, due to sepsis in the primary growth. Borderline cases, if at all possible, should be given a chance. Either treat the primary with gold seed implant or diathermy, and block at the same time; or, if external radiation is used, then block the day after radiation treatment (assuming a one-day intensive treatment is given). Do not wait for the reaction. Flaps are apt to necrose and sepsis to supervene, if the block is done during the reaction phase.

Group IV.—Advanced cases, in which the glands are inoperable and fixed. If the primary can be controlled—and this, of course, cannot be foretold, especially in advanced cases—occasionally it is possible by external radiation to bring an apparently inoperable mass to a stage when it is operable, by reducing the size and the fixity, but these are desperate cases, and only occasionally can one be salvaged.

Three types of operation are in use: (1) The suprahyoid block. (2) The supra-omohyoid block. (3) The full radical block, founded on the Crile block operation of forty years ago. All may be unilateral or bilateral.

The first two types of operation are partial block operations, and consist chiefly in dissection of glands. They are in my considered opinion incomplete, and therefore dangerous. The supra-omohyoid operation takes in a wider sweep than the suprahyoid in that it includes a dissection of the upper deep cervical glands, but any gland dissection is an operation to be avoided.

The radical block is the operation of choice. The cases are usually males, in the proportion of ten to one female, in the region of 60 years old, often in poor general condition because of pain and difficulty in feeding. Arteriosclerosis and chest complaints are common. Yet, in spite of these disabilities, it is remarkable how well they stand up to a full block. Complications are few, and the mortality is 3%. In the last 50 cases our mortality has been nil. It is therefore as safe a procedure as a radical mastectomy.

The anæsthetic we use is pentothal-intratracheal gas and oxygen with a minimum of chloroform. The skin flaps do not include the platysma. The block of tissue is turned back from the mid-line to the trapezius as a hinge. The block includes digastric (both bellies), the omohyoid and the sternomastoid. The spinal accessory is cut across at the level of the transverse process of the atlas, and at this level the internal jugular is double-ligatured.

The block of tissue is freed from carotid and vagus, and all the small cross veins (pharyngeal, facial and thyroid) tied, before the internal jugular is double-ligatured above and below. The second, third and fourth cervical nerves are cut across as the block of tissue is carried back. The fascia is stripped clean from splenius and levator anguli muscles. Any attempt to preserve spinal accessory and cervical nerves interferes with a clean dissection, and therefore might affect the end-result. On the left side the thoracic duct may be injured. This is of no

MEETING HELD AT MANCHESTER ROYAL EYE HOSPITAL

Isolated Oculomotor Palsy Caused by Intracranial Aneurysm

By GEOFFREY JEFFERSON, C.B.E., M.S., F.R.S.

ABSTRACT.—The present paper is concerned with the 55 aneurysms out of a total of 158 that caused isolated paralysis of the oculomotor nerve. The majority arose from the internal carotid artery after it had pierced the dura (supraclinoid). Rarely the aneurysm sprang from the basilar artery. In two-thirds of the cases there had been a subarachnoid hæmorrhage from leakage. Not more than 10% of patients had arteriosclerosis. Calcification of the sac is not a sign that the aneurysm has thrombosed. The only certain way of demonstrating the position and size of an intracranial aneurysm is by arteriography, which is a safe procedure.

The correct treatment is by carotid ligature. In about 8% of normals the circle of Willis is incomplete, therefore percutaneous compression must first be tried. The only fatalities from ligature were in persons in the acute stage of subarachnoid hæmorrhage. Such cases died because of intracerebral hæmorrhage, not from meningeal bleeding alone. In this type of case a clip applied to the neck of the sac is probably a better method. In the more usual cases where the hæmorrhage has been spontaneously arrested common carotid ligature in the neck is probably a little safer than intracranial clipping.

RÉSUMÉ.—Sur 158 anévrysmes, 55 ont donné lieu à une paralysie isolée du nerf oculomoteur. Il s'agit ici de ces 55 cas. Le plus souvent ces anévrysmes sont situés sur la carotide interne au-dessus de sa perforation de la dure-mère (supra-clinoïde), et très rarement sur l'artère basilaire. Deux tiers des cas avaient eu une hémorragie sous-arachnoïdienne par fissure de l'anévrysme. Seulement 10 pour cent des malades souffraient d'artériosclérose. La calcification du sac n'est pas un signe de thrombose de l'anévrysme. La localisation et la grosseur de l'anévrysme ne peuvent être montrées avec certitude que par l'artériographie, qui est peu dangereuse.

Le traitement correct est la ligature de la carotide. Le cercle de Willis étant incomplet dans environ 8 pour cent des cas normaux, il est nécessaire d'essayer d'abord la compression percutanée. Les seuls décès après la ligature survinrent chez des malades opérés dans la phase aigüe de l'hémorragie sous-arachnoïdienne. Ces malades sont morts d'une hémorragie intracérébrale, et non pas d'une simple hémorragie méningée. Dans les cas de ce genre il est probablement préférable de poser un clip sur la tige de l'anévrysme. Dans les cas plus ordinaires, où l'hémorragie s'est arrêtée spontanément, il est probablement un peu moins dangereux de lier la carotide primitive que de poser un clip intracranien.

SUMARIO.—En éste trabajo se estudian los 55 aneurismas que, de un total de 158, causaron parálisis aisladas del nervio motor ocular común. La mayoria radicaban en la arteria carótida interna después de su penetración en la duramadre. En casos excepcionales el aneurisma se hallaba asentado en la arteria basilar. En las dos terceras partes de los casos, existia el antecedente de hemorragia subaracnoidea causada por pérdida sanguínea gota á gota. Los enfermos afectos de arterio-esclerosis no excedieron del 10%. La calcificación del saco no presupone que el aneurisma se halle trombosado. El único procedimiento para demostrar la situación y el tamaño del aneurisma intracraneal con certeza, lo proporciona la arteriografía, procedimiento desprovisto de peligro.

Stage III— Anterior site, 98 Posterior site, 56 Whole tongue 8	Number	Survived 5 years	Died with cancer	Died without cancer	Untraced

	3	—	3	—	—

A method of estimating the five-year survival rate by comparing the actual survival time in months with the expected survival for five years of a group of the general population having the same age-sex constitution was then explained. Expressing the actual survival time as a percentage of the expected survival, the results of treatment are shown in Table II.

TABLE II

	Number of cases	% of expected Stage I	 Stage III
Surgical or diathermy excision	37	88·4	28·3
Interstitial radium	66	64·1	43·5
Teleradium	33	62·8	32·9
High-voltage X-rays	44	59·7	34·7

The above figures deal only with the treatment of the primary growths.

Mr. Anthony Green: *Radon seed chains for carcinoma of the tongue.*—Two points have been brought out by previous speakers: First, that interstitial radiation gives the best results in treatment of cancer of the tongue, and second that radon seeds are in some instances desirable because of the site and extent of growth and/or the general condition of the patient.

At the Royal Northern Hospital a method of chain radon seed implant has been developed. This has the advantages of a radon seed implant in that an old patient can move his tongue, cough and spit without distress. Moreover many of the advantages of the radium needles are preserved in so far as the distribution of radiation is very much better than with individual radon seeds and that the seed chains can be removed at any time during the treatment. Strong end loading of the seeds saves the necessity of crossing the ends as with radium needles.

The radiographs (not reproduced) show two cases of chain seed implants into the tongue indicating how evenly the distribution can be obtained for the dorsum of the tongue or the lateral surface of the tongue; moreover the flexible nature of these chains makes it possible to irradiate curved surfaces such as the base of the tongue. This method of implantation depends for success on careful and close team-work with physicists.

The seeds are introduced with difficulty by pulling them after a stout needle inserted through the tissues, or better still by inserting them through a trochar and cannula especially made for the purpose.

The results of this new method, which is now between two and three years old, are encouraging, and the King Edward's Hospital Fund for London has financed further investigation and development of this type of treatment for this and other sites in the body.

the internal carotid, middle cerebral and basilar arteries are the commonest sites for aneurysm and are roughly equally vulnerable in this respect. Carotid aneurysms are reasonably easy to diagnose but the basilar are much more difficult, so that the former produce the chief material for clinical, as opposed to pathological, study. This fact is made abundantly clear from the fact that of 143 basilar aneurysms collected by McDonald and Korb, no less than 139 were post-mortem discoveries. Had every case been correctly diagnosed beforehand the result would have been no different, for surgery has no answer to the basilar aneurysm. The case is fortunately quite different with aneurysms of the carotid tree, as my own material shows, for in arteriography, carotid or vertebral, we have a method which shows clearly in most cases the exact site of the aneurysm, a fact of great practical importance.

The congenital nature of the majority of these aneurysms from defects in the muscular coat (Eppinger, 1887; Forbus, 1930) is agreed on all hands, the word "congenital" being used in the same sense as when it is applied to an inguinal hernia appearing in later life. It is unlikely that aneurysms often exist from birth onwards, they develop later through inborn defects. Occasionally they must be truly congenital as in one patient of mine, a baby 9 months old who nearly died of a subarachnoid hæmorrhage and was blind for nearly three weeks from subhyaloid hæmorrhages. She is recovering. This is one of the youngest patients on record.

My own material of 158 cases seems to be the largest in which the patients have been observed during life by one man. Beadles' (1907) famous collection contained 555 cases but 114 came from the post-mortem room and from hospital museums, 441 from the literature; Dandy describes 108 cases in his book, but 44 of them were from the post-mortem register at Johns Hopkins Hospital, the valuable study of McDonald and Korb is entirely a compilation save for 2 cases. My own cases are analysed in Table I. I have not used the necropsy material of the Royal Infirmary unless I had observed the case whilst alive.

TABLE I

A. Subarachnoid hæmorrhages without local signature			32
B. Supraclinoid carotid aneurysms (after the vessel has penetrated the dura) ..			55
C. Carotid aneurysms in cavernous sinus (infraclinoid)			45

E. Aneurysms producing neurological signs other than ocular or oculomotor ..			7

This is very much a surgeon's picture because the first group of plain subarachnoid bleeding is relatively small; such cases are usually admitted to medical wards. Of the 32 cases of this kind, 10 died in hospital, 16 are known to be alive and well, 6 are untraced. The lengths of survival have been 13, 12, 12, 11, 7, 7, 5, 4 and less years.

THE ISOLATED OCULOMOTOR PALSIES

That an intracranial aneurysm might cause oculomotor palsy has long been known. Examples can be found in those admirable collections of cases made by Brinton (1851-52), Gull (1859), Peacock (1876), von Hoffmann (1894), Fearnsides (1916), Conway (1926) and Szekely (1928), papers that are amongst the classics of the earlier literature of aneurysm. One of the first, if not the first, to speak specifically of the relationship between oculomotor palsy and aneurysm was France, ophthalmic surgeon to Guy's Hospital. Writing in 1846 he said that given a third nerve palsy with no evidence of tumour we should not be far wrong in assuming that the cause was "a sanguineous effusion of circumscribed vascular enlargement in the vicinity of the nerve of the third pair". He based this opinion on the post-mortem findings in a clinically observed case. This was an inspired deduction but although the fact was there to know it must have been remembered by very few, since the establishment of a real clinical picture of aneurysm as a clinical entity rather than as a museum piece, as something likely to cause signs that could be recognized and traced to a source during life, was left to C. P. Symonds (1923). The relationship between oculomotor palsy and aneurysm was further observed by Albright (1929), Dott (1933), Nattrass (1928), E. Bramwell (1934), Garvey (1934) and by myself in published and unpublished material.

The third nerve leaves the mid-brain from the medial border of the crus cerebri and as Weber long ago pointed out the approximation allows perfectly of a syndrome of crossed

El tratamiento correcto consiste en la ligadura de la arteria carótida. Cerca del 8% de los individuos normales poseen el círculo de Willis incompleto y por ésta razón la compresión transcutánea debe intentarse inicialmente. Los únicos resultados fatales de la ligadura ocurrieron durante el período agudo de la hemorragia subaracnoidea. La causa de la muerte fué, no solo la hemorragia meníngea, sino también la hemorragia intracerebral. En estos casos es probablemente lo mejor aplicar un *clip* al cuello del saco. En casos más frecuentes, en los que la hemorragia ha cesado espontáneamente, la ligadura de la arteria carótida en el cuello es probablemente algo más segura que la aplicación de un *clip* intracraneal.

АБСТРАКТ.—Настоящая статья касается только 55-ти из 158-ти случаев аневризм, которые произвели изолированный паралич глазо-моторного нерва. Большинство аневризм возникло из внутренней сонной артерии после ее прободения через верхне-клиноидную часть твердой оболочки. Реже аневризма возникала из базилярной артерии. В двух третях случаев было субарахноидальное кровотечение вследствие просачивания крови. Не более как 10% больных страдало артериосклерозом. Кальцификация аневризменного мешка не является признаком тромбоза аневризмы. Единственным способом демонстрации позиции и величины интракраниальной аневризмы является артериография, которая представляет из себя совсем безопасную процедуру.

Правильным лечением является лигатура сонной артерии. В 8% артериальный круг Виллиса несовершенный, и оттого необходимо прежде всего испробовать чрезкожное сдавливание артерии. Смертельный исход от лигатуры бывает только в тех случаях, когда имеется острая стадия субарахноидального кровотечения. Такие больные умирали не исключительно от менингиального, а от внутримозгового кровотечения. В таких случаях перевязка шейки аневризменного мешка является лучшим способом. В более обыкновенных случаях, когда кровотечение останавливалось самопроизвольно, лигатура общей сонной артерии на шее более безопасна, чем внутримозговая перевязка.

In my previous writings a beginning was made at systematizing the semiology of aneurysms of the circle of Willis according to dominant symptom-sign patterns. This breaking down of the neurological consequences of aneurysms has always appeared to me to be a major work and a necessary prelude to the growth of knowledge, for it is likely that the prognosis of vascular abnormalities in different situations may well have different significances in terms of working capacity and survival. I propose to carry the matter further by presenting my 55 cases in which an isolated third nerve paralysis has been the essential feature.

This subject is one of great fascination and since many of the clinical syndromes come within the province of the ophthalmologist it should be of interest to present the relative frequency with which they have occurred in so far as illustrations can be drawn from the experience of one man. I have reviewed the literature in my previous papers (1937, 1938). Since then there have been some notable contributions: McDonald and Korb (1939), Richardson and Hyland of Toronto (1941), Krayenbühl of Zürich (1941), and Dandy of Baltimore (1944). The diagram of McDonald and Korb constructed from a review of 1,125 reported cases is so generally informative that it is reproduced here (fig. 1). This shows that

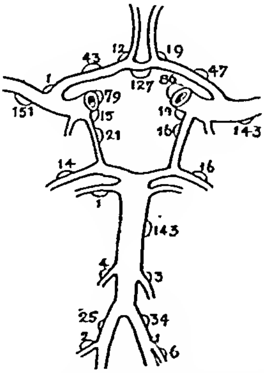

FIG. 1.—Schema of aneurysmal sites in 1,023 (of 1,125) cases.
From McDonald and Korb, *Arch. Neurol. Psychiat., Chicago*, 1939, 42, 298.

the internal carotid, middle cerebral and basilar arteries are the commonest sites for aneurysm and are roughly equally vulnerable in this respect. Carotid aneurysms are reasonably easy to diagnose but the basilar are much more difficult, so that the former produce the chief material for clinical, as opposed to pathological, study. This fact is made abundantly clear from the fact that of 143 basilar aneurysms collected by McDonald and Korb, no less than 139 were post-mortem discoveries. Had every case been correctly diagnosed beforehand the result would have been no different, for surgery has no answer to the basilar aneurysm. The case is fortunately quite different with aneurysms of the carotid tree, as my own material shows, for in arteriography, carotid or vertebral, we have a method which shows clearly in most cases the exact site of the aneurysm, a fact of great practical importance.

The congenital nature of the majority of these aneurysms from defects in the muscular coat (Eppinger, 1887; Forbus, 1930) is agreed on all hands, the word "congenital" being used in the same sense as when it is applied to an inguinal hernia appearing in later life. It is unlikely that aneurysms often exist from birth onwards, they develop later through inborn defects. THE ISOLATED OCULOMOTOR PALSIES

That an intracranial aneurysm might cause oculomotor palsy has long been known. Examples can be found in those admirable collections of cases made by Brinton (1851-52), Gull (1859), Peacock (1876), von Hoffmann (1894), Fearnsides (1916), Conway (1926) and Szekely (1928), papers that are amongst the classics of the earlier literature of aneurysm. One of the first, if not the first, to speak specifically of the relationship between oculomotor palsy and aneurysm was France, ophthalmic surgeon to Guy's Hospital. Writing in 1846 he said that given a third nerve palsy with no evidence of tumour we should not be far wrong in assuming that the cause was "a sanguineous effusion of circumscribed vascular enlargement in the vicinity of the nerve of the third pair". He based this opinion on the post-mortem findings in a clinically observed case. This was an inspired deduction but although the fact was there to know it must have been remembered by very few, since the establishment of a real clinical picture of aneurysm as a clinical entity rather than as a museum piece, as something likely to cause signs that could be recognized and traced to a source during life, was left to C. P. Symonds (1923). The relationship between oculomotor palsy and aneurysm was further observed by Albright (1929), Dott (1933), Nattrass (1928), E. Bramwell (1934), Garvey (1934) and by myself in published and unpublished material.

The third nerve leaves the mid-brain from the medial border of the crus cerebri and as Weber long ago pointed out the approximation allows perfectly of a syndrome of crossed or alternating hemiplegia. When contralateral limb signs are present they usually indicate a small intracerebral hæmorrhage, rather than crus compression. The latter is a rare happening and aneurysms which affect the nerve do not usually impinge on the crus (*see* Milletti's exceptional case, 1946). The reason is what we might call the "type aneurysm", producing oculomotor palsy alone, is rarely large enough to reach the crus, the nerve being compressed at the anterior end of its course through the basal cisterns and just as it plunges into the dural covering of the cavernous sinus. Reference to fig. 2 will make this clearer; it will be seen that a relatively small aneurysm easily reaches the oculomotor nerve and I have indicated that the nerve is vulnerable to blow-outs on the walls of either the carotid or of one or the other of the vessels that comprise the posterior end of the circle of Willis. In point of fact, the anterior (i.e. carotid) aneurysms of the circle of Willis far outnumber the basilar in causing oculomotor palsy —52 of my 55 cases. It seems rather curious considering the high necropsy incidence of basilar aneurysms that in surgical practice they should so uncommonly compress the third nerve. The deduction that I draw is that, although theoretically (*see* fig. 2) they could produce much the same cranial nerve palsies as do those of carotid origin, they do not. The probability of a third nerve palsy is not in fact great unless the aneurysm springs from the basilar at its bifurcation and the majority occur on the stem more caudally. A fairly large number of basilar aneurysms gives rise to a plain subarachnoid hæmorrhage, the source of the hæmorrhage remaining clinically undecipherable.

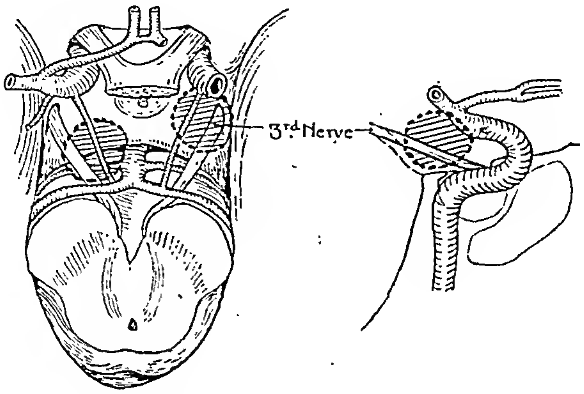

FIG. 2.—Relationship of carotid to third nerve.

A very good example of an average supraclinoid aneurysm is shown in a drawing by that most intelligent and accomplished man, the late Dr. E. W. Twining (fig. 3). The case illus-

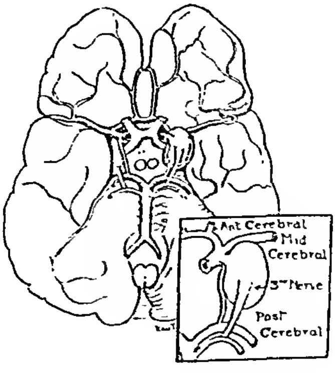

FIG. 3.—Drawing of supraclinoid aneurysm, causing third nerve palsy (E. W. Twining).

trated is of some historical importance since it is the first in which a direct attack was made on an intracranial aneurysm. This was in 1927 and although I failed to accomplish anything it was a first step in the right direction, i.e. verification and cure.

In the illustration the aneurysm can be seen to arise from the carotid trunk soon after it has entered the cranial cavity by piercing the dura. It is, therefore, supraclinoid in position. The posterior communicating artery runs back below the aneurysm, but in another example it might have been above it. The sac is directed backwards and is pear-shaped, two features which are remarkably constant. Eppinger noticed that aneurysmal sacs were usually orientated in the direction of the blood flow but we may be sure that whatever the factors are that rule the configuration of aneurysms, they take their shape, size and direction because they must. In fig. 4 (p. 429) the sacs of aneurysms will be seen delineated in life by arteriography; the aneurysms are small and strikingly similar in shape and situation, all arise from roughly the same point on the carotid. I can see no other explanation for such relative uniformity except (*a*) that the area of vessel wall that gives way is always very limited, probably no more than 2 or 3 mm. in diameter, (*b*) that it is nearly always in the same place, and (*c*) that the aneurysm's eventual size depends on the intravascular pressure and the material available for repair. I fancy that the small extent of the weakened wall is the most important feature.

Referring again to fig. 3 the third nerve is seen to be flattened and to disappear on the sac. The nerve is rarely completely divided by the pressure of the sac, for in all survivors but one it has recovered, though recovery may be long delayed and incomplete. Judged from proven cases in my own series the aneurysm that caused the oculomotor palsy sprang from the carotid in all but three, who had negative carotid angiograms. Presumably in those the site of the aneurysm was the basilar or posterior cerebral in the beginning of its course. Had they come from the posterior communicating artery they would probably have filled with thorotrast; the basilar aneurysm never does so unless the vertebrals are themselves injected.

SIGNS AND SYMPTOMATOLOGY

The most striking feature of any third nerve palsy is, of course, ptosis. The closure of the eye has in every case been preceded by a short period of diplopia and visual confusion which patients have not always correctly analysed subjectively.The sufferers are usually in such severe pain in the ipsilateral forehead and in the eye that they have been in no state for introspection. The majority of the patients localize the pain to the forehead, side of the nose and inner canthus where it is singularly sharp and penetrating; this seems to be a characteristic pain. A constant feature, too, has been the statement that they have closed the lid because it felt heavy and because the pain was so severe that it made them close the eye. They wake one morning, one to seven days after the onset, to find that it will no longer open. It then remains closed for several weeks, but very rarely indeed permanently, whether the carotid is ligatured or not. The cause of the recovery is partly shrinkage by thrombosis sufficient to free the nerve to some extent as a sequel either of ligature or of natural causes. It may be due partly to the action of Müller's muscle. Although considerable recovery takes place in time, the nerve in my experience almost never regains function so completely that there is perfect mobility of the globus oculi in all directions and with parallel visual axes. The movement that returns best is internal rotation; by synergy with the external rectus horizontal movement is good. The muscle that recovers least well is the superior rectus and here is often seen a curious paradox, that the upper lid recovers and is elevated enough to allow of free vision while the superior rectus remains paralysed. The cause is most likely to be found in the action of Müller's muscle: I discussed this important feature of dissociated recovery in my 1938 paper, adopting an explanation by axon crossing in regeneration even although the internal pattern of the nerve is not much disrupted. The same features were observed in experimental division of the third nerve in the macaque by Mahoney and Sheehan (1936). They ascribe the opening of the lid to Müller's muscle. Another curious feature can be observed in downward movement, the lid often elevates a millimetre or so for a fraction of a second as the globe turns down and then the lid descends. L. Rogers (1946) has recently described another feature—opening of the lid on turning the eyes to the opposite side.

The pupil is only at first classically dilated and fixed but within two to four weeks it usually contracts somewhat, though remaining larger than that on the normal side. Occasionally a sluggish light reaction reappears and a parasympathetic reinnervation may be assumed. The reduction of the pupillary aperture as a natural event before the recti recover seems to indicate that the dilator fibres are incapable of maintaining a constant and permanent maximal contracture tonus. The lack of complete recovery in the nerve as a whole may be of the same order as in the severer cases of facial palsy where movement never returns with all the nuances and qualities of the normal. The failure is very likely contributed to by the pressure of the aneurysm, for even should it completely thrombose there will still remain a mass submitting to the pulsations of the carotid artery. That the nerve can escape from it seems impossible.

The pain in the head which is the characteristic and distinguishing accompaniment of aneurysmal compression of the third nerve is unilateral and within the distribution of the first division of the trigeminus. This is a referred pain and must be due to stimulation by the aneurysm of sensitive basal structures. The most likely site for this is the upper border of the cavernous sinus, to which the sac may become adherent. I have found that electrical stimulation at this place under local anæsthesia causes severe pain in the eye and forehead. The only alternative mechanism that suggests itself is that the pain is caused by a drag on the arterial trunk itself, i.e. that the aneurysm's pulsation pulls on the vessel. This is possibly the commoner cause. Either explanation would give the reason why pain ceases when the aneurysm thromboses, for this is the case.

There may be overflow beyond the confines of the ophthalmic trigeminal division when the pain is severe, but violent occipital pain, especially when associated with nuchal stiffness, indicates that the aneurysm is leaking into the subarachnoid spaces. In parenthesis, it may be recollected that it was the pain accompanying the oculomotor palsy that led the older clinicians to diagnose these aneurysmal cases as examples of neuritis of some theoretical sort or another, or of periostitis of the superior orbital fissure. Actual anæsthesia of the first division does not occur with supraclinoid aneurysms. When present it is a sure indication of a subclinoid anterior cavernous aneurysm and usually carries with it paralysis of more motor nerves to the globus oculi than the third alone (Jefferson, 1938).

On the other hand these supraclinoid aneurysms not uncommonly produce a subjective feeling of numbness in the forehead and nose when the pain is very severe though the corneal reflex is not recognizably diminished. This is a puzzling symptom. It might be due to the aneurysm exerting pressure from without on the ophthalmic fibres of the trigeminal nerve as they lie in the roof of the cavernous sinus.

Subarachnoid hæmorrhage: There have been in my series of 55 cases of aneurysmal isolated oculomotor palsy, 40 in which a subarachnoid hæmorrhage has occurred by leakage, i.e. about 70%. In 7 it was so severe as to be fatal whilst the patients were still in hospital but was usually not very bad. The results in the others will be given later, nearly all immediate survivors are still alive (*see* Table of Cases). There is no doubt that the most dangerous period is the initial bleeding, the period of the sufferer's first admission to hospital. If he recovers then his chances are very fair but not perfect. The following cases illustrate these hazards:

CASE I.—A. S., female, aged 21, was admitted to the medical ward of the Royal Infirmary 23.8.27 as an urgency complaining of head pains and diplopia. She had collapsed during her honeymoon with terrific pain in the head and neck, had lost consciousness and remained semiconscious for a week, then slowly recovered. The left eye was found to be closed when she was conscious enough to test it and remained so for four months when it opened with consequent diplopia. The pain was situated in the left forehead low down, at the inner canthus. A year later she was readmitted after an attack of severe pain like a knife entering the left vertex, she lost consciousness for an hour or so and was doubly incontinent. The positive neurological signs were partial left third nerve palsy, dilated fixed left pupil and hæmorrhages into the left disc. She rapidly recovered. She was then lost sight of for eleven years when she was readmitted 30.8.39. She had collapsed in the street from a subarachnoid hæmorrhage. She was transferred from a neighbouring hospital twelve days later; there were still 150,000 red cells in a yellowish cerebrospinal fluid indicating that some leakage from her aneurysm had continued. There were again hæmorrhages in the discs and a complete left oculomotor palsy. There was no trigeminal anæsthesia. She gave a history of several losses of consciousness during the years past; these were epileptic episodes and were no doubt caused by a brain-scar from leakage of blood into brain tissue. Epilepsy is a not uncommon sequel in survivors of aneurysmal hæmorrhages (Jefferson, 1937). X-rays of her skull showed a fine pea-shaped scale of calcification opposite the tip of the left posterior clinoid process. This was evidently the wall of the aneurysm; recent hæmorrhage demonstrated that however impervious the wall might be in its calcified part it was still frangible elsewhere on its circumference. That the weak place was at the neck subsequent events were to show. Arteriograms were made revealing a sizable cavity inside the aneurysm (fig. 4c). I decided to put a silver clip on the neck of the aneurysm. This was done through a transfrontal flap on 14.9.39. After a ventricular tap had removed 25 c.c. of yellow fluid the left frontal lobe was easily elevated. There were dense arachnoidal adhesions about the left optic nerve. The aneurysm was at once visible behind and lateral to the trunk of the carotid artery. It was round and greyish-yellow, measuring about 1·5 cm. across. By gentle dissection and by rotating the aneurysm laterally its neck was well seen. A silver clip was placed upon it but I was not satisfied that it grasped it completely across. A second clip was therefore tightened on the neck. The closure of the clip was followed by an immediate gush of blood that filled the wound in a second or two. Clearly the neck had given way. The bleeding was controlled with hot wet cotton packs held in situ by gentle pressure whilst the anæsthetist compressed the carotid in the neck and Mr. Schorstein cut a muscle graft from the thigh. The cotton packs were removed and the hæmorrhage was found to be arrested. Muscle was tucked in around the aneurysm to form as complete an ensheathing layer as possible. The wound was closed and a transfusion given. Later I regretted very bitterly that I had not made more sure of hæmostasis by either ligaturing the carotid in the neck or clipping it right across intracranially.

Although at first blush, it seems to be a dangerous step to clip or ligature the carotid intracranially there is in truth extremely little difference between that and tying it in the neck. The ophthalmic artery is the only important branch given off between these two sites of election if we disregard the very small branches to the pars glandularis of the pituitary. However, that the possible anastomotic channel is of some importance is shown by the fact that in three fistulous aneurysms in which I have tied the artery in the neck and in the head as well, the vision in the ipsilateral eye has not been lost, which speaks well for the collaterals of the ophthalmic artery. The most disturbing feature of intracranial carotid ligature is that if the patient were to become hemiparetic it is next to impossible to take the clip off again.

The course of the case under discussion was that she did excellently and was transferred to the Convalescent Branch 9.10.39 but six days later she suddenly bled again, this time into the ventricles and died on the twenty-ninth day after operation. The neck of the aneurysm had given way again. The specimen was lost when the Surgical Research Department was destroyed by enemy action shortly afterwards. In the afterthought it is clear that nothing would have saved the patient but two clips on the carotid intracranially, one above and one below the origin of the aneurysm. It is not known, of course, whether she would have survived that procedure.

CASE II.—Miss M. P., aged 29. The writer was asked to see this patient in 1932 by his colleague Dr. Hilliard Holmes. She was then aged 14 and a few days before she had had a severe subarachnoid hæmorrhage proved by lumbar puncture, after which a third nerve palsy had appeared. The question of ligature was discussed but was not proceeded with because we were, as we would now think, unnecessarily pessimistic about its risks. It was thought that even if nothing was done, her chances of survival were, at the worst, very fair. This proved to be a correct conjecture. For the first five years she did housework and for the next seven she worked as a nurse. Her oculomotor palsy had never quite recovered and at times she used to have severe pain in the forehead and inner canthus lasting for days on end. On 29.9.46 she had a "faint" and fell, losing consciousness for half an hour. She had very severe pains in her head and neck and was readmitted to the Manchester Royal Infirmary under Professor Oliver as a probable fresh rupture of her aneurysm. The C.S.F. was, however, clear, cells 7, protein 30. Skull X-rays showed a small shell of calcification slightly above and to the right of the posterior clinoid process. This was evidently the old aneurysm of nearly fifteen years ago. Angiography 19.10.46 by my Chief Assistant, Mr. A. N. Guthkelch, showed that it was not thrombosed since thorotrast entered the sac. He accordingly tied the common carotid artery and four weeks later the internal. No untoward signs followed and she was discharged, more free from pain than she had been for many years.

These two cases demonstrate how an aneurysm may in young persons persist for years before it causes urgent symptoms again and that although in the meantime the wall has calcified in part the cavity has not been obliterated by thrombosis. In neither of these patients did the original third nerve palsy fully recover in the intervals of twelve and fourteen and a half years respectively between their hospital admissions.

C.C.A. = Common carotid artery (15 ligations). I.C.A. = Internal carotid artery (8 ligations).

ARTERIOSCLEROTIC ANEURYSMS

Besides the congenital aneurysms there is another group, larger than is often realized, in older people with arteriosclerosis; its size is only impressive in a large series of cases (cp. Berger, 1923; Saphir, 1933). Five of my isolated third nerve palsies were hypertensives and in the whole series were 15 such patients, about 10%. The prognosis is naturally graver, but old though they often are, they do not die as quickly or universally as might be imagined, as the appended table shows.

Moderate hypertension is not an absolute contra-indication to ligature, though the majority must be refused. The internal carotid of one and the common of another have been tied with survival—for eight years in the first, the second has been done only six months. This is a much lower proportion of ligatures than in the more usual type with normal ranges of blood-pressure. The supposed increased speed of the intracranial circulation in hypertension might be taken as favourable to the establishment of a collateral circulation but against this must be set the state of the arteries themselves, for in many the lumen is so much reduced by endarterial proliferation that any supposed benefit conferred by speed is in fact more than offset by diminution of flow. Angiography may help in making visible the calibre of the vessels, but some are obviously such poor risks that the clinician can make up his mind without angiography that the aneurysm is incurable and must be left to its fate. Even then some of the patients die not from rupture of their aneurysm but from angina or myocardial failure. This has happened in 4 of my own cases.

15 PATIENTS WITH ANEURYSM, HYPERPIESIS AND ARTERIOSCLEROSIS.

In Cases 1 and 15 the carotid was successfully tied.

DIFFERENTIAL DIAGNOSIS

It must be reiterated that this paper concerns itself with paralysis of the oculomotor nerve alone without coincident lesions of others of the cranial nerves. This removes from consideration a number of possible ætiological agents. At different times in the past all manner of causes have been suggested for third nerve palsy: cold, debility, rheumatism of the sphenoidal (superior orbital) fissure, sinusitis, syphilis, neuritis, diabetes, disseminated sclerosis, brain tumour, almost anything except aneurysm. A man can only speak authoritatively from his own experience and the writer's has been that there has been only one really frequent cause, namely aneurysm, and this he has taught for many years. It was the strength of this conviction which led to the first known exploration for aneurysm in 1927. At this date the relationship was recognized by few others. Of other causes, there is a group due to head injury, either directly or from expanding clot and a very few caused by brain tumours. Isolated third nerve palsy is not often seen with brain tumours and when it occurs the mechanism is usually herniation of the temporal lobe into the tentorial hiatus (Jefferson, 1937). In 3 cases a frank palsy with complete ptosis resulted from a pituitary tumour but it was never then unassociated with chiasmal and other neurological signs. Only twice has a positive Wassermann reaction been present, and that without an aneurysm, for the reaction was negative in the whole 158 cases of the aneurysmal series. Of course, taking the diplopias by and large, disseminated sclerosis and myasthenia gravis would account for the majority but these diseases do not cause pure, unilateral and complete third nerve palsies. It is the completeness of the paralysis in the vast majority that is so characteristic of aneurysm. The aneurysm, because of the relationship of carotid and oculomotor nerve, always seems to press on the nerve severely enough to interrupt entirely its conduction for a time, at all events. It cannot be said that the exceptions are never met with, recovery occasionally manifests itself quickly and by the time the case is seen the palsy may be partial. But the patients almost invariably say that the behaviour of the eye has been such that a total palsy at one time could safely be inferred.

Another important feature is that the onset of paralysis is speedy, a matter of hours or, at the most, days and that it is always accompanied by very severe pain in the distribution of the first trigeminal division, and especially at the inner canthus. The only disorder which exactly mimics aneurysmal paralysis of the third nerve is periodic or intermittent third nerve palsy. I will not attach the term "ophthalmoplegic migraine" to this condition for I feel that knowledge is not advanced by including one condition which I do not fully understand in another almost equally obscure. Edwin Bramwell (1934) did much to extract the aneurysms from these vague clinical groupings. It is true that periodic oculomotor palsy is a condition that, like migraine, begins in youth and is associated with headache but its cause is purely conjectural. I have seen half a dozen or so cases, one of whom had had 30 attacks of oculomotor palsy. Angiograms have been made on 4 with absolutely negative results. The vessels were of excellent calibre, their distribution was normal and there was no sign of angiospasm. The difference between these cases and aneurysmal compression is that in the periodic palsies the nerve usually recovers so completely that an entirely fresh palsy is possible and may be repeated time after time. In the aneurysms the recovery after a single episode is never complete enough for so strikingly fresh a palsy to present itself. It is in this disparity between the degrees of recovery that the key to differentiation usually lies.

Even if after many attacks some permanent defect in oculomotor function persists there will still be the history of earlier attacks with complete return of function. Nor is that all, for although aneurysms can occur in youth and even in babyhood as I have briefly illustrated it is rarely that they do so, whereas the periodic palsies usually start in childhood. Further still, not only the completeness but the rapidity of the recovery gives a further differentiating clue.

A condition which also may mimic aneurysm, though the similitude is nearer with infra- than with supra-clinoid aneurysms, is carcinoma or endothelioma of the nasopharynges. The symptomatology of neurological complications caused by invasion of the skull base has recently been described by Erik Godtfredsen (1944) in an admirable monograph. Curiously, Godtfredsen does not consider aneurysm in his differential diagnosis, though the mimicry can be nearly but not absolutely exact. I have found difficulty in not more than 3 cases because there is usually a striking difference in the initial and in the dominant signs of the two conditions which can be systematized thus:

A. Isolated oculomotor palsy never occurs with nasopharyngeal carcinoma as the only sign.

B. In nasopharyngeal tumours the commonest nerve involved is the trigeminal (71%, Godtfredsen) and of the motor nerves to the eyeball the abducens is the one most often paralysed. This is quite different from the cavernous aneurysm syndrome where lesions of trigeminus are associated with palsy not only of the sixth nerve but of the third and fourth as well.

C. With nasopharyngeal tumours paralysis of the ninth to twelfth cranial nerves not uncommonly accompanies ocular palsies. This could only happen with basilar or vertebral aneurysms; third nerve palsies are rare in the first and absent in the second of these sources.

D. Metastatic deposits in the cervical glands, often unilateral, are very common in nasopharyngeal tumours; they never, of course, occur with aneurysms.

In angiography we have a method of differential diagnosis which is very reliable but it should be added that plain X-rays will sometimes show calcification in the aneurysmal wall, though not until it has been there for some years. In one patient whose carotid I tied in 1935 no calcification was then present, but in 1945 on review the aneurysmal wall could be clearly seen reproducing to a nicety the angiographic appearances of ten years before. In another case (Case II) reviewed twelve years after the aneurysm first made its appearance the wall was also calcified but in this case the vessel had not been ligatured. The importance of this case is that it shows the calcification is not in itself a sign that the aneurysm is "dead", and further, since the patient was a girl of 16 when first seen, that calcification can occur in youth as well as in age. It should be added that erosion of the petrous bone may sometimes be seen in basal projection X-rays of patients suspected of malignant invasion. X-rays can thus assist in the diagnosis of either condition.

ANGIOGRAPHY

A brief comment will suffice for a subject on which there are already several monographs and important papers (Moniz, 1927, 1931, 1933; Reichert, 1943; Engeset, 1944; List *et al.*, 1945). The first three angiograms that showed up aneurysms were all made independently in 1933 by Dott, Moniz and Lima, and the writer. Angiography is the surest way in which the presence of an aneurysm can be diagnosed and its exact site and dimensions made visible. It has been done in 24 cases. In fig. 4 A–E the silhouettes of a few cases are shown. It will be observed that the aneurysms look very similar, that they arise in much the same place, that most of them are situated posterior to the carotid trunk in the direction of the blood flow, taking into account the syphon bend of the carotid which Moniz was the first to demonstrate *in vivo*. In one case there is an anterior as well as a posterior aneurysm. This is rare. Irregularities in shape and in shadow density are due, not to peculiarities of external contour but to laminated clot inside. In other words, the angiogram is a picture of the inside of the aneurysm. In fig. 4 F no aneurysm was present but the horizontal part of the artery in the cavernous sinus is seen to be elevated above the skull floor. This was a case of nasopharyngeal tumour and the arteriogram demonstrates not only the absence of an aneurysm but an abnormality in the course of the carotid which is evidently running over a mound of tumour infiltrating the skull base. This was proved to be so at operation.

TREATMENT

This revolves round the question of carotid-ligature, a subject which has a huge literature of its own. The first surgeon to tie the carotid was Astley Cooper; his cases were aneurysms in the neck. The operation was first done for a carotico-cavernous aneurysm inside the skull by Benjamin Travers (1809). Krayenbühl (1941) says that the first operators for saccular aneurysms were Coe and Le Fort but in reality both these aneurysms were fistulous. Horsley (Beadles, 1907) seems to have been, in fact, the pioneer. Nor could an operation for saccular aneurysm have been performed before Horsley's day, until, that is, neurology was sufficiently advanced to differentiate the condition and neurosurgery sufficiently perfected to allow of verification during the life of the sufferer, relatively recent events.

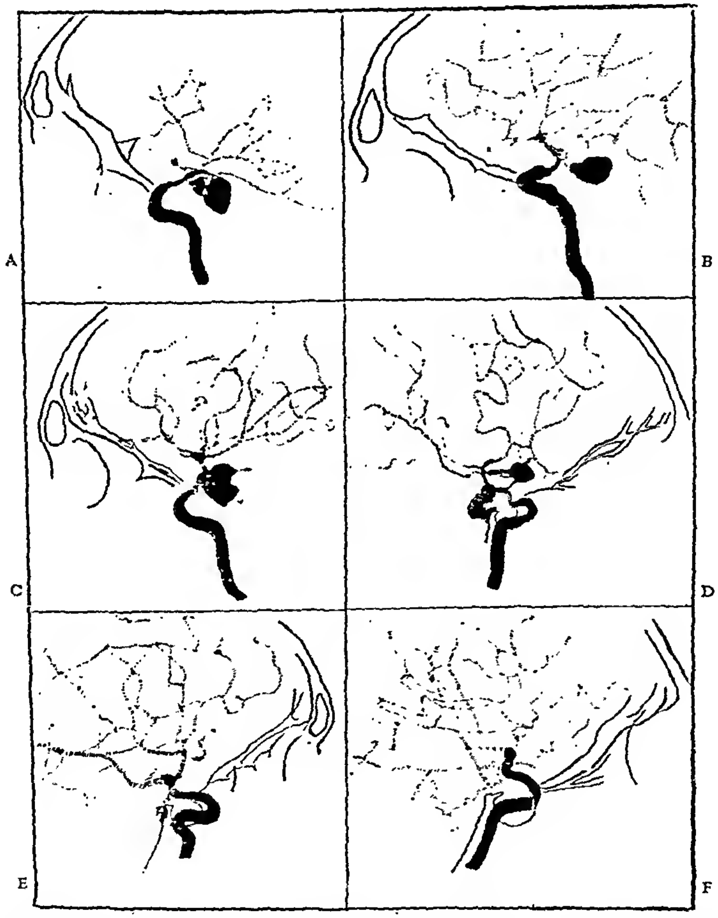

FIG. 4.—Angiograms of supraclinoid aneurysms (A–E). Elevation of carotid by invading nasopharyngeal tumour (F).

I will first deal with the alternatives to ligature. There are but two: (*a*) the packing of hammered muscle tissue transplant around the aneurysm (Dott, 1933; Jefferson, 1938); (*b*) the occlusion of the neck of the aneurysm by a silver clip at the point where it springs from the carotid (Dandy, 1944). I have used muscle packs three times, two patients survive, respectively five and four years, but in one I tied the common carotid two months after the pack, because he continued with pain, always a sign that the aneurysm is not securely thrombosed. In the *third* case (Case I, *see* p. 424) I had to pack muscle around the artery because the silver clip that I applied to the neck of the sac cut through, leading to a torrential hæmorrhage. This patient did well for a month and then died in a few hours from a recurrent hæmorrhage that broke through into the ventricles. This experience deflected me from further attempts to clip the neck of the sac and indeed, although it has many attractions, it is not a sound procedure because the wall close to the artery is, in the nature of things, friable and likely to give way when a metal band is applied. Dandy had the same experience and although he was the inventor of the method, and a courageous one it was, he seems to have become less enthusiastic and latterly preferred to put clips on the carotid above and below the point where the aneurysm left it.

This is a better method, for the main artery takes the clip well, but if a good collateral circulation is to be ensured, it requires that it should occlude the vessel below the posterior communicating artery, a matter of luck because that vessel can be seen.

In another case I applied a clip to the aneurysm but the patient died of operative wound infection. What other clips I have applied have been to occlude the carotid trunk intracranially in cases with carotico-cavernous fistulæ, the vessel being secured in the neck as well.

The operations alternative to the clipping of the neck of the sac are (*a*) ligature of the artery in the neck, (*b*) ligature or occlusive clipping of the carotid trunk inside the skull. There is little to choose between them. In all of the cases operated on, other than those mentioned above, the carotid trunk usually the common, sometimes the internal, has been tied in the neck. In a few we have used the two-stage method of tying the common first and the internal after an interval. The common carotid seems to have done as well as the internal carotid ligatures, probably because the subarachnoid aneurysms are usually small and thrombose readily if the circulation is slowed for a time.

This operation has been done in 23 cases of the present series by myself or my associates—G. F. Rowbotham, James Hardman, J. Schorstein, R. A. Bailey, D. Farley and A. N. Guthkelch. Of these patients all survive but one who died seven years later from an unknown cause and 3 who died very quickly from intracerebral bleeding (*see* Schorstein, 1940). An attempt to tie the carotid was made in 3 other cases but had to be abandoned because hemiplegic signs appeared within five to fifteen minutes of closing the vessel. There are some who say that this never happens if the Matas' test of percutaneous compression is negative. This is not true. It is difficult to see why it should occur unless the tightening of the ligature on the vessel sets up a spasm of the vessel intracranially. It might prove to be the case that if the ligature were left on the hemiplegic signs would disappear but it would be a risky experiment. Possibly periarterial sympathectomy and carotid body strip (Olivercrona, 1944) are worth while but I have not tried them yet.

Three of the cases died, as I have said, within a day or so of ligature. They were all emergency ties in semi-comatose patients and were experimental. These examples were described by Schorstein in his 1940 paper. Despite adverse criticism by Dandy, I still believe that the work that Schorstein (1940) did in my Department on carotid ligature is correct. He concluded that cerebral anoxia rather than thrombosis is the chief danger and that thrombosis or embolism have been incorrectly believed to be the prime factors. When it is remembered that in about 8% of individuals the circle of Willis is wanting in some part, the failure of some patients to "take" a ligature is not surprising. The most serious anomaly is the origin of both anterior cerebrals from one side, and that the side to be ligatured.

In all, we have ligatured one or other carotid fifty times and the three deaths mentioned were the only fatalities. Of the 23 ties for supraclinoid aneurysms, the 19 survivors are all well, though the recovery of the oculomotor nerve has never been absolute. The oldest survivor is now 71, having had her carotid tied in 1933. The youngest was a boy of 12 who two years ago had had a hæmorrhage after his oculomotor palsy developed and was in hospital when a fresh hæmorrhage started. The internal carotid was ligatured with success. We had the mortification of seeing one patient die in hospital from intraventricular rupture whilst awaiting operation. I am convinced that patients rarely die from subarachnoid hæmorrhage alone, not at least quickly. I am sure that Richardson and Hyland (1941) are right when they say that in the majority of apparently plain subarachnoid bleedings there is some hæmorrhage into the adjacent brain. Its mass or its situation may quickly cause death and is the most usual reason for it.

An important word must be added about the cases on whom no operation was performed Why were some left alone? There were two main causes, first that some were aged hypertensives with arteriosclerotic vessels, secondly because patients refused operation when they were told the risks. No patient who had severe pain refused but there were several who had long got over the worst and were only referred to hospital because of residual ptosis or diplopia. On the whole it must be confessed that these patients have done well. It is an important conclusion that patients can survive by natural processes. Upon what grounds, then, can a patient be left to his own defences? I have come to regard pain as the most dangerous sign in aneurysms and would make the decision considerably on that factor; so far few patients who remained pain-free came to any harm whether operated upon or not. But the decision to do nothing would be much fortified if an arteriogram showed conclusively that the sac was small or difficult to see clearly as is the case when it is well filled with clot. This has happened twice and the carotids were not tied. The patients gave characteristic histories but were pain free. They remain well.

CONCLUSIONS

(1) The commonest cause of isolated oculomotor palsy is supraclinoid carotid aneurysm.

(2) In the writer's personal series of 158 intracranial aneurysms, the conjunction was seen in 55.

(3) Valuable information as to shape, size, position and origin can be obtained by angiography and by no other method.

(4) Persistent pain is the most informative sign of activity in the aneurysm.

(5) Carotid ligature is not only a satisfactory but a reasonably safe procedure. Of 19 patients who survived ligature only one has since died, seven years later. The others are alive thirteen, twelve and less years after operation.

(6) The characteristics of oculomotor palsies as exhibited by these cases are discussed.

Cases were shown and discussed but owing to shortage of space the following are recorded here by title only:

(1) Right and Left Iridocyclitis, ? Sympathetic. (2) Retinitis Pigmentosa with Bitemporal Hemianopia. (3) Infantile Glaucoma in a Child of 3 Months—Bilateral Iridectomy. (4) Congenital Coloboma of the Iris and Choroid, with Cataracts, Left Intracapsular Extraction.—Shown by Mr. R. STEWART SCOTT (for Mr. T. MILNES BRIDE).

Boeck's Sarcoid.—Dr. W. STIRLING.

(1) Phakomatosis. (2) Ptosis with Pseudo-Graefe Phenomenon. (3) Krukenberg's Spindle. (4) Pseudoglioma.—Dr. G. RENWICK.

(1) Pigmentation of Conjunctiva. (2) Iris Inclusion—Intracapsular Extraction of Lens. (3) Undifferentiated Malignant Neoplasm of Inner Canthal Region. (4) Fulminating Exophthalmic Ophthalmoplegia.—Dr. O. M. DUTHIE.

Atypical Pigmentary Degeneration of the Retina.—Dr. S. B. SMITH.

(1) Neuroretinitis of Undetermined Ætiology. (2) Gross Esophoria, Corrected Surgically.—Dr. F. JANUS.

Section of Urology

President—R. H. O. B. Robinson, F.R.C.S.

[*January* 23, 1947]

The following cases and specimens were shown:

Squamous Metaplasia in Papillary Carcinoma of the Kidney.—Mr. E. W. Riches.

Kidney Showing Calculi and Tuberculosis.—Professor R. J. Willan.

Hypoplastic Kidney and Hyperpiesia.—Mr. A. Wilfrid Adams.

(1) Retroperitoneal Fibrosarcoma Completely Enveloping the Kidney. (2) Unusual Ruptured Kidney.—Mr. Howard G. Hanley.

An "Early" Renal Cancer Showing Calcification.—Mr. Hugh Donovan.

Anaplastic Hypernephroma with Calculus and Hydronephrosis.—Mr. J. D. Fergusson.

Hydatid Disease of the Kidney (Two Cases).—Mr. Clifford Morson.

(1) Hydatids of the Kidney. (2) Hydatids of the Bladder. (3) Hydatids Passed in Micturition.—Mr. F. R. Kilpatrick.

Uretero-colic Anastomosis.—Mr. Hugh Donovan.

A Hazard of Uretero-intestinal Anastomosis.—Mr. Howard G. Hanley.

Carcinoma of the Ureter.—Mr. J. D. Fergusson.

Achalasia of the Uretero-vesical Orifice and Pyelitis of Pregnancy.—Mr. J. H. Carver.

Diverticulum of the Bladder (Two Cases: One Male, One Female).—Mr. Harold Dodd.

(1) Hairpin in Male Bladder. (2) X-ray of Pencil in Female Bladder. (3) X-ray of Paper Clip in Wall of Male Bladder.—Mr. A. W. Badenoch.

Leiomyoma of Bladder treated by Cystectomy.—Mr. Henry Vernon.

Preputial Fistula.—Mr. A. Wilfrid Adams.

DISCUSSION ON THE USE OF PENICILLIN IN UROLOGY

Dr. A. L. P. Peeney, *Department of Clinical Pathology and Bacteriology, Birmingham United Hospital:* The assessment of the value of penicillin in urology may be carried out under two headings, namely as a prophylactic agent, or for the treatment of active infections.

The position of penicillin in prophylaxis can best be determined by a long-term statistical survey and it is intended to undertake such an investigation in the near future. The purpose of this paper, however, is to consider only the possibilities of penicillin in the treatment of those patients in whom active infection is established, excluding cases of venereal disease.

The important points governing penicillin treatment are the degree of sensitivity of the infecting organism to penicillin, and whether the indicated concentration of the drug can be maintained in that system of the body in which the infection occurs.

In the genito-urinary field many infections are due to Gram-negative bacilli or *Streptococcus fæcalis*, but comparatively few detailed studies have been made of these common invaders of the urinary tract. The early literature (Fleming, 1929; McKee and Rake, 1942; Hobby, Meyer and Chaffee, 1942) contains many references to the insensitivity to penicillin of these bacterial species, with little attempt to determine if there is any variation in their degree of resistance.

Bornstein (1940) examined 27 strains of *Streptococcus fæcalis* and found them all insensitive to a concentration of 8 units of penicillin per c.c., whereas Helmholz and Sung (1944) by a viable count technique, demonstrated the bactericidal effect of 3 units of penicillin per c.c. for *Streptococcus fæcalis* and of 8 units of penicillin per c.c. for Proteus. Coliform organisms they found of intermediate sensitivity between these bacterial species and the highly resistant forms such as *Bact. aerogenes* and *Ps. pyocyanea.*

The technique of determination of sensitivity to penicillin is important. The usual methods, such as ditch plate, cup plate or filter paper discs do not offer very close correlation with fluid titrations which, as a rule, show bacteriostasis with much smaller concentrations of penicillin than do the common solid media methods. For this reason the sensitivity tests recorded in this paper were carried out in fluid titrations in 1 c.c. quantities and the minimum bacteriostatic concentration was the lowest concentration of penicillin which prevented visible growth of a small inoculum when incubated overnight. No attempt was made to demonstrate penicillinase production since Bondi and Dietz (1944) have shown that the inability to produce penicillinase is not a factor in determining sensitivity to penicillin, though they pointed out that organisms forming the enzyme were not likely to be highly susceptible.

It was decided to limit the upper range of the titration to 200 units of penicillin per c.c., as this was considered the maximum concentration which could be reasonably maintained in the urine with moderate economy of penicillin. Tables I and II show the penicillin dilution ranges used in the titrations, and the minimum bacteriostatic concentration for 215 strains isolated from urinary cultures. Approximately 53% of Gram-negative bacillary forms are sensitive to concentrations of penicillin which can be maintained in the urine, but all strains of *Ps. pyocyanea* examined were resistant. On the other hand, Gram-positive cocci, including *Streptococcus fæcalis*, were much more sensitive to penicillin, with fewer resistant strains.

Sarcinæ	—	—	—	—	—	—	—	—	1	1
	3									77

Having established the degrees of sensitivity to penicillin of the common invaders, we must now consider what urine concentrations may be obtained with reasonable doses of penicillin. Florey and his co-workers (1941) first showed that parenteral injection of penicillin caused a high blood concentration followed by a sharp fall due to excretion in concentrated form in the urine. The excretion varies greatly in different individuals, possibly from 50% to 90%, and has been shown by Rammelkamp and Bradley (1943) with diodrast, and Beyer *et al.* (1944) with para-amino hippuric acid by tubule blockade methods, to be mainly tubular in type. The urine concentrations in a small group of cases following different doses of penicillin by intramuscular injection are shown in Table III. When the patient was receiving interrupted injections the specimen was collected at as long a period of time after the injection as possible. The urine was immediately filtered through a Seitz filter and the estimation carried out by a modification of Rammelkamp's (1942) technique.

TABLE III.—URINE PENICILLIN CONCENTRATIONS AFTER ADMINISTRATION OF DIFFERENT DOSES.

Patient	Dose Units	Route of administration	Urine concentration Units per c.c.
M. K. ..	5,000	I.M. 3-hourly	12
H. K. ..	15,000	I.M. 3-hourly	21

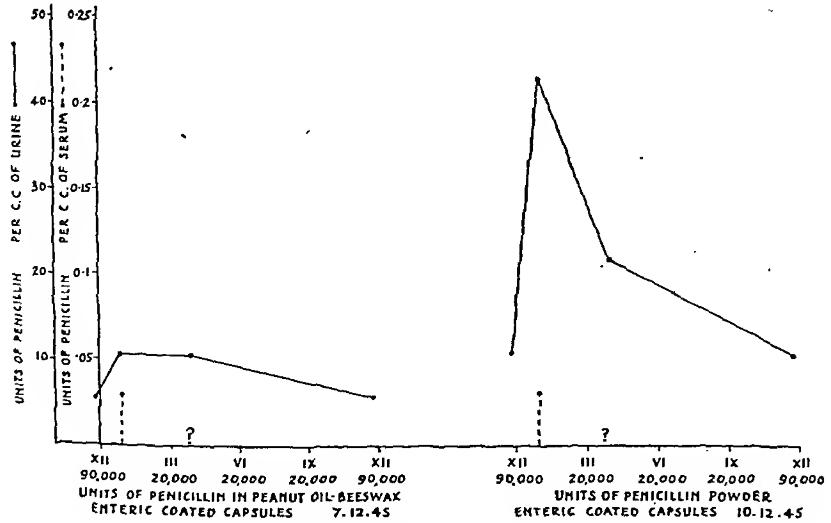
S. K. ..	200,000	I.M. C.D.	85
J. W. ..	400,000	I.M. C.D.	256

*Urine massively infected.

C.D.=Continuous drip, total fluid volume=100 c.c. in twenty-four hours.

The effect of oral administration by enteric coated capsules was also investigated in one case. The capsules used were of hard gelatin and received two coatings with liquor salol ether (B.P.C. 1911) which were allowed to dry between each application. Diagram I shows the blood and urine concentrations obtained when the capsules contained solid penicillin in peanut oil-beeswax mixture, as compared with similar capsules containing only penicillin powder without a slow release medium or antacid. The capsules were, as far as possible, administered to an empty stomach, and fluid intake restricted to 3 pints in twenty-four hours. Whenever feasible this regime of restricted controlled fluid intake was maintained for all the patients in this investigation.



ROMAN NUMERALS = time in hours. ? = less than lower limit of titration (0·03 unit per c.c.)

DIAGRAM I.

The single experiment suggests that once the acid reaction of the stomach has been negotiated it is advisable to have a preparation which is readily absorbed. It may be contended infecting organism to penicillin, and whether the indicated concentration of the drug can be maintained in that system of the body in which the infection occurs.

In the genito-urinary field many infections are due to Gram-negative bacilli or *Streptococcus fæcalis*, but comparatively few detailed studies have been made of these common invaders of the urinary tract. The early literature (Fleming, 1929; McKee and Rake, 1942; Hobby, Meyer and Chaffee, 1942) contains many references to the insensitivity to penicillin of these bacterial species, with little attempt to determine if there is any variation in their degree of resistance.

Bornstein (1940) examined 27 strains of *Streptococcus fæcalis* and found them all insensitive to a concentration of 8 units of penicillin per c.c., whereas Helmholz and Sung (1944) by a viable count technique, demonstrated the bactericidal effect of 3 units of penicillin per c.c. for *Streptococcus fæcalis* and of 8 units of penicillin per c.c. for Proteus. Coliform organisms they found of intermediate sensitivity between these bacterial species and the highly resistant forms such as *Bact. aerogenes* and *Ps. pyocyanea.*

The technique of determination of sensitivity to penicillin is important. The usual methods, such as ditch plate, cup plate or filter paper discs do not offer very close correlation with fluid titrations which, as a rule, show bacteriostasis with much smaller concentrations of penicillin than do the common solid media methods. For this reason the sensitivity tests recorded in this paper were carried out in fluid titrations in 1 c.c. quantities and the minimum bacteriostatic concentration was the lowest concentration of penicillin which prevented visible growth of a small inoculum when incubated overnight. 	3									77

Having established the degrees of sensitivity to penicillin of the common invaders, we must now consider what urine concentrations may be obtained with reasonable doses of penicillin. Florey and his co-workers (1941) first showed that parenteral injection of penicillin caused a high blood concentration followed by a sharp fall due to excretion in concentrated

(1945) method. In view of the previous history of staphylococcal infections it was decided to use the dose scheme recommended by Bigger (1944) in the hope that we might eliminate both the urinary infection and any existing focus of staphylococci. She was accordingly given a continuous intramuscular drip of 400,000 units of penicillin in twenty-four hours by Eudrip apparatus, and fluid intake restricted to 3 pints during this period. A blood concentration of 0·75 unit per c.c. and a urine level of 256 units per c.c. were obtained. Within forty-eight hours of starting penicillin there was a marked reduction in the quantity of pus in the urine, bacteria were not seen in films of the centrifuged deposit, and cultures, after the addition of penicillinase prepared by Duthie's (1944) method, remained sterile. The treatment was maintained for five days and daily examination showed a progressive reduction in the pus cell content and consistently sterile cultures.

During the past two years there has been no recurrence either of the skin lesions or the pyelitis.

Comment.—The criticism may be offered that penicillin played no direct part in the cure of this patient, since cases of acute pyelitis with satisfactory drainage may be self-limiting. An unequivocal answer can only be provided by the investigation of a large series of cases.

CASE II.—M. R., female, aged 56. Was admitted to hospital 20.11.45 with a history of cystitis for the past twelve to fourteen years. This had been associated with considerable lower abdominal pain, intermittent hæmaturia, frequency and scalding on micturition. Cystoscopic examination by Mr. Donovan confirmed the presence of a very severe cystitis just as the late Sir John Thompson-Walker apparently had found ten years earlier in this case. The urine contained many pus cells and Gram-negative bacilli, and cultures yielded a growth of *Proteus morgani*, which was sensitive to 50 units of penicillin per c.c.

She was treated by the instillation into the bladder twice daily of 100 c.c. of saline containing 200 units of penicillin per c.c., and instructed to retain this for as long as possible. Five days after the treatment started a catheter specimen of urine showed no pus and a very scanty growth of Morgan's bacillus. Treatment was continued for fourteen days at which time there was no pyuria and cultures were sterile.

She was discharged from hospital 21.12.45 free from symptoms and with a clean urine. A letter from this patient twelve months later informed us that she felt extremely well and complained of no urinary symptoms whatsoever.

Comment.—This most unusual method of treatment was decided on because the patient was extremely averse to injections, and it is possible that the favourable result was somewhat fortuitous. The obvious contra-indication to this form of therapy is repeated catheterization with the attendant risk of the introduction of penicillin-insensitive micro-organisms.

Stul (1945) investigated 22 cases of Proteus infection of the urinary tract and considered the effect of usual urinary disinfectants, lavage and chemotherapy to be uncertain. This type of urinary infection is probably worthy of an extensive trial with penicillin by injection, though not necessarily by the instillation technique.

CASE III.—J. N., male, aged 29, a Dutch N.C.O., was admitted to the hospital following D-day with an automatic bladder due to a penetrating wound of spine in the upper thoracic region. There was considerable residual urine. Cultures showed a massive urinary infection containing large numbers of *Proteus vulgaris*, atypical Morgan's bacilli, diphtheroid organisms, *Staphylococcus aureus* (coagulase negative), non-hæmolytic streptococci, coliform organisms and *Streptococcus viridans*.

The Gram-positive organisms were all found to be sensitive to low concentrations of penicillin (less than 0·1 unit per c.c.), the proteus was sensitive to 8 units per c.c., the atypical Morgan's bacillus and the coliform were insensitive to concentrations of 200 units of penicillin per c.c. He was treated by penicillin, 50,000 units three-hourly intramuscularly, which produced a concentration of 85 units per c.c. At the end of five days the urine still contained pus and a large number of red blood cells; in smear a fairly large number of Gram-negative bacilli, and cultures yielded a heavy growth of coliform organisms, pyocyaneus, Morgan's bacillus and diphtheroids. These organisms were tested for sulphathiazole sensitivity and it was found that the coliforms were sensitive to 5 mg.%, the diphtheroids to 50 mg.% and the *Ps. pyocyanea* insensitive to the latter concentration. He was, therefore, treated with heavy doses of sulphathiazole and although the urine thirteen days after showed large numbers of Gram-negative bacilli, the only organism recovered in culture was *Ps. pyocyanea*, which is generally insensitive to penicillin and sulphonamide. Chemotherapy was discontinued and within the space of a few weeks the urine was once again heavily infected with mixed bacterial types.

Comment.—Although it was felt that the patient's condition would render permanent sterilization of the urinary tract impossible, the case report is included because it shows the close correlation which may be obtained between *in vitro* findings and *in vivo* results.

CASE IV.—B. R., female, aged 39. Admitted to hospital 5.2.45 with a history of frequency of micturition for three years and incontinence of urine for three days prior to admission. Cystoscopic examination showed an extremely irritable bladder with leukoplakia. The urine contained a moderate number of pus cells and occasional red blood cells, with many Gram-negative bacilli and a small number of streptococci. Cultures yielded a heavy growth of *Proteus vulgaris* (sensitive to 66 units of penicillin per c.c.) and a moderate number of *Streptococcus viridans* (sensitive to 0·08 unit of penicillin per c.c.). The patient was given a continuous intramuscular drip by Eudrip of 200,000 units of that similar urine and blood values could have been obtained by other methods of oral administration, but we were not so greatly concerned to define the best technique for oral treatment as to confirm that levels effective for the *Streptococcus fæcalis* could be readily obtained in the urine by oral administration.

Many investigators have reported on the oral use of penicillin: Little and Lumb (1945) combined it with raw egg, Perlstein *et al.* (1945) with lanoline and corn oil in capsules, McDermott *et al.* (1945) in each of the following substances—corn oil, water, preceded by magnesium trisilicate and in peanut oil-beeswax. All the workers observed that the resultant blood and urine levels showed considerable wastage as compared with parenteral injection. Seager *et al.* (1946), investigating the effect of oral penicillin, used resin-coated capsules, and found that three to six times the intramuscular dose was necessary to produce equal blood concentrations. Nevertheless, since penicillin is now freely available, we agree with Heatley (1945) that the convenience of oral administration will, in some cases, more than compensate for the larger amounts of the drug required. This it would seem applies more especially to urinary infections by all except the most resistant bacterial species.

Before passing to a review of clinical cases, it might be of interest to examine the effect on the blood and urine of a single large injection of penicillin, at the same time emphasizing that groups of individuals exhibit quite marked variations in the rate of excretion of penicillin and consequently in their blood and urine levels when followed over a period of hours. Diagram II shows the effect of 100,000 units of penicillin in 2 c.c. of saline intramuscularly.

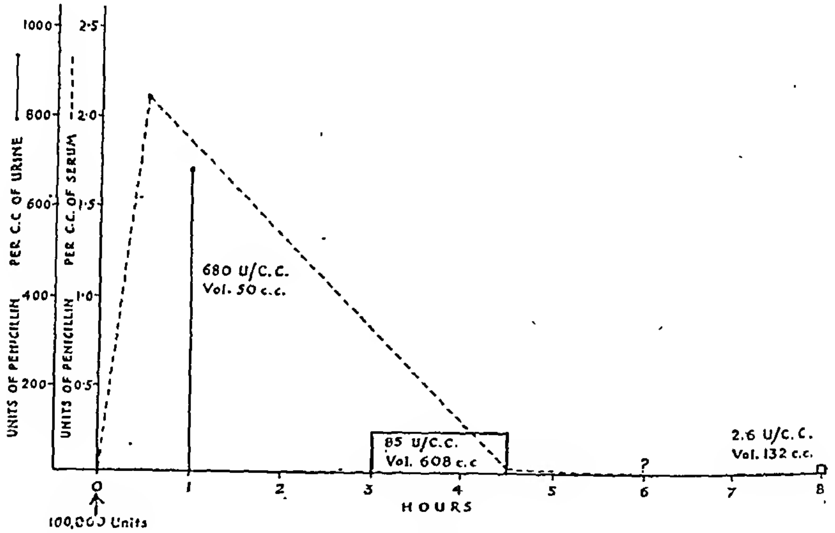

DIAGRAM II.—Urine and blood concentrations after intramuscular injection of 100,000 units of penicillin.

The bladder was emptied immediately before the injection. It will be seen that although there was a blood "peak" of 2·1 units of penicillin per c.c. at thirty minutes, there was only 0·03 unit per c.c. at four and a half hours, and at six hours the concentration was below the limits of titration (0·03 unit per c.c.). On the other hand, the urine collected one hour after the injection showed 680 units per c.c. (34% excretion), and a specimen collected at eight hours was still actively bacteriostatic for all fully sensitive bacteria. The total excretion over the eight-hour period was approximately 86%. It would appear that a dose of this order at six to eight-hourly intervals should yield in most cases a urinary concentration adequate for the majority of strains of *Streptococcus fæcalis*.

The following is a description of a selected small group of treated cases.

CASE I.—J. W., female, aged 34. Long history of frequent recurrent boils and abscesses from one of which a staphylococcus was isolated and found to be sensitive to 0·04 unit of penicillin per c.c. She was admitted urgently to hospital on 13.3.45 with a provisional diagnosis of perinephric abscess, where she was found to have fever, pain in the loin, frequency and slight dysuria. The urine showed a marked pyuria and heavy infection with *B. coli*, which was sensitive to a concentration of 83 units of penicillin per c.c., and insensitive to 5 mg. of sulphathiazole per 100 c.c. by Harper and Cawston's

(1945) method. In view of the previous history of staphylococcal infections it was decided to use the dose scheme recommended by Bigger (1944) in the hope that we might eliminate both the urinary infection and any existing focus of staphylococci. She was accordingly given a continuous intramuscular drip of 400,000 units of penicillin in twenty-four hours by Eudrip apparatus, and fluid intake restricted to 3 pints during this period. A blood concentration of 0·75 unit per c.c. and a urine level of 256 units per c.c. were obtained. Within forty-eight hours of starting penicillin there was a marked reduction in the quantity of pus in the urine, bacteria were not seen in films of the centrifuged deposit, and cultures, after the addition of penicillinase prepared by Duthie's (1944) method, remained sterile. The treatment was maintained for five days and daily examination showed a progressive reduction in the pus cell content and consistently sterile cultures.

During the past two years there has been no recurrence either of the skin lesions or the pyelitis.

Comment.—The criticism may be offered that penicillin played no direct part in the cure of this patient, since cases of acute pyelitis with satisfactory drainage may be self-limiting. An unequivocal answer can only be provided by the investigation of a large series of cases.

CASE II.—M. R., female, aged 56. Was admitted to hospital 20.11.45 with a history of cystitis for the past twelve to fourteen years. This had been associated with considerable lower abdominal pain, intermittent hæmaturia, frequency and scalding on micturition. Cystoscopic examination by Mr. Donovan confirmed the presence of a very severe cystitis just as the late Sir John Thompson-Walker apparently had found ten years earlier in this case. The urine contained many pus cells and Gram-negative bacilli, and cultures yielded a growth of *Proteus morgoni*, which was sensitive to 50 units of penicillin per c.c.

She was treated by the instillation into the bladder twice daily of 100 c.c. of saline containing 200 units of penicillin per c.c., and instructed to retain this for as long as possible. Five days after the treatment started a catheter specimen of urine showed no pus and a very scanty growth of Morgan's bacillus. Treatment was continued for fourteen days at which time there was no pyuria and cultures were sterile.

She was discharged from hospital 21.12.45 free from symptoms and with a clean urine. A letter from this patient twelve months later informed us that she felt extremely well and complained of no urinary symptoms whatsoever.

Comment.—This most unusual method of treatment was decided on because the patient was extremely averse to injections, and it is possible that the favourable result was somewhat fortuitous. The obvious contra-indication to this form of therapy is repeated catheterization with the attendant risk of the introduction of penicillin-insensitive micro-organisms.

Stul (1945) investigated 22 cases of Proteus infection of the urinary tract and considered the effect of usual urinary disinfectants, lavage and chemotherapy to be uncertain. This type of urinary infection is probably worthy of an extensive trial with penicillin by injection, though not necessarily by the instillation technique.

CASE III.—J. N., male, aged 29, a Dutch N.C.O., was admitted to the hospital following D-day with an automatic bladder due to a penetrating wound of spine in the upper thoracic region. There was considerable residual urine. Cultures showed a massive urinary infection containing large numbers of *Proteus vulgaris*, atypical Morgan's bacilli, diphtheroid organisms, *Staphylococcus aureus* (coagulase negative), non-hæmolytic streptococci, coliform organisms and *Streptococcus viridans*.

The Gram-positive organisms were all found to be sensitive to low concentrations of penicillin (less than 0·1 unit per c.c.), the proteus was sensitive to 8 units per c.c., the atypical Morgan's bacillus and the coliform were insensitive to concentrations of 200 units of penicillin per c.c. He was treated by penicillin, 50,000 units three-hourly intramuscularly, which produced a concentration of 85 units per c.c. At the end of five days the urine still contained pus and a large number of red blood cells; in smear a fairly large number of Gram-negative bacilli, and cultures yielded a heavy growth of coliform organisms, pyocyaneus, Morgan's bacillus and diphtheroids. These organisms were tested for sulphathiazole sensitivity and it was found that the coliforms were sensitive to 5 mg.%, the diphtheroids to 50 mg.% and the *Ps. pyocyonea* insensitive to the latter concentration. He was, therefore, treated with heavy doses of sulphathiazole and although the urine thirteen days after showed large numbers of Gram-negative bacilli, the only organism recovered in culture was *Ps. pyocyanea*, which is generally insensitive to penicillin and sulphonamide. Chemotherapy was discontinued and within the space of a few weeks the urine was once again heavily infected with mixed bacterial types.

Comment.—Although it was felt that the patient's condition would render permanent sterilization of the urinary tract impossible, the case report is included because it shows the close correlation which may be obtained between *in vitro* findings and *in vivo* results.

CASE IV.—B. R., female, aged 39. Admitted to hospital 5.2.45 with a history of frequency of micturition for three years and incontinence of urine for three days prior to admission. Cystoscopic examination showed an extremely irritable bladder with leukoplakia. The urine contained a moderate number of pus cells and occasional red blood cells, with many Gram-negative bacilli and a small number of streptococci. Cultures yielded a heavy growth of *Proteus vulgoris* (sensitive to 66 units of penicillin per c.c.) and a moderate number of *Streptococcus viridans* (sensitive to 0·08 unit of penicillin per c.c.). The patient was given a continuous intramuscular drip by Eudrip of 200,000 units of that similar urine and blood values could have been obtained by other methods of oral administration, but we were not so greatly concerned to define the best technique for oral treatment as to confirm that levels effective for the *Streptococcus fæcalis* could be readily obtained in the urine by oral administration.

Many investigators have reported on the oral use of penicillin: Little and Lumb (1945) combined it with raw egg, Perlstein *et al.* (1945) with lanoline and corn oil in capsules, McDermott *et al.* (1945) in each of the following substances—corn oil, water, preceded by magnesium trisilicate and in peanut oil-beeswax. All the workers observed that the resultant blood and urine levels showed considerable wastage as compared with parenteral injection. Seager *et al.* (1946), investigating the effect of oral penicillin, used resin-coated capsules, and found that three to six times the intramuscular dose was necessary to produce equal blood concentrations. Nevertheless, since penicillin is now freely available, we agree with Heatley (1945) that the convenience of oral administration will, in some cases, more than compensate for the larger amounts of the drug required. This it would seem applies more especially to urinary infections by all except the most resistant bacterial species.

Before passing to a review of clinical cases, it might be of interest to examine the effect on the blood and urine of a single large injection of penicillin, at the same time emphasizing that groups of individuals exhibit quite marked variations in the rate of excretion of penicillin and consequently in their blood and urine levels when followed over a period of hours. Diagram II shows the effect of 100,000 units of penicillin in 2 c.c. of saline intramuscularly.

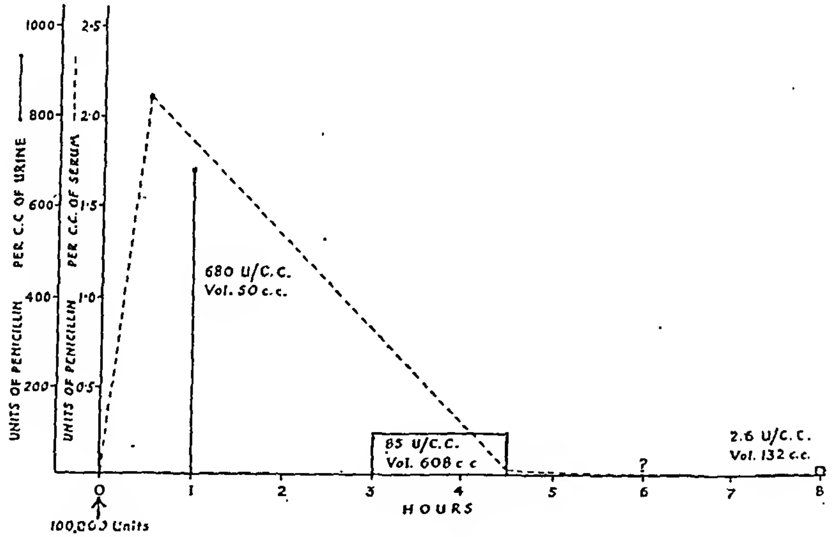

DIAGRAM II.—Urine and blood concentrations after intramuscular injection of 100,000 units of penicillin.

The bladder was emptied immediately before the injection. It will be seen that although there was a blood "peak" of 2·1 units of penicillin per c.c. at thirty minutes, there was only 0·03 unit per c.c. at four and a half hours, and at six hours the concentration was below the limits of titration (0·03 unit per c.c.). On the other hand, the urine collected one hour after the injection showed 680 units per c.c. (34% excretion), and a specimen collected at eight hours was still actively bacteriostatic for all fully sensitive bacteria. The total excretion over the eight-hour period was approximately 86%. It would appear that a dose of this order at six to eight-hourly intervals should yield in most cases a urinary concentration adequate for the majority of strains of *Streptococcus fæcalis.*

The following is a description of a selected small group of treated cases.

CASE I.—J. W., female, aged 34. Long history of frequent recurrent boils and abscesses from one of which a staphylococcus was isolated and found to be sensitive to 0·04 unit of penicillin per c.c. She was admitted urgently to hospital on 13.3.45 with a provisional diagnosis of perinephric abscess, where she was found to have fever, pain in the loin, frequency and slight dysuria. The urine showed a marked pyuria and heavy infection with *B. coli*, which was sensitive to a concentration of 83 units of penicillin per c.c., and insensitive to 5 mg. of sulphathiazole per 100 c.c. by Harper and Cawston's urinary symptoms. It would appear, therefore, that the *Streptococcus fæcalis* is a probable urinary pathogen.

That being so, this case is recorded as showing the effect which may be obtained by the use of penicillin, and in this patient the only operative therapy was by virtue of the urine concentration, since the blood levels were at all significant times below those necessary for inhibition of the *Streptococcus fæcalis*, as shown by *in vitro* tests.

It is noteworthy that *Streptococcus fæcalis* is usually resistant to all sulphonamide compounds so far available.

We have not had the opportunity to treat essentially intra- and peri-renal infections with penicillin, but since the majority of such infections are staphylococcal in nature, the results obtained should be directly conditioned by the sensitivity of the causal strain to the drug. Handfield-Jones (1946) states that in adults the results of penicillin treatment of perinephric abscess are dramatic, with rapid resolution and healing. In carbuncle the results are usually good, but treatment must be continued for at least three to four weeks if relapse is to be avoided. He stresses that pyelographic control is essential in addition to ordinary criteria of cure. Fort (1946) reports the cure of a case of perinephric cellulitis following an abscess of the index finger, by penicillin without suppuration or incision. Signs and symptoms and X-ray findings were clearly those of perinephric cellulitis.

It would appear from reports in the literature that abacterial pyuria does not respond to penicillin. Moore (1945) states that this condition resists all forms of therapy except organic arsenical preparations, and Bodner (1945) reported the case of a patient with this condition resistant to both sulphonamide and penicillin treatment who rapidly responded to mapharsan. Baines (1947) has had similar experiences.

It will be obvious from what has already been stated that we are only at the beginning of our investigations of the position of penicillin in genito-urinary infections, but it must be evident that such infections can only be treated adequately when the closest collaboration exists between the clinician and the bacteriologist. In all cases it is essential reliably to determine the sensitivity of the infecting organism to penicillin, to control by estimation that the necessary concentration is being maintained in the urine, and to assess the result of treatment, both clinically and bacteriologically. Even when such conditions obtain, it is almost certain that relapses will occur, due to anatomical deformity of the passages or the presence of inaccessible foci, possibly in calculi, deep crypts, prostatic abscesses or necrotic tissue, some of which would not be influenced even by high blood concentrations. We have treated a small number of patients with urinary calculi and infection, and although they have, on the whole, been materially improved, we have frequently failed completely to eradicate the urinary infection. This was almost certainly due in large measure to the calculus forming a reinfecting nidus.

Exley (1946) suggested that the presence of calculi in 8 cases investigated led to failure of penicillin to eliminate the infection, though 4 of these cases were cleared up with penicillin after the removal of the calculi. Bodner and Moulder (1945), however, were able to sterilize the urine of a patient with recurrent calculus formation and a staphylococcal infection with relatively small doses of penicillin after all other forms of therapy had failed. This patient's urine was still sterile and there was no evidence of recurrence of calculi nine months after discharge from hospital.

Nevertheless, in all urinary infections which resist other forms of treatment, and especially those due to the *Streptococcus fæcalis*, penicillin may afford the only satisfactory therapy. Similarly, penicillin should be considered in patients sensitive to the sulphonamides or where, for any other reason, the use of these drugs is precluded.

It may be that streptomycin with its wider range of activity against the Gram-negative bacillary forms may offer better possibilities, but it is not free from toxic effects and so far is in very short supply. I would prefer to look forward to the time when penicillin may be synthesized, in the hope that by some rearrangement of its molecule we shall be given a product of wider activity and with increased stability, so that patients may be spared repeated injections and an equal degree of susceptibility be introduced into the ranks of the Gram-negative bacilli as now exists in those of the Gram-positive cocci.

It is a pleasure to thank Professor A. P. Thomson, Dr. E. Bulmer, Mr. H. Donovan and Mr. Barnie-Adshead for permission to treat their patients and publish the case reports.

ADDENDUM.—Since this paper was read, a strain of *Streptococcus fæcalis* has been isolated from a urinary culture, which had a minimum bacteriostatic concentration of 33 units of penicillin per c.c.

penicillin in 100 c.c. of saline in twenty-four hours. The urine forty-eight hours later showed that the streptococcus had been eradicated but that the Proteus organism was still present in moderate numbers. The urine penicillin concentration was only 32 units per c.c. and the blood level 0·30 unit per c.c. As previously shown by *in vitro* test, the urine concentration was insufficient to inhibit the growth of the strain of Proteus present. The dose of penicillin was therefore raised to 400,000 units daily, and remained so for seven days—this increased the urine level to 64 units per c.c. Two days after increasing the dose, the urine was found to contain small amounts of pus, but no organisms were seen. Cultures, however, yielded a scanty growth of *Ps. pyocyanea* (insensitive to 1,000 units per c.c.) and *Bact. anaerogenes* (insensitive to 500 units per c.c.). Frequent subsequent urine examinations showed a progressive increase of the pyuria and Gram-negative bacillus content, and cultures repeatedly yielded a growth of the two resistant bacteria. The pyocyaneus was found to be sensitive to 5 mg.% of sulphathiazole but the anaerogenes was insensitive to 50 mg.% of sulphathiazole and sulphamethazine and 15 mg.% of sulphadiazine. This patient was discharged on 15.3.45, on sulphathiazole, having had nine days of intramuscular penicillin treatment.

In view of the intractable cystitis, the patient was readmitted 11.6.46, and the urine findings closely resembled those found before penicillin treatment had been instituted. At operation for ureteric transplantation (Mr. H. Donovan) the ureters were found to be normal and he successfully carried out a bilateral simultaneous transplantation of the ureters into the pelvic colon. The patient was discharged, very much improved, 30.7.46.

Comment.—Although this patient's original infecting organisms were eradicated, she was unfortunately left with a mixed pyocyaneus and anaerogenes infection which was insensitive to penicillin. The gross anatomical change in the bladder greatly militated against the therapeutic possibilities of any treatment. Subsequent history proved such to be the case. Mr. Donovan transplanted the ureters into the pelvic colon.

CASE V.—H. W., male, aged 56. History of intermittent pyelitis since 1931. Cystoscopic examination by B. J. Ward in 1941 showed pyelitis and cystitis, and there was a heavy infection with an indeterminate pigment-producing coagulase-negative staphylococcus. No calculus. Considerable improvement with sulphapyridine. Readmitted 18.4.45. The staphylococcus was sensitive to 0·03 unit of penicillin per c.c. and there was considerable pyuria. He was treated with penicillin, 20,000 units three-hourly intramuscularly, and the urine was sterile after five days' treatment. Frequent relapses occurred and the patient was again readmitted 1.12.45. At this time he was stated to have become sensitive to sulphonamides. The urine contained many pus cells and Gram-positive cocci, and cultures yielded a heavy growth of *Staphylococcus pyogenes* which were sensitive to 0·03 unit of penicillin per c.c. In view of the high susceptibility of this organism to penicillin, it was decided to try the effect of oral penicillin in enteric-coated capsules. The blood and urine concentrations obtained were those shown in Diagram I. Within forty-eight hours the patient was free from symptoms, and after five days' treatment the urine contained no pus or bacteria. Discharged on 14.1.46. His condition relapsed three weeks after leaving but five days' oral penicillin, as an outpatient, again rendered the urine normal and the patient free from symptoms. It was considered that a deep-seated focus must be present and he was advised to be readmitted for surgical investigation of the genito-urinary tract. This he refused.

Comment.—In this case the originally isolated staphylococcus differed in its coagulase reaction from the strain present in the later stages, which suggests that the original invader had been effectively removed by the systemic penicillin. Nevertheless, it did not reduce his tendency to relapse. Although his infection was readily amenable to penicillin, we should have given him a much longer course of treatment, since there was the possibility of a deep-seated, relatively inaccessible, focus, either in the kidney or prostate. As pointed out by Handfield-Jones (1946), long courses of penicillin are indicated in certain intra-renal infections. Florey *et al.* (1941) described the oral administration of penicillin to a child of 6 months which cured a staphylococcal infection of the urinary tract.

CASE VI.—A. S., female, aged 46. Admitted for Cæsarean section; a living child was delivered. Seven days after the operation the urine was found to be heavily infected and stained films showed large numbers of Gram-positive cocci and cultures yielded a heavy growth of *Streptococcus fæcalis*. She was treated with sulphathiazole, 1 gramme six-hourly, for four days, but the urine showed no change. The *Streptococcus fæcalis* isolated from the second specimen was found to be insensitive to 5 mg.% of sulphathiazole but sensitive to 2·5 units of penicillin per c.c. It was decided to treat the patient with penicillin, but since she was feeding her baby, fluid intake could not be restricted and she was allowed 7 pints of fluid in twenty-four hours. On 20,000 units of penicillin three-hourly, her blood was shown to contain 0·06 unit of penicillin thirty minutes after the injection, and less than 0·03 unit two hours fifty-five minutes after injection. The total urine voided over one complete three-hour period was 122 c.c., and contained 8·5 units of penicillin per c.c. After forty-eight hours the centrifuged deposit of the urine showed no pus cells or organisms, and cultures, with penicillinase, remained sterile. A further examination at the end of five days gave similar findings. Penicillin was then discontinued. The slight frequency and dysuria which existed in the early stages had, by this time, completely disappeared and the patient felt very well.

Comment.—It may be asked whether *Streptococcus fæcalis* is really pathogenic. The answer to this would appear to be that cases are frequently encountered in which there is pyuria and the only organism recovered is a *Streptococcus fæcalis*. Such cases are usually associated with low-grade urinary symptoms. It would appear, therefore, that the *Streptococcus fæcalis* is a probable urinary pathogen.

That being so, this case is recorded as showing the effect which may be obtained by the use of penicillin, and in this patient the only operative therapy was by virtue of the urine concentration, since the blood levels were at all significant times below those necessary for inhibition of the *Streptococcus fæcalis*, as shown by *in vitro* tests.

It is noteworthy that *Streptococcus fæcalis* is usually resistant to all sulphonamide compounds so far available.

We have not had the opportunity to treat essentially intra- and peri-renal infections with penicillin, but since the majority of such infections are staphylococcal in nature, the results obtained should be directly conditioned by the sensitivity of the causal strain to the drug. Handfield-Jones (1946) states that in adults the results of penicillin treatment of perinephric abscess are dramatic, with rapid resolution and healing. In carbuncle the results are usually good, but treatment must be continued for at least three to four weeks if relapse is to be avoided. He stresses that pyelographic control is essential in addition to ordinary criteria of cure. Fort (1946) reports the cure of a case of perinephric cellulitis following an abscess of the index finger, by penicillin without suppuration or incision. Signs and symptoms and X-ray findings were clearly those of perinephric cellulitis.

It would appear from reports in the literature that abacterial pyuria does not respond to penicillin. Moore (1945) states that this condition resists all forms of therapy except organic arsenical preparations, and Bodner (1945) reported the case of a patient with this condition resistant to both sulphonamide and penicillin treatment who rapidly responded to mapharsan. Baines (1947) has had similar experiences.

It will be obvious from what has already been stated that we are only at the beginning of our investigations of the position of penicillin in genito-urinary infections, but it must be evident that such infections can only be treated adequately when the closest collaboration exists between the clinician and the bacteriologist. In all cases it is essential reliably to determine the sensitivity of the infecting organism to penicillin, to control by estimation that the necessary concentration is being maintained in the urine, and to assess the result of treatment, both clinically and bacteriologically. Even when such conditions obtain, it is almost certain that relapses will occur, due to anatomical deformity of the passages or the presence of inaccessible foci, possibly in calculi, deep crypts, prostatic abscesses or necrotic tissue, some of which would not be influenced even by high blood concentrations. We have treated a small number of patients with urinary calculi and infection, and although they have, on the whole, been materially improved, we have frequently failed completely to eradicate the urinary infection. This was almost certainly due in large measure to the calculus forming a reinfecting nidus.

Exley (1946) suggested that the presence of calculi in 8 cases investigated led to failure of penicillin to eliminate the infection, though 4 of these cases were cleared up with penicillin after the removal of the calculi. Lady Florey: The intermittent intramuscular injection of penicillin is of such inconvenience that a great many efforts have been made to find other means which would have equally good therapeutic effects. A type of administration is required which can be given to patients while they live at home and can be carried on for long enough periods to ensure that the infection has been eliminated. The methods most widely investigated have been those of single daily injections of penicillin in a vehicle delaying absorption—usually 4·8% beeswax in peanut oil and of oral administration.

For infections of the urinary tract it is important to compare the percentage of the dose excreted in the urine by the different methods. It has been found that after intramuscular injections of aqueous solutions 65% to 80% of the dose is excreted in the urine; after injections of penicillin in beeswax and peanut oil 33% and after oral administration only 8% to 23% of the dose is found in the urine. There is thus no question as to which is the most efficient method of administration.

There is a possibility, however, that injections even of aqueous solutions can be spaced widely enough to make treatment practicable at home and over sufficiently long periods of time.

Amongst a dozen healthy young men lying in bed recovering from battle wounds, the urinary excretion of penicillin following a single intramuscular injection of 100,000 units was measured.

The following approximate figures were obtained:

3 to 4 hours after injection	3,000 to 5,000 units per 100 c.c.
12 hours after injection	140 to 700 units per 100 c.c.
20 hours after injection	2 to 400 units per 100 c.c.
24 hours after injection	0 to 100 units per 100 c.c.

These concentrations can be compared with the upper limits of sensitivity of the organisms found in urinary tract infections:

Gonococci Hæmolytic streptococci	up to 18 units per 100 c.c.
Staphylococci *Strept. viridans*	up to 500 units per 100 c.c.
Non-hæmolytic streptococci *Strept. fæcalis*	up to 2,000 units per 100 c.c.
Gram-negative organisms	?

so it can be seen that a single injection of 100,000 units in aqueous solution per twenty-four hours should be sufficient to rid the urinary tract of the most sensitive organisms, twelve-hourly injections should do the same for the next group but the remainder should require more frequent injections or higher individual doses.

The question of whether infections caused by Proteus, *Bact. coli* or *Ps. pyocyanea* can be permanently cured by penicillin still remains a moot point. Use of local applications of penicillin in wounds in concentrations well above those found in the urine did not have any effect in reducing the percentage of cultures free of these organisms except in the case of coliform organisms, and here the amount was so slight as to be attributable to chance.

A very interesting outcome of this study of Gram-negative flora in wounds was the association between the appearance of *Staph. aureus* and the disappearance of all three species. A warning is issued in consequence that the treatment of a streptococcal or staphylococcal infection of the urinary tract by penicillin may end in a condition in which the main infecting organisms are Proteus, *Bact. coli* or *Ps. pyocyanea.*

These latter observations lead one to emphasize the close interrelation between mechanical and bacteriological factors in any infection. Obstruction caused by calculi or strictures, a foreign body, or slough, an atonic or fibrotic bladder or loculated pus will be responsible for the continuance of infection irrespective of the amount or duration of chemotherapy. The functions of surgery and chemotherapy are therefore closely linked in treatment, and responsibility for achieving a cure should rarely be placed entirely on one or the other.

Mr. Clifford Morson pointed out the importance of giving large doses of penicillin. He described the case of a woman of 61 who for fifteen years had suffered from one-hourly frequency of micturition due to a systolic bladder. Cystoscopy revealed a small ulcer above the right ureteric orifice and a bladder capacity of 2 oz. The organism isolated from the urine was the *Staph. aureus* which proved to be penicillin sensitive. As there was some doubt about the nature of the ulcer it was excised by open operation. Fortunately the pathologist reported that it was non-malignant. When the wound had nearly healed, a ten-day course of penicillin was given, the first dose being 150,000 units and the two subsequent doses 100,000 units, followed by 50,000 units at three-hourly intervals. The urine became sterile after forty-eight hours and the bladder capacity steadily increased so that now over two years since the treatment she can hold her urine for three hours. He gave an account of another case to illustrate the danger of the replacement of a penicillin-sensitive organism by one which was penicillin resistant. A dental surgeon was referred to him three years ago on account of bilateral hydronephrosis complicated by a *Staph. aureus* infection which caused so much urgency of micturition as to necessitate his retirement from practice. One injection of 50,000 units of penicillin followed at three-hourly intervals by 20,000 units for five days caused the disappearance of the *Staph. aureus*, but there followed an acute attack of *Bacillus coli* infection. The latter has been resistant to all kinds of drug treatment and his condition to-day is no better than it was three years ago.

Mr. Yates Bell agreed with Lady Florey that with insufficient penicillin dosage staphylococci were eliminated in early urine specimens without a decrease in the *B. coli*, which, however, decreased as the staphylococcus increased in later specimens.

His attention had been drawn to the long periods (six months or more) that an indwelling urethral catheter was tolerated in paraplegic cases without the development of a urethritis and therefore with a decrease in urinary infection; and for the past two years had accordingly used penicillin as a prophylactic in prostatic surgery during the period of indwelling catheter. During this time it had become possible to avoid two-stage operations (apart from rare

Lady Florey: The intermittent intramuscular injection of penicillin is of such inconvenience that a great many efforts have been made to find other means which would have equally good therapeutic effects. A type of administration is required which can be given to patients while they live at home and can be carried on for long enough periods to ensure that the infection has been eliminated. The methods most widely investigated have been those of single daily injections of penicillin in a vehicle delaying absorption—usually 4·8% beeswax in peanut oil and of oral administration.

For infections of the urinary tract it is important to compare the percentage of the dose excreted in the urine by the different methods. It has been found that after intramuscular injections of aqueous solutions 65% to 80% of the dose is excreted in the urine; after injections of penicillin in beeswax and peanut oil 33% and after oral administration only 8% to 23% of the dose is found in the urine. There is thus no question as to which is the most efficient method of administration.

There is a possibility, however, that injections even of aqueous solutions can be spaced widely enough to make treatment practicable at home and over sufficiently long periods of time.

Amongst a dozen healthy young men lying in bed recovering from battle wounds, the urinary excretion of penicillin following a single intramuscular injection of 100,000 units was measured.

The following approximate figures were obtained:

3 to 4 hours after injection	3,000 to 5,000 units per 100 c.c.
12 hours after injection	140 to 700 units per 100 c.c.
20 hours after injection	2 to 400 units per 100 c.c.
24 hours after injection	0 to 100 units per 100 c.c.

These concentrations can be compared with the upper limits of sensitivity of the organisms found in urinary tract infections:

Gonococci Hæmolytic streptococci	up to 18 units per 100 c.c.
Staphylococci *Strept. viridans*	up to 500 units per 100 c.c.
Non-hæmolytic streptococci *Strept. fæcalis*	up to 2,000 units per 100 c.c.
Gram-negative organisms	?

so it can be seen that a single injection of 100,000 units in aqueous solution per twenty-four hours should be sufficient to rid the urinary tract of the most sensitive organisms, twelve-hourly injections should do the same for the next group but the remainder should require more frequent injections or higher individual doses.

The question of whether infections caused by Proteus, *Bact. coli* or *Ps. pyocyanea* can be permanently cured by penicillin still remains a moot point. Use of local applications of penicillin in wounds in concentrations well above those found in the urine did not have any effect in reducing the percentage of cultures free of these organisms except in the case of coliform organisms, and here the amount was so slight as to be attributable to chance.

A very interesting outcome of this study of Gram-negative flora in wounds was the association between the appearance of *Staph. aureus* and the disappearance of all three species. A warning is issued in consequence that the treatment of a streptococcal or staphylococcal infection of the urinary tract by penicillin may end in a condition in which the main infecting organisms are Proteus, *Bact. coli* or *Ps. pyocyanea.*

These latter observations lead one to emphasize the close interrelation between mechanical and bacteriological factors in any infection. Obstruction caused by calculi or strictures, a foreign body, or slough, an atonic or fibrotic bladder or loculated pus will be responsible for the continuance of infection irrespective of the amount or duration of chemotherapy. The functions of surgery and chemotherapy are therefore closely linked in treatment, and responsibility for achieving a cure should rarely be placed entirely on one or the other.

Mr. Clifford Morson pointed out the importance of giving large doses of penicillin. He described the case of a woman of 61 who for fifteen years had suffered from one-hourly frequency of micturition due to a systolic bladder. Cystoscopy revealed a small ulcer above the right ureteric orifice and a bladder capacity of 2 oz. The organism isolated from the urine was the *Staph. aureus* which proved to be penicillin sensitive. As there was some doubt about the nature of the ulcer it was excised by open operation. Fortunately the pathologist reported that it was non-malignant. When the wound had nearly healed, a ten-day course of penicillin was given, the first dose being 150,000 units and the two subsequent doses 100,000 units, followed by 50,000 units at three-hourly intervals. The urine became sterile after forty-eight hours and the bladder capacity steadily increased so that now over two years since the treatment she can hold her urine for three hours. He gave an account of another case to illustrate the danger of the replacement of a penicillin-sensitive organism by one which was penicillin resistant. A dental surgeon was referred to him three years ago on account of bilateral hydronephrosis complicated by a *Staph. aureus* infection which caused so much urgency of micturition as to necessitate his retirement from practice. One injection of 50,000 units of penicillin followed at three-hourly intervals by 20,000 units for five days caused the disappearance of the *Staph. aureus*, but there followed an acute attack of *Bacillus coli* infection. The latter has been resistant to all kinds of drug treatment and his condition to-day is no better than it was three years ago.

Mr. Yates Bell agreed with Lady Florey that with insufficient penicillin dosage staphylococci were eliminated in early urine specimens without a decrease in the *B. coli*, which, however, decreased as the staphylococcus increased in later specimens.

His attention had been drawn to the long periods (six months or more) that an indwelling urethral catheter was tolerated in paraplegic cases without the development of a urethritis and therefore with a decrease in urinary infection; and for the past two years had accordingly used penicillin as a prophylactic in prostatic surgery during the period of indwelling catheter. During this time it had become possible to avoid two-stage operations (apart from rare mechanical failure to catheterize a patient), and the associated high mortality of suprapubic cystotomy. Penicillin was given as a routine, 100,000 units six-hourly, during pre-operative and post-operative periods of an indwelling catheter in association with chemotherapy if pyrexia developed. In view of Dr. Peeney's work increase of dosage to 200,000 units might be preferable, certainly if fever developed.

Mr. Edgar Freshman quoted a case of complete bladder paralysis following thrombosis of the veins of the spinal cord in which it seemed probable that the bladder would recover. The bladder was drained for seven weeks by an indwelling rubber catheter which was changed four times, and throughout the period of drainage he was given 100,000 units of penicillin and 1 gramme of sulphadiazine eight-hourly. His average fluid intake was over 100 oz. a day and he had no bladder irrigations. The urine was examined repeatedly, but remained sterile throughout the period of drainage, and there was no urethritis. His bladder gradually recovered its tone, and when he left hospital micturition was practically normal.

Mr. Hugh Donovan said that the use of penicillin to prevent infection after bladder surgery would need careful statistical study, which it was proposed to carry out. He had noted the practical abolition of post-operative chest complications when using penicillin as a routine urinary antiseptic. He could confirm that the bladder flora were penicillin resistant in a ward where penicillin had been much used. This was found to be the case in the Midland Regional Spinal Unit.

He pointed out that Helstrom had found masses of staphylococci in urinary calculi, even when the urine was sterile, and suggested that penicillin might improve the outcome of operation on bilateral staghorn stones.

SAMUEL HYDE MEMORIAL LECTURE

Rheumatic Diseases: A Challenge And An Opportunity

By Professor HENRY COHEN, M.D., F.R.C.P.

> "Therefore the moon, the governess of floods,
> Pale in her anger washes all the air,
> That rheumatic diseases do abound."
> (Shakespeare: "Midsummer Night's Dream", Act II, Sc. 2.)

MY first duty is to express my deep and sincere gratitude for the honour your Council have done me by their invitation to deliver this lecture commemorating the work of the late Dr. Samuel Hyde of Buxton, who founded the British Balneological and Climatological Society, which is incorporated in this Section of Physical Medicine. Those who control the assigning of this notable and rare distinction, conferred on only six occasions in the past thirty-six years, have clearly been moved in to-day's choice, not by any inherent merit of mine but by the office of Chairman of the Ministry of Health's Advisory Subcommittee on Rheumatism which for the moment I happen to hold. I have therefore grasped this opportunity to examine afresh some of the major problems confronting those who seek to alleviate the sufferings of the victims of Medicine's neglected stepchild—the Rheumatic Diseases.

INCIDENCE

What is the size of the problem? The first serious effort in this country to find an answer to this question is embodied in a Report of the Ministry of Health published in 1924 of an investigation undertaken in 1922 [1]. This covered insured (N.H.I.) workers only. It was thus confined to manual workers and others earning less than £250 a year. As these categories embraced less than half the population (13½ million) and excluded housewives, the sample investigated was not fully representative. Moreover the rural districts, Wales, and the industrial North West (where rheumatic disease is thought to be prevalent) were poorly represented in this survey. Despite these limitations, which on the whole would tend to yield too small an incidence, the report reveals a problem of startling size. For this survey a number of practitioners were chosen and asked to record all patients consulting them for rheumatism. The total number of insured patients in the sample was 90,891; of these, in 1922, 42,288 (46·5%) consulted their doctors. A diagnosis of rheumatic disease was made in 2,510 (2·76% of the total). (This represents a "prevalence" and not an "attack" rate, i.e. a patient who had more than one attack during 1922 is counted only once in the incidence tables.) On the mechanical failure to catheterize a patient), and the associated high mortality of suprapubic cystotomy. Penicillin was given as a routine, 100,000 units six-hourly, during pre-operative and post-operative periods of an indwelling catheter in association with chemotherapy if pyrexia developed. In view of Dr. Peeney's work increase of dosage to 200,000 units might be preferable, certainly if fever developed.

Mr. Edgar Freshman quoted a case of complete bladder paralysis following thrombosis of the veins of the spinal cord in which it seemed probable that the bladder would recover. The bladder was drained for seven weeks by an indwelling rubber catheter which was changed four times, and throughout the period of drainage he was given 100,000 units of penicillin and 1 gramme of sulphadiazine eight-hourly. His average fluid intake was over 100 oz. a day and he had no bladder irrigations. The urine was examined repeatedly, but remained sterile throughout the period of drainage, and there was no urethritis. His bladder gradually recovered its tone, and when he left hospital micturition was practically normal.

Mr. Hugh Donovan said that the use of penicillin to prevent infection after bladder surgery would need careful statistical study, which it was proposed to carry out. He had noted the practical abolition of post-operative chest complications when using penicillin as a routine urinary antiseptic. He could confirm that the bladder flora were penicillin resistant in a ward where penicillin had been much used. This was found to be the case in the Midland Regional Spinal Unit.

He pointed out that Helstrom had found masses of staphylococci in urinary calculi, even when the urine was sterile, and suggested that penicillin might improve the outcome of operation on bilateral staghorn stones.

The most recent figures showing a heavy incidence are from Sweden where in 1923 Kahlmeter had reported that chronic articular rheumatism was the cause of retirement of 9% of insured workers. In 1944-45 Edström [4] investigated 72,000 persons—half in rural districts and half in villages—differing in social and economic status and environment. Of these 5,679 (7·9%) had rheumatic disease, and in 2,745 (3·8%) it was active; 480 (6·7 per 1,000) were permanently incapacitated.

It would be idle to claim that any of these statistical surveys is comparable with another or that from them can be gathered more than a general impression of the prevalence and morbidity of the rheumatic diseases. The samples examined are inadequate in number, type and variety; for example, the necessary omission of housewives from the 1924 English survey of insured persons is a cardinal defect. They refer to different age-groups, and different years in which the relative numbers in the different age-groups may vary. The differences in occupation, geography, climate and subsoil, social and economic status, nutrition and other significant features in these heterogeneous groups forbid strict comparison. There is a lack of differentiation of "attack" rate (morbidity incidence) and "prevalence" rate (morbidity prevalence). In some, e.g. the Social Surveys, the recorded diagnosis is usually that given by the subject of the interview; this self-diagnosis by those for whom any pain is "a touch of the rheumatics" is a flimsy basis for statistical records and analyses. It may indeed account for the fact previously noted, that in the most recent surveys half the population is recorded as suffering from non-incapacitating rheumatism. Finally, and of great importance, is the use in these reports of a varying nomenclature and classification of rheumatic disease, and the absence of any definitive criteria for the diagnosis of its diverse forms.

Any projected future surveys must take cognizance of all these points if they are to resist the attacks of the critics. In all fields of medicine the fallacies in interpreting the results of clinical investigations are a ready snare for the unwary. In rheumatic disease there is need for the greatest care not only in defining the results of observation but also in planning large-scale field and therapeutic experiments if they are to be most fruitful. To this end I would plead for the closest co-operation between the statistician and the clinician in this work. If this be achieved we shall hear less of the old gibe that "statistics may be made to tell anything, even the truth", and see fewer of those papers claiming, for a remedy in these diseases, 100% cures but written in that apologetic tone which is intended to convey that the author hopes to do better next time.

As an example of the tyranny of names and the absurd conclusions to which they may lead, let me quote, without acknowledgment for obvious reasons, a table from a recent paper, with the names of the collieries omitted.

Type of rheumatic ailment	Colliery A	B	C	Total
Rheumatoid arthritis..	8	5	9	22
Lumbago	5	10	13	28
Fibrositis	31	17	Nil	48
Sciatica	Nil	2	11	13
Neuritis	Nil	Nil	2	2

From an analysis of these figures which do not even specify the number of miners employed at each colliery so that an absolute and not a relative incidence alone can be seen, and without any diagnostic criteria for his differentiation of, for example, lumbago and fibrositis, the author concludes that as "there has not been observed a single case of fibrositis during the period of three months under review at Colliery C (the largest of the three)" this "surprising fact can be due to one thing only: Colliery C has pithead baths and the others have not". "This", he states, "is a striking illustration of the great medical value of such baths." But

evidence accumulated in this investigation it was concluded that the rheumatic diseases accounted for (1) nearly one-sixth of the total industrial invalidism in England and Wales; (2) an expenditure of £2,000,000 yearly in sickness benefit; and (3) a loss of 3,000,000 weeks of working time. Chronic arthritis was said to have been responsible for half the loss both in money and time.

An interesting community survey was made by Davidson and Duthie in 1937 in Aberdeenshire (2). It covered a population of 135,000. In an average winter month the total doctors' visits and consultations were 50,900 and of these 5,800 (11·4%) were for rheumatic disease. 875 were new cases; of these 672 were assigned to the muscular and neuritic groups, 68 to acute and subacute rheumatism, 82 to osteoarthritis and 53 to rheumatoid arthritis. The incidence in this series is higher than in many others; it may be explained by the adverse wintry climatic conditions of the north. But this work has one merit, rare in other surveys. In order to ensure, as far as practicable, uniformity of classification and diagnosis, Davidson and Duthie explained in detail to each practitioner taking part the criteria to be followed.

The Department of Health for Scotland in its Report on Chronic Rheumatic Diseases (1945) records significant morbidity statistics relevant to the year 1937-38 [2]. During this period, 1 in 50 insured men and 1 in 60 insured women were incapacitated by "muscular" rheumatism for a period of up to four weeks or by "neuritic" rheumatism for up to six weeks. The rheumatic diseases headed the incapacity tables with 3,000,000 days' incapacity, the digestive diseases (all forms) being second with 2,400,000 days. There were 45,300 new rheumatic cases of which 3,000 were articular in site and represented 270,000 days' incapacity but the ravages of arthritis are seen most strikingly in the fact that the disability of 1,600 patients incapacitated by arthritis in the preceding year continued throughout the period reviewed.

The most recent records for this country are to be found in the Social Health Surveys published in the Monthly Bulletin of the Ministry of Health and the Emergency Public Health Laboratory Service. These suggest that over 7% of the population is incapacitated by "rheumatism" for at least a day each year and that half the population suffers at some period of the year from "rheumatism" which is not disabling; but the figures, as recorded, are not wholly free from ambiguity. Figures from E.M.S. hospitals (1942-44) show that among Service patients about one-quarter of all rheumatic disease is arthritic at the age of 25, and that the proportion increases to one-third by the age of 45-50.

The incidence in other countries is revealing. In the National Health Survey of the United States in 1935-36, 6,850,000 (over 5%) of the population of 127,000,000 suffered from some form of rheumatic disease and of these 3,000,000 were arthritic [3]. Rheumatism was the commonest chronic illness of over a week's duration. It was twice as frequent as heart disease, seven times as frequent as cancer, and ten times as frequent as tuberculosis, but it ranked only fourteenth in the causes of death. Yet in 1935-36 it completely disabled 147,600 men and women in the United States (1·2 per 1,000 of the population) and another 800,000 were partially disabled to the extent of losing an average of five months' work each year. It is estimated that 100,000,000 days are lost yearly by partially and completely disabled victims, thus surpassing the loss arising from any other single cause. This figure for lost time due to rheumatism corresponds almost exactly, relative to the different populations of the two countries, with the 3,000,000 weeks of the 1924 report for England and Wales. At £4 a week in wages this represents a cost of £12,000,000 per annum to this country solely in work lost through disability; the total loss would be much greater if the costs of insurance benefits and medical care were included. A grave feature of the economic repercussions of rheumatism is that 50% of its victims are under 45 and should be at their optimum productive capacity; 70% are under 55—an age at which many workers are still at their most active.

The most recent figures showing a heavy incidence are from Sweden where in 1923 Kahlmeter had reported that chronic articular rheumatism was the cause of retirement of 9% of insured workers. In 1944-45 Edström [4] investigated 72,000 persons—half in rural districts and half in villages—differing in social and economic status and environment. Of these 5,679 (7·9%) had rheumatic disease, and in 2,745 (3·8%) it was active; 480 (6·7 per 1,000) were permanently incapacitated.

It would be idle to claim that any of these statistical surveys is comparable with another or that from them can be gathered more than a general impression of the prevalence and morbidity of the rheumatic diseases. The samples examined are inadequate in number, type and variety; for example, the necessary omission of housewives from the 1924 English survey of insured persons is a cardinal defect. They refer to different age-groups, and different years in which the relative numbers in the different age-groups may vary. The differences in occupation, geography, climate and subsoil, social and economic status, nutrition and other significant features in these heterogeneous groups forbid strict comparison. There is a lack of differentiation of "attack" rate (morbidity incidence) and "prevalence" rate (morbidity prevalence). During this period, 1 in 50 insured men and 1 in 60 insured women were incapacitated by "muscular" rheumatism for a period of up to four weeks or by "neuritic" rheumatism for up to six weeks. The rheumatic diseases headed the incapacity tables with 3,000,000 days' incapacity, the digestive diseases (all forms) being second with 2,400,000 days. There were 45,300 new rheumatic cases of which 3,000 were articular in site and represented 270,000 days' incapacity but the ravages of arthritis are seen most strikingly in the fact that the disability of 1,600 patients incapacitated by arthritis in the preceding year continued throughout the period reviewed.

The most recent records for this country are to be found in the Social Health Surveys published in the Monthly Bulletin of the Ministry of Health and the Emergency Public Health Laboratory Service. These suggest that over 7% of the population is incapacitated by "rheumatism" for at least a day each year and that half the population suffers at some period of the year from "rheumatism" which is not disabling; but the figures, as recorded, are not wholly free from ambiguity. Figures from E.M.S. hospitals (1942-44) show that among Service patients about one-quarter of all rheumatic disease is arthritic at the age of 25, and that the proportion increases to one-third by the age of 45-50.

The incidence in other countries is revealing. In the National Health Survey of the United States in 1935-36, 6,850,000 (over 5%) of the population of 127,000,000 suffered from some form of rheumatic disease and of these 3,000,000 were arthritic [3]. Rheumatism was the commonest chronic illness of over a week's duration. It was twice as frequent as heart disease, seven times as frequent as cancer, and ten times as frequent as tuberculosis, but it ranked only fourteenth in the causes of death. Yet in 1935-36 it completely disabled 147,600 men and women in the United States (1·2 per 1,000 of the population) and another 800,000 were partially disabled to the extent of losing an average of five months' work each year. It is estimated that 100,000,000 days are lost yearly by partially and completely disabled victims, thus surpassing the loss arising from any other single cause. This figure for lost time due to rheumatism corresponds almost exactly, relative to the different populations of the two countries, with the 3,000,000 weeks of the 1924 report for England and Wales. At £4 a week in wages this represents a cost of £12,000,000 per annum to this country solely in work lost through disability; the total loss would be much greater if the costs of insurance benefits and medical care were included. A grave feature of the economic repercussions of rheumatism is that 50% of its victims are under 45 and should be at their optimum productive capacity; 70% are under 55—an age at which many workers are still at their most active.

The most recent figures showing a heavy incidence are from Sweden where in 1923 Kahlmeter had reported that chronic articular rheumatism was the cause of retirement of 9% of insured workers. In 1944-45 Edström [4] investigated 72,000 persons—half in rural districts and half in villages—differing in social and economic status and environment. Of these 5,679 (7·9%) had rheumatic disease, and in 2,745 (3·8%) it was active; 480 (6·7 per 1,000) were permanently incapacitated.

It would be idle to claim that any of these statistical surveys is comparable with another or that from them can be gathered more than a general impression of the prevalence and morbidity of the rheumatic diseases. The samples examined are inadequate in number, type and variety; for example, the necessary omission of housewives from the 1924 English survey of insured persons is a cardinal defect. They refer to different age-groups, and different years in which the relative numbers in the different age-groups may vary. The differences in occupation, geography, climate and subsoil, social and economic status, nutrition and other significant features in these heterogeneous groups forbid strict comparison. There is a lack of differentiation of "attack" rate (morbidity incidence) and "prevalence" rate (morbidity prevalence). In some, e.g. the Social Surveys, the recorded diagnosis is usually that given by the subject of the interview; this self-diagnosis by those for whom any pain is "a touch of the rheumatics" is a flimsy basis for statistical records and analyses. It may indeed account for the fact previously noted, that in the most recent surveys half the population is recorded as suffering from non-incapacitating rheumatism. Finally, and of great importance, is the use in these reports of a varying nomenclature and classification of rheumatic disease, and the absence of any definitive criteria for the diagnosis of its diverse forms.

Any projected future surveys must take cognizance of all these points if they are to resist the attacks of the critics. In all fields of medicine the fallacies in interpreting the results of clinical investigations are a ready snare for the unwary. In rheumatic disease there is need for the greatest care not only in defining the results of observation but also in planning large-scale field and therapeutic experiments if they are to be most fruitful. To this end I would plead for the closest co-operation between the statistician and the clinician in this work. If this be achieved we shall hear less of the old gibe that "statistics may be made to tell anything, even the truth", and see fewer of those papers claiming, for a remedy in these diseases, 100% cures but written in that apologetic tone which is intended to convey that the author hopes to do better next time.

As an example of the tyranny of names and the absurd conclusions to which they may lead, let me quote, without acknowledgment for obvious reasons, a table from a recent paper, with the names of the collieries omitted.

Type of rheumatic ailment	Colliery A	B	C	Total
Rheumatoid arthritis..	8	5	9	22
Lumbago	5	10	13	28
Fibrositis	31	17	Nil	48
Sciatica	Nil	2	11	13
Neuritis	Nil	Nil	2	2

From an analysis of these figures which do not even specify the number of miners employed at each colliery so that an absolute and not a relative incidence alone can be seen, and without any diagnostic criteria for his differentiation of, for example, lumbago and fibrositis, the author concludes that as "there has not been observed a single case of fibrositis during the period of three months under review at Colliery C (the largest of the three)" this "surprising fact can be due to one thing only: Colliery C has pithead baths and the others have not". "This", he states, "is a striking illustration of the great medical value of such baths." But

assuming that, by a diagnostic talent vouchsafed to a select few only, he is able to differentiate between lumbago and fibrositis, what of the eleven cases of sciatica at Colliery C and their complete absence at A; and what of the greater incidence of lumbago at C? Would it not be just as tenable to infer that the pithead baths at C increased significantly the tendency there to sciatica and lumbago?

NOMENCLATURE AND CLASSIFICATION

To such a pass are we brought when we juggle with names. Yet it is impossible to speak of the objects of our study or to think clearly about them unless we give them names, and it is impossible to examine their relationships to each other, and their places in the almost infinite and incredibly complex phenomena of disease, in short to handle them scientifically, without classifying them in a formal way. But names must be our servants not our masters, and we must realize that it is man, and not God, who classifies.

The names we give to disease vary in worth and implication. Some signify a symptom—a deviation from the normal, e.g. dyspnœa; others suggest the tissue from which the symptom is alleged to arise, e.g. neuralgia and myalgia; whilst still others specify the exact anatomical reference of a symptom, e.g. sciatica, brachial neuralgia. Others refer to disorders of bodily function, e.g. jaundice, glycosuria. Yet others give in their nomenclature the pathology underlying the disease, e.g. arthritis, tenosynovitis, bursitis, and where possible its cause, e.g. gonococcal arthritis. Some recognize the association of phenomena in a regular, recurring pattern, e.g. Reiter's disease. Many are based on unconfirmed hypotheses of causation, e.g. fibrositis, whilst others, e.g. rheumatism and gout, have sufficiently strong historical roots to have survived an outmoded humoral pathology and need, if they are to be useful, to be defined anew. Is it surprising that the many classifications of rheumatic disease which include names of such diverse import should have failed in their purpose? I would suggest at the outset that the only basis on which to found a valid classification of the rheumatic diseases is primarily *anatomical*, i.e. involvement of skeletal, articular and neuromuscular structures. To suggest that rheumatic disorders should be defined as "painful locomotor disorders of unknown ætiology" is to exclude from the rheumatic group such conditions as dysenteric arthritis and sciatica associated with a prolapsed intervertebral disc, and thus to ignore what is the basis of a useful classification, viz. an emphasis on similarities.

Such a widening of the group might well include conditions not usually regarded as rheumatic diseases, e.g. trichinous myositis, yet there can be no sound reason which excludes this and yet includes, as does the Royal College of Physicians classification, gonococcal arthritis. We must find a fresh starting-point which takes note of established fact and present-day views rather than of traditional lore. We should in our classification recognize rheumatic fever, with its distinctive features of age-incidence, cardiac and neural involvement, and its response to salicylates, even though its ætiology remains obscure. We shall note arthritis of known cause —infective, traumatic, metabolic, allergic, neuropathic, hæmophilic—and arthritis in which the primary cause is unknown, be it called rheumatoid, cryptogenic, non-specific or idiopathic. But a common name is no guarantee of a common ætiology, so we shall not think of the group, rheumatoid arthritis, as necessarily homogeneous and of like cause. The name will unmask our ignorance as well as our knowledge and we shall endeavour by accurate and detailed observation of these cases to provide material for a clinical analysis related to age, sex, heredity, occupation, housing, geography, climate, social and economic conditions, previous infection, pregnancy, endocrine disturbances, allergic factors and the like, and thus to isolate groups which from their natural history and similar pattern may with advantage be studied together. Osteoarthritis will then be recognized as a possible sequel of any form of arthritis as well as an apparently primary degenerative process consequent on age or vascular changes. If we are wise we shall eschew such terms in our clinical classification as fibrositis, neuritis, strains, adhesions, and their associates, appreciating that in the vast majority of cases they are the refuges of the diagnostically destitute when confronted with inexplicable pains and that a hypothetical pathology may mask a problem but never solve it. In formulating any scheme for the treatment of rheumatism we must recognize that the persistence of pains labelled fibrositic, neuritic and the like, call for the use of every necessary diagnostic aid. In one week recently, I met a neurofibroma of the cauda equina, a vertebral metastasis from a bronchial carcinoma, a primary ovarian carcinoma, a chronic perinephric abscess, a prolapsed intervertebral disc, and a spondylolisthesis, all of which had been treated for several months as lumbago, fibrositis, or sciatica. These illustrate the dangers of "surrendering judgment" to the "fascination of a name".

AVAILABLE FACILITIES FOR TREATMENT

I was led into this digression from my main theme because I wished to stress that if we seek not simply more accurate statistical data but also a better understanding of the rheumatic diseases we must clarify and define our nomenclature and amend our classifications. But our present knowledge, inadequate and faulty though it be, leaves no doubt about the extent of the provision which must be made if sufferers are to be given "all the advice and treatment and care which they may need in matters of personal health", which is the avowed objective of Government policy in the proposed National Health Service. It would be idle to suppose that this can be provided overnight, but a start must be made and plans formulated. Contrast the incidence of rheumatism with the available facilities for treatment and it will be seen that even on the most generous estimate the gap will take many years to bridge. Davidson and Duthie estimated that in the nine large voluntary hospitals of Scotland there were treated annually only 1,000 rheumatic in-patients and 5,000 out-patients. In this country there are almost certainly less than 1,000 beds (including the special hospitals at spas) for the treatment of rheumatic disease. At eight British spas the maximum total daily treatments which can be provided in an eight-hour day is 8,340. Yet the figures available suggest that on any day in this country there are tens of thousands who suffer from and need treatment for rheumatism.

PAST NEGLECT

Why has there been hitherto so flagrant a neglect of rheumatic disease?

In the first place, rheumatism is not one of the fatal diseases; it ranks fourteenth in the causes of death. It lacks the dramatic appeal of cancer, tuberculosis and heart disease which in a few months may cut off their victims at an early age. In the days when facilities for research and the provision of treatment depended on voluntary gifts, the more fatal diseases attracted the attention of the philanthropist. But any Government must view with grave concern the major cause of industrial invalidism and the present Minister of Health has declared that the Government "attach the utmost importance to the attack on the group of illnesses known as rheumatism".

Secondly, the treatment of arthritis is much less spectacular and less overtly rewarding than most other diseases. It is prolonged and often tedious to both patient and doctor, and even the most satisfactory treatment may leave the patient with impaired function and ungainly deformity. Moreover in this treatment there has in the past been absent, all too often, the necessary co-operation between physician, orthopædic surgeon, physiotherapist and various specialists whose team work is essential if maximum recovery is to be secured. Neglect by the competent has left the field widely open to the incompetent and the unbridled therapeutic enthusiast. Sufferers, many hopeless and others disappointed, have succumbed to the blandishments of the unorthodox. The law has permitted the sale of nostrums "guaranteed to cure" and these have survived because many rheumatic complaints tend to natural remissions, and most patients and many doctors fail to distinguish *propter* from *post*.

This neglect by physicians is seen not only in the inadequate equipment, facilities and personnel for treating rheumatism in our larger teaching and general hospitals but, more seriously, in the absence from the medical student's curriculum of any adequate experience of rheumatic disease. He may be able to recognize many advanced types quite accurately but his knowledge of the early manifestations and the natural course of, for example, the various forms of arthritis; of the potentialities of treatment, and of the place and value of orthopædic methods, physiotherapy, occupational therapy, rehabilitation, both physical and psychological, in the management of rheumatic disease, is a lamentable void.

Finally, research into rheumatism failed to attract the support of academic bodies, such as the Medical Research Council. Their view has been expressed by Mellanby: "Extensive *ad hoc* research on a disease like rheumatism, however important as a practical problem, is liable to be unprofitable until the master key of its ætiology, or some other essential fact has been disclosed. This master key is just as likely to be discovered by the use of the experimental method over a wide field, as by directly studying a disease in which the experimental method is hardly available." This apology for withholding support is, I suggest, unwarranted on two counts. First, clinical observation and investigation by known methods may yield many secrets if pursued by competent investigators along sound lines. The differentiation of typhoid and typhus and their virtual elimination by general hygienic measures long antedated the discovery of their specific causes. It cannot be too strongly urged, in view of the orientation of so many laboratory research workers in medicine, that a so-called specific or necessary cause of disease is not of itself a wholly sufficient cause, except in the rarest instances. There are many contributory factors. For example, in the United States Public Health Survey disability from rheumatic disease was observed to be two to three times as great in the lower income group as in the higher. Secondly, the discovery of a specific cause is not necessarily followed by the discovery of a specific remedy. Though over half a century has passed since the tubercle bacillus was found we still seek the specific remedy for tuberculosis, but whilst awaiting its advent we continue to achieve cure in a large number of vicitims by non-specific measures. And so it is with chronic arthritis. Medical treatment, the prevention and correction of deformities, physiotherapy, exercises, manipulations, and a host of other measures lead in an increasing number of cases, especially when applied early, to a satisfactory outcome. Are not enquiries into their mode of action, and field investigations into the influence of such conditions as climate, occupation, and social and economic factors, sufficiently important for medical science to merit support from specifically designated "medical research" organizations? Until quite recently those who direct their policy have not thought so. The considerations thus far outlined call for action in four directions: (1) Research into the problems of rheumatism; (2) planning a service which makes available to all who need it all necessary treatment; (3) stimulating, in students and practitioners, a greater interest in the scope and methods of diagnosis and treatment of rheumatic disease; and (4) making available opportunities for the training of those who wish to specialize in this field.

RESEARCH

Research must be encouraged and supported. Money must be forthcoming, for though money never solves problems it helps men to solve them. This research must be closely associated with Universities and Medical Schools and their hospitals. Not only its prestige but its need in men and material demand this liaison. Only in this way will the co-operation of other experts, e.g. biochemists, physicists, pathologists and bacteriologists, be secured at the highest level. Programmes of research will cover all aspects of rheumatism. They will include fundamental problems in bone, muscle and joint physiology and pathology; they will cover epidemiology, diagnosis, and therapy. Some will be pursued in the laboratory, others in the field, and yet others in the clinics, but most will need data derived from all these sources and demand the services of a team. Many major investigations can even now be defined; here are a few:—

(1) Accurate statistical studies on morbidity rates, both national and local; and more intensive local studies dealing with selected areas of adequate size (say 50,000 to 100,000) which vary in climate, geography, subsoil, social and economic factors, diet, dominant occupations, and other possibly significant ways. Such local surveys would be intimate and detailed studies needing the co-operation of family and works' doctors, hospitals and their staffs, and medical officers of health.

(2) Rheumatism as an industrial problem; its incidence in selected occupations, e.g. among miners, dockers, postmen. It is here that the most careful scrutiny of clinical data given on certificates is needed. Statistics hitherto available are vitiated by many factors which tended to increase "rheumatism" as a certified cause of illness. A doctor in a mining practice tells me that before the advent of the paid holiday in the coal trade the increase of purely symptomatic rheumatism at holiday seasons was a noticeable feature. Moreover, it is the non-objective rheumatic complaints—"myalgia", "muscular rheumatism", "fibrositis"—which form the bulk of the diagnoses on medical certificates given to men who wish to leave the coal-mining industry on medical grounds. What are the conditions which predispose to rheumatism in certain industries? In miners, for example, what is the influence in the mine of atmospheric humidity; of passing from return (warm) roadways to intake (cold) roadways; of cramped posture especially when working in the seams; of the strenuous nature of the work; and of deprivation of sunlight? What is the effect at the surface of waiting about in wet clothes for buses and cycling or walking home after strenuous work in wet and cold weather? How far do housing conditions in mining villages, faulty diet, and neglect of general health contribute to a miner's rheumatism? It cannot be said that there has been an adequate investigation into these alleged predisposing causes. Careful studies in prophylaxis need to be undertaken. The influence of personal and domestic hygiene should be examined, so also conditions at work—working hours, fatigue, psychological factors, the nature of the work—and the influence of rest periods, pithead baths and ultraviolet light treatments in mines and factories. Available statistics emanate almost entirely from enthusiasts who, having formed an opinion on the merits of a method of treatment, find their results support their preconceived views. I have noted one such example earlier. A warning on this count is found in Dr. Dora Colebrook's admirable report, issued recently by the Industrial Health Research Board, on "Artificial Sunlight Treatment in Industry: A Report of results of three trials—in an office, a factory and a coal-mine". It had been widely claimed that ultraviolet radiation has a general "tonic" effect and not only prevents and corrects minor conditions of ill-health but reduces the amount of absenteeism due to accidents, rheumatism, common colds and general ill-health. Dr. Colebrook's report is a clear and careful presentation of a large-scale inquiry into this important subject, which is a model for such controlled therapeutic experiments. It reveals that the general application of ultraviolet radiation in small dosage has none of the "tonic" effects attributed to it. The use of artificial sunlight in this field is not a prophylactic measure but simply a modern version of sun-worship.

(3) There are many fundamental aspects of the growth of articular, skeletal and neuromuscular tissues and their normal senescence which need elucidation. Metabolic, nutritional, allergic, circulatory and other changes in the rheumatic subject need probing. Experimental arthritis and its relation to human arthritis and virus studies must be tackled. The local metabolism of joint tissues, e.g. the respiration of articular cartilage, the permeability of the synovia in health and disease—all these and a host of other problems come to mind, and new ones present themselves with discoveries in other fields. An interesting example has recently been published [5]. It is known that rheumatic fever affects predominantly mesenchymal tissues whose principal substrate is hyaluronic acid. The enzyme, hyaluronidase (which is the "diffusion factor" derived from many organisms including hæmolytic streptococci, and many tissues, especially testis) is capable of hydrolysing hyaluronic acid thus decreasing the viscosity of the tissues and favouring the passage of liquids, exudates and pathogenic micro-organisms into them. These are the tissues forming the synovial membranes and connective tissues of the articulations. What is impressive and might be of great significance is first, that oral or intravenous sodium salicylate inhibits this spread by as much as 66%, the degree of inhibition varying according to the dose of salicylate given; and secondly, that in patients with acute rheumatic fever or in those who have previously had rheumatic fever, "unique reactions with enormous diffusion of the dye and local œdema" sometimes follow the intradermal injection of dye and hyaluronidase. It is too early to assess the significance of these observations but they are illuminating in that they offer for the first time a rational explanation of the action of salicylates in acute rheumatism and throw light on an enzyme system which is capable of producing profound and dramatic effects in special regions without direct bacterial invasion.

(4) Many clinical investigations need launching. I have already referred to the need for accurate and detailed clinical records in the hope that these will lead to a sounder regrouping of the rheumatic disorders. Each of you will be prepared to give a list of clinical inquiries which should be undertaken, e.g. a critical reassessment of the role in rheumatic diseases of focal sepsis, of allergy, of endocrinous disturbances and the influence of the menopause; of the effects of gold and related drugs; of radiological studies and so forth. Some of these have been started on a large scale and we may look forward to useful knowledge emerging from them. But before this Section I would crave especially for basic investigation into the modes of action and the effects of the methods of physical medicine—heat, light, hydrotherapy, radiotherapy, mechanotherapy, and the physical factors governing the clinical application of these measures. In this the association of clinician and physicist is essential. How fruitful this partnership may be is shown by the work carried out in the Nuffield Department of Clinical Medicine at Oxford under Professor Witts' direction.

From this recital of possible research topics covering many fields, but by no means exhaustive, can it not be inferred that many valuable enquiries can be conducted even in the absence of a "master key"? Fortunately all do not hold Mellanby's view and the generous grant by the Nuffield Foundation of £100,000 to the University of Manchester to establish a research centre is welcome evidence of a renewed interest in rheumatism; the appointment of Professor S. L. Baker as Pathological Director of this new research centre is a guarantee of its status. The Foundation is also offering research fellowships in rheumatism so that no young and competent enthusiast need be deterred, as he was in the past, from working in this field because of financial obstacles.

A SERVICE FOR THE NATION

In planning a service for rheumatic disease which shall form part of a National

Health Service we have to bear in mind: (1) The paramount need for accurate diagnosis; (2) the parallel pursuit of clinical and basic research into the problems of rheumatism especially prophylaxis; (3) the provision of staff, and hospital beds in which patients may remain if need be for months in order to ensure that all the necessary treatment can be given; (4) the setting-up of clinics near the homes of patients or near their places of employment where minor forms of rheumatism can be treated and where those who have earlier been hospitalized can continue physical therapy. Moreover, it is necessary to consider what immediate action is possible to improve existing facilities for the diagnosis and treatment of the rheumatic diseases and the long-term development of such facilities. The plan suggested for immediate action is similar in structure to that of the scheme which is envisaged as a permanent service, so that our long-term policy will develop naturally out of the interim schedule. It is in brief suggested that:

(1) The teaching hospitals and a number of major general hospitals shall act as diagnostic and research centres.

(2) Each of these centres will be linked on the one side with one or more out-patient clinics with adequate facilities for physical therapy of most forms, and on the other with a base hospital providing long-stay beds and all necessary medical and surgical treatment, including occupational therapy and rehabilitation, for the chronic patient.

(3) Each diagnostic centre will provide the short-stay beds for investigation (it is unlikely that circumstances will free hospital beds in the diagnostic centre for long-stay patients) and also an out-patient clinic, though where more convenient the patient may be referred to one of the associated clinics.

(4) Patients will be referred by their family doctor, or by a works' doctor after consultation with the family doctor, to out-patient clinics in the first instance. These clinics, appropriately staffed, can and will deal with most patients giving them the appropriate treatment. But where the diagnosis is in doubt or where, after a few weeks, treatment has failed to benefit, then the patient is to be referred to the associated diagnostic centre.

(5) Base hospitals will care for long-stay cases referred for treatment by associated diagnostic centres; some will have out-patient departments and they too will refer doubtful or intractable cases to an associated diagnostic centre.

These constituents of the service will form a functional unit. Their staffs will be able to follow the progress of a case wherever it may be. We believe that this scheme will show not only "how good and how pleasant" but also how profitable it is for brethren in arms against the evils of rheumatism to "dwell together in unity". Already in some parts of the country a skeleton service based on the plan here described has been inaugurated.

EDUCATIONAL NEEDS

I have earlier referred to the deficiencies of our undergraduate medical curriculum in the teaching of rheumatic disease, especially its early diagnosis and the potentialities of treatment. No one is better aware than myself of the overcrowding of the students' timetable and no one would more earnestly plead for its pruning, but I will say no more than that I hold strongly that the major cause of industrial invalidism deserves some attention even if it be at the expense of rarer and more exotic topics. As a past sinner, I am heartened to observe that increasing efforts are being made in some schools to correct the omissions of the past.

We need to interest the students so that later some may be attracted to this special field. Now that we have heard on the highest authority that the fullest facilities for the treatment of rheumatic disease are to be provided as

(3) There are many fundamental aspects of the growth of articular, skeletal and neuromuscular tissues and their normal senescence which need elucidation. Metabolic, nutritional, allergic, circulatory and other changes in the rheumatic subject need probing. Experimental arthritis and its relation to human arthritis and virus studies must be tackled. The local metabolism of joint tissues, e.g. the respiration of articular cartilage, the permeability of the synovia in health and disease—all these and a host of other problems come to mind, and new ones present themselves with discoveries in other fields. [*January* 8, 1947]

Clinical Science in the Light of History

By A. P. CAWADIAS, O.B.E., M.D., F.R.C.P.

MEDICINE is an Art, and as such has existed since the beginnings of humanity. The Greeks, who created Science in that century tremendous in the development of humanity, the seventh century B.C., introduced as basis of the art or practice of medicine the scientific knowledge embodied in two sciences, Physiology in its wider sense, that is, Physio-pathology, and Clinical Science.

PHYSIO-PATHOLOGY AND CLINICAL SCIENCE

The object of Physiology in its wide sense, or Physio-pathology, is study of the functions of the human body, of the deviations of these functions, and of the action of various agents on these functions in their normal and their diseased state. It thus includes physiology proper, pathology, pharmacology and general therapy. Its method is *a priori* thinking, hypothesis, experimentation for the control of hypothesis, and reasoning on the basis of experimental facts towards the discovery of general laws concerning health and disease. In his reasoning the Physio-pathologist takes into consideration the facts of clinical observation, of Clinical Science. Pathology is thus a branch of physiology, and as this is the section of Physiology in closest contact with medicine I shall use indifferently the terms Physio-pathology and Pathology.

The object of Clinical Science is study of the morbid phenomena exhibited by human beings. Its method is clinical observation of these phenomena, their classification into morbid categories or diseases, and reasoning on the basis of clinical observation for discovery of methods of diagnosis and treatment of patients showing these particular morbid categories or diseases. In his reasoning the Clinical Scientist takes into consideration the data of Physio-pathology.

This science was known by the more general term *ἰητρική* translated into "Medicine". Sydenham introduced the more accurate and expressive term "Natural History of Diseases". Later the terms "Nosology" and "Clinical Medicine" were used. I do not know who first used the term Clinical Science, but I find it in the work of Sir James Paget and later in that of Knud Faber. It is to Sir Thomas Lewis, however, that we owe the general use of the term Clinical Science. Unfortunately, this great physician over-emphasized what I shall call later the "pathogenic chapter" of the natural history of diseases, and stressed certain clinical experimental procedures to which he seemingly attributed greater scientific status than to the great and real method of Clinical Science, namely, clinical observation. Neither can I accept his division into "Theoretical Medicine" and "Curative Medicine". There are only two divisions in medicine as a science, Physio-pathology and Clinical Science. We must therefore take the term "Clinical Science" in its traditional Sydenhamian sense of "Natural History of Diseases".

Although intimately connected—all sciences are connected—Pathology and Clinical Science are independent and separate sciences. Hippocrates in his *Ancient Medicine* had contrasted the *ἰητρική* with "Ὅτι Ἐμπεδοκλῆς ἢ ἄλλοι οἵ περί φύσεως γεγράφασι" (Empedocles and others have written on Nature). This is shown not only by the difference in their primary object and in their method, but also by the history of their creation and development.

part of the proposed national health service any competent specialist in this field can face the future with equanimity. The training of such specialists has been given careful consideration by my committee. A sound discipline in general medicine and the possession of a higher qualification are essential passports to specialized training. This will comprise medical work in the rheumatic field, practice in the non-operative orthopædic techniques necessary in the treatment of rheumatism, a working knowledge of the methods and machines of physiotherapy and the practical applications of physical medicine, occupational therapy and rehabilitation. Visits to foreign centres should be encouraged. The reawakening of interest in physical methods of treatment during the war makes it certain that given financial support during training, and satisfactory prospects for practising after training is completed, the right type of practitioner in sufficient numbers will be attracted to this field.

In the title of this lecture, I referred to "a challenge and an opportunity". The challenge lies in the incidence of rheumatic disease, in our inadequate understanding of it and in our past neglect. The opportunity for facing afresh the problems which this challenge presents comes with the introduction of a health service which promises to every citizen the treatment appropriate to his needs. But the opportunity is also a heavy responsibility for medicine. I have sought in this Address to indicate how it may be shouldered. Even with present knowledge, limited though it be, if we had sufficient trained personnel, hospital beds, and treatment facilities we could substantially lessen the invalidism resulting from rheumatism. We are appreciating in medicine, more and more fully, the importance of team work; in the rheumatic diseases the members of the team are many but they must work as a unit. Research will extend the frontiers of our knowledge, and we must see to it that in the future administrative medicine will repent its shortcomings of the past and keep pace with advancing knowledge. Mr. Bevan said, fifteen months ago, concerning suggestions embodied in a report on physical medicine, that he hoped the responsible Minister would "not be given any peace till they were carried out". We accept the challenge and shall act on this Ministerial injunction for in so doing we shall seek again to justify what was written of our profession many decades ago—"In it are united the aims and aspirations of the best and noblest of mankind".

Clinical Science in the Light of History

By A. P. CAWADIAS, O.B.E., M.D., F.R.C.P.

MEDICINE is an Art, and as such has existed since the beginnings of humanity. The Greeks, who created Science in that century tremendous in the development of humanity, the seventh century B.C., introduced as basis of the art or practice of medicine the scientific knowledge embodied in two sciences, Physiology in its wider sense, that is, Physio-pathology, and Clinical Science.

PHYSIO-PATHOLOGY AND CLINICAL SCIENCE

The object of Physiology in its wide sense, or Physio-pathology, is study of the functions of the human body, of the deviations of these functions, and of the action of various agents on these functions in their normal and their diseased state. It thus includes physiology proper, pathology, pharmacology and general therapy. Its method is *a priori* thinking, hypothesis, experimentation for the control of hypothesis, and reasoning on the basis of experimental facts towards the discovery of general laws concerning health and disease. In his reasoning the Physio-pathologist takes into consideration the facts of clinical observation, of Clinical Science. Pathology is thus a branch of physiology, and as this is the section of Physiology in closest contact with medicine I shall use indifferently the terms Physio-pathology and Pathology.

The object of Clinical Science is study of the morbid phenomena exhibited by human beings. Its method is clinical observation of these phenomena, their classification into morbid categories or diseases, and reasoning on the basis of clinical observation for discovery of methods of diagnosis and treatment of patients showing these particular morbid categories or diseases. In his reasoning the Clinical Scientist takes into consideration the data of Physio-pathology.

This science was known by the more general term *ἰητρική* translated into ‘‘Medicine’’. Sydenham introduced the more accurate and expressive term ‘‘Natural History of Diseases’’. Later the terms ‘‘Nosology’’ and ‘‘Clinical Medicine’’ were used. I do not know who first used the term Clinical Science, but I find it in the work of Sir James Paget and later in that of Knud Faber. It is to Sir Thomas Lewis, however, that we owe the general use of the term Clinical Science. Unfortunately, this great physician over-emphasized what I shall call later the ‘‘pathogenic chapter’’ of the natural history of diseases, and stressed certain clinical experimental procedures to which he seemingly attributed greater scientific status than to the great and real method of Clinical Science, namely, clinical observation. Neither can I accept his division into ‘‘Theoretical Medicine’’ and ‘‘Curative Medicine’’. There are only two divisions in medicine as a science, Physio-pathology and Clinical Science. We must therefore take the term ‘‘Clinical Science’’ in its traditional Sydenhamian sense of ‘‘Natural History of Diseases’’.

Although intimately connected—all sciences are connected—Pathology and Clinical Science are independent and separate sciences. Hippocrates in his *Ancient Medicine* had contrasted the *ἰητρική* with ‘‘‘Οτι ’Εμπεδοκλῆς ἤ ἄλλοι οἵ περί φύσεως γεγράφασι’’ (Empedocles and others have written on Nature). This is shown not only by the difference in their primary object and in their method, but also by the history of their creation and development.

Physio-pathology was created in the sixth century B.C. The first scientists, the Ionian Greeks, were designated Physiologists, meaning students of Nature in general. They were the first to reject the supernatural explanation of the universe current amongst the ancient Eastern peoples, and showed that all phenomena had a "natural explanation" and that the secrets of the world could be penetrated by the unprejudiced observation of things and the power of reason. When Pythagoras brought the torch of the Ionian Physiology to the Italo-Sicilian Greeks in the late sixth and early fifth centuries B.C., a group of physiologists passed from consideration of Nature in general to that of animal and principally human nature, and since then the term Physiology has been restricted to the study of the functions of the human body. The originators of this movement, apart from Pythagoras, were Alcmeon of Croton, Empedocles of Agrigentum, Diogenes of Apollonia, Hippon and Anaxagoras. From its inception Physiology was Physio-pathology, these first physiologists studying the functions of the human body in health and disease, as shown in the conception of disease expressed in the works of Alcmeon, Empedocles and Diogenes. In fact these first Physio-pathologists were the first physicians. The intimate union between Physiology and Pathology has persisted ever since. It was developed in the work of Galen, the greatest of the Greek Physio-pathologists. It was codified later through the work of John Hunter, Magendie and Claude Bernard, and is embodied in Magendie's famous dictum, "Medicine (meaning pathology) is the physiology of the diseased individual".

The method adopted by the first physiologists was *a priori* reasoning and observation, including dissections. Experimentation was introduced by the Alexandrians of the third century B.C. and principally by Galen, but received its greatest impetus from Harvey, who thus revived Physio-pathology as his contemporary, Sydenham, revived Clinical Science. Since Harvey the basic method of Physio-pathology has been experimentation.

Clinical Science was introduced a little later, in fact in the fifth century, by the Coan physicians represented by Hippocrates, by the Cnidians represented by Euryphon and also by the physicians of Rhodes. The islands of Cos and Rhodes and the peninsula of Cnidos were colonized by that most virile section of the Greek people, the Dorians, who were, however, influenced by the neighbouring Ionia and also by East Asia. Asclepios, the God of Medicine, was one of the chief Dorian gods, and from the Dorian peninsula of Peloponnesus with its great sanctuary of Asclepios at Epidauros, this cult was brought to Cos, Cnidos and Rhodes. The priests of Asclepios, the Asclepiadæ, formed a princely priest-family which attributed its origin to Podalirios, son of Asclepios. The Asclepiadæ did not continue in their purely priestly caste spirit. They were not Egyptians, they were Greeks. Just as the Ionians had detached themselves from the magic and supernatural explanations of the universe and interpreted Nature through natural laws, the Coan and Cnidian Asclepiadæ abandoned purely religious healing rites and, with the object of giving more effective help to the patients who sought relief in the temples of Asclepios, they adopted clinical observation and healing on the basis of clinical observation.

THE METHOD OF CLINICAL SCIENCE

The method of Hippocrates, the founder of Clinical Science, consists, as described by Plato, in careful analysis of nature (*Διελέσθαι τήν φύσιν* or clinical observation), in enumeration of its types (*ἀριθμήσασθαι τά εἴδη* or nosographical classification), and in definition of the appropriate treatment for each (*προσαρμόττειν ἕκαστον ἑκάστῳ*).

The Egyptians also observed and recorded observations of their patients, but clinical observation as introduced by the Coans and Cnidians is an active critical observation demanding not only keen sense but also a special intellectual structure. The heights attained by this method among the ancient Greeks can be gathered from what we know of the Empiricists and particularly from the book of *Sextus Empiricus*, which is the *Novum Organum* of the ancient Greek clinicians. The Empiricists built their clinical science on their famous tripod *ἱστορία* (observation of others), *τήρησις* (observation of the physician himself), and *ἀπό τοῦ ὁμοίου ἀκολουθία* (conclusion from the similarities of both). This special method of clinical observation has penetrated subconsciously into our own work, and we forget the painful steps through which it was elaborated, just as we forget that our mode of thought in general derives from the clear logic constructed by the ancient Greeks, and for this reason our mode of thought differs from that of certain peoples such as the Far Eastern peoples, who have not so far come under Hellenic influence.

It is difficult to go through *Sextus Empiricus* and the passages from Hippocrates and Galen relating to the method of clinical observation, but nearer to us there is a remarkable treatise on clinical observation, the *On Experience in Medicine* of Johann Georg Zimmermann (1728-1795), a Swiss physician at the Court of Hanover. This work, inspired by study of the Greek works and often read by the French clinicians of the nineteenth century, deserves more popularity amongst us. The following definition is from that work. "Observation is an aptitude for seeing an object in its true light and distinguishing what there is in it more or less useful. . . . It is nothing more than the conception of the affinity of things and of the signs which point out to us their order and combination. The perception of our senses would be of little use if the mind remained in a state of inactivity. The soul would be rich in images but very barren in ideas. We are obliged to have a certain activity of mind whenever we see—and in this there is an element of comparison."

Thus, what we call clinical observation, as codified by the ancient Greek clinical scientists, is a complicated process and consists of far more than merely "seeing" and noting what falls before our senses. It consists in the perception of apparent and hidden symptoms (thus in perception of biochemical disturbances, for example) and principally in comparison and synthesis into an all-embracing "intuition" of the totality of symptoms. It is thus a far more complex and active procedure than physiological experiment. The term "observation" is up to a certain point a misnomer. Clinical observation is more than observation.

Connected with clinical observation, and indispensably united with it in the mind of the clinical scientist, is nosological thinking. The clinician classifies his observations into special categories, "diseases". He constructs such diseases, or he enters his observations into "diseases" already described. This nosological thinking was also introduced by the Coans and the Cnidians, who saw that the morbid phenomena exhibited by patients are of immense variety and that for their study a method of classification was necessary. They arrived at that method of classification by observing that certain symptoms occurred in patients in a certain regularity of combination and development. They abstracted these combinations of morbid phenomena from the individual and constructed special categories, "diseases". The Coan and Cnidian Asclepiadæ thus introduced into science in general the conception of the εἶδος or type by abstracting essential features, and this conception of type has helped enormously the development of all sciences.

A subsidiary process in the development of clinical science consists in a special utilization of the findings of pathology. Pathology (physio-pathology) and Clinical Science have always been intimately connected. As already stated, the early Egyptians also made clinical observations, and these physicians had little to learn about specialization and empirical observation but were unable to build a clinical science. The Coan and Cnidian Asclepiadæ achieved this because they had learned from the Ionian Physiologists how to look for universal laws that could create a theoretical system capable of upholding a real scientific movement. As Professor Jaeger puts it (*Paedia*, p. 20): "Truth can never be dissolved into the infinite variety of individual cases; or if it could it would have no real meaning for us."

Physio-pathology was created in the sixth century B.C. The first scientists, the Ionian Greeks, were designated Physiologists, meaning students of Nature in general. They were the first to reject the supernatural explanation of the universe current amongst the ancient Eastern peoples, and showed that all phenomena had a "natural explanation" and that the secrets of the world could be penetrated by the unprejudiced observation of things and the power of reason. When Pythagoras brought the torch of the Ionian Physiology to the Italo-Sicilian Greeks in the late sixth and early fifth centuries B.C., a group of physiologists passed from consideration of Nature in general to that of animal and principally human nature, and since then the term Physiology has been restricted to the study of the functions of the human body. The originators of this movement, apart from Pythagoras, were Alcmeon of Croton, Empedocles of Agrigentum, Diogenes of Apollonia, Hippon and Anaxagoras. From its inception Physiology was Physio-pathology, these first physiologists studying the functions of the human body in health and disease, as shown in the conception of disease expressed in the works of Alcmeon, Empedocles and Diogenes. In fact these first Physio-pathologists were the first physicians. The intimate union between Physiology and Pathology has persisted ever since. It was developed in the work of Galen, the greatest of the Greek Physio-pathologists. It was codified later through the work of John Hunter, Magendie and Claude Bernard, and is embodied in Magendie's famous dictum, "Medicine (meaning pathology) is the physiology of the diseased individual".

The method adopted by the first physiologists was *a priori* reasoning and observation, including dissections. Experimentation was introduced by the Alexandrians of the third century B.C. and principally by Galen, but received its greatest impetus from Harvey, who thus revived Physio-pathology as his contemporary, Sydenham, revived Clinical Science. Since Harvey the basic method of Physio-pathology has been experimentation.

Clinical Science was introduced a little later, in fact in the fifth century, by the Coan physicians represented by Hippocrates, by the Cnidians represented by Euryphon and also by the physicians of Rhodes. The islands of Cos and Rhodes and the peninsula of Cnidos were colonized by that most virile section of the Greek people, the Dorians, who were, however, influenced by the neighbouring Ionia and also by East Asia. Asclepios, the God of Medicine, was one of the chief Dorian gods, and from the Dorian peninsula of Peloponnesus with its great sanctuary of Asclepios at Epidauros, this cult was brought to Cos, Cnidos and Rhodes. The priests of Asclepios, the Asclepiadæ, formed a princely priest-family which attributed its origin to Podalirios, son of Asclepios. The Asclepiadæ did not continue in their purely priestly caste spirit. They were not Egyptians, they were Greeks. Just as the Ionians had detached themselves from the magic and supernatural explanations of the universe and interpreted Nature through natural laws, the Coan and Cnidian Asclepiadæ abandoned purely religious healing rites and, with the object of giving more effective help to the patients who sought relief in the temples of Asclepios, they adopted clinical observation and healing on the basis of clinical observation.

THE METHOD OF CLINICAL SCIENCE

The method of Hippocrates, the founder of Clinical Science, consists, as described by Plato, in careful analysis of nature (*Διελέσθαι τήν φύσιν* or clinical observation), in enumeration of its types (*ἀριθμήσασθαι τά εἴδη* or nosographical classification), and in definition of the appropriate treatment for each (*προσαρμόττειν ἕκαστον ἑκάστῳ*).

The Egyptians also observed and recorded observations of their patients, but clinical observation as introduced by the Coans and Cnidians is an active critical observation demanding not only keen sense but also a special intellectual structure. The heights attained by this method among the ancient Greeks can be gathered from what we know of the Empiricists and particularly from the book of *Sextus Empiricus*, which is the *Novum Organum* of the ancient Greek clinicians. The Empiricists built their clinical science on their famous tripod *ίστορία* (observation of others), *τήρησις* (observation of the physician himself), and *ἀπό τοῦ όμοίου ἀκολουθία* (conclusion from the similarities of both). This special method of clinical observation has penetrated subconsciously into our own work, and we forget the painful steps through which it was elaborated, just as we forget that our mode of thought in general derives from the clear logic constructed by the ancient Greeks, and for this reason our mode of thought differs from that of certain peoples such as the Far Eastern peoples, who have not so far come under Hellenic influence.

It is difficult to go through *Sextus Empiricus* and the passages from Hippocrates and Galen relating to the method of clinical observation, but nearer to us there is a remarkable treatise on clinical observation, the *On Experience in Medicine* of Johann Georg Zimmermann (1728-1795), a Swiss physician at the Court of Hanover. This work, inspired by study of the Greek works and often read by the French clinicians of the nineteenth century, deserves more popularity amongst us. The following definition is from that work. "Observation is an aptitude for seeing an object in its true light and distinguishing what there is in it more or less useful. . . . It is nothing more than the conception of the affinity of things and of the signs which point out to us their order and combination. The perception of our senses would be of little use if the mind remained in a state of inactivity. The soul would be rich in images but very barren in ideas. We are obliged to have a certain activity of mind whenever we see—and in this there is an element of comparison."

Thus, what we call clinical observation, as codified by the ancient Greek clinical scientists, is a complicated process and consists of far more than merely "seeing" and noting what falls before our senses. It consists in the perception of apparent and hidden symptoms (thus in perception of biochemical disturbances, for example) and principally in comparison and synthesis into an all-embracing "intuition" of the totality of symptoms. It is thus a far more complex and active procedure than physiological experiment. The term "observation" is up to a certain point a misnomer. Clinical observation is more than observation.

Connected with clinical observation, and indispensably united with it in the mind of the clinical scientist, is nosological thinking. The clinician classifies his observations into special categories, "diseases". He constructs such diseases, or he enters his observations into "diseases" already described. This nosological thinking was also introduced by the Coans and the Cnidians, who saw that the morbid phenomena exhibited by patients are of immense variety and that for their study a method of classification was necessary. They arrived at that method of classification by observing that certain symptoms occurred in patients in a certain regularity of combination and development. They abstracted these combinations of morbid phenomena from the individual and constructed special categories, "diseases". The Coan and Cnidian Asclepiadæ thus introduced into science in general the conception of the εἶδος or type by abstracting essential features, and this conception of type has helped enormously the development of all sciences.

A subsidiary process in the development of clinical science consists in a special utilization of the findings of pathology. Pathology (physio-pathology) and Clinical Science have always been intimately connected. As already stated, the early Egyptians also made clinical observations, and these physicians had little to learn about specialization and empirical observation but were unable to build a clinical science. The Coan and Cnidian Asclepiadæ achieved this because they had learned from the Ionian Physiologists how to look for universal laws that could create a theoretical system capable of upholding a real scientific movement. As Professor Jaeger puts it (*Paedia*, p. 20): "Truth can never be dissolved into the infinite variety of individual cases; or if it could it would have no real meaning for us."

The Pathologist has to take the findings of Clinical Science into consideration and the Clinical Scientist is indebted to progress in knowledge of his diseases to the findings of Pathology. However, the Clinical Scientist must utilize pathological findings in the light of his method of clinical observation and nosographical classification. He cannot take pathological findings uncritically and deduce from them clinical scientific principles. Pathology helps but cannot dominate Clinical Science. Whenever it has attempted to dominate, the result has been disastrous. This was recognized by Hippocrates, who in his *Ancient Medicine* pointed out the danger of domination of *ἰητρική* (what we to-day call clinical science) by the Ionian Physio-pathology. Two examples from recent history confirm this opinion of Hippocrates.

On the basis of the clinical scientific method of observation (clinico-anatomical), Laennec had shown the similar nature of tubercles, caseiform processes and cavities. Virchow and his pupil Niemeyer, on the basis of pure pathology, separated these processes and embarked on speculation about chronic catarrhal pneumonia, caseous and destructive phthisis and so on, until the discoveries of Villemin and Koch proved them wrong and the despised "ontologist" Laennec right. Bretonneau, also on the basis of clinico-anatomical observation, identified pharyngeal diphtheria and croup. With Teutonic dogmatism Virchow declared them to be separate and started semi-metaphysical speculations on diphtheria and croupous inflammation. Of course, Bretonneau was shown to be right. This does not imply criticism of the general work of Virchow and his pupils. Virchow did much for Pathology, but he had no understanding of Clinical Science and by attempting to suppress it he gave to German in contrast to British and French medicine an un-Hippocratic theoretical and unclinical spirit which has persisted until to-day.

THE IMPORTANCE OF CLINICAL SCIENCE

From the beginning certain arguments were directed against the nosographical method of Clinical Science. They were stated and answered by Hippocrates himself. They were shown to arise from confusion between the science of medicine (clinical science) and the art of medicine. Diseases are artificial constructions, but necessary for the classification of knowledge, and thus necessary as far as scientific method is concerned. In practice, in art we deal not with diseases but with individual patients. Our object is not to place our patient into a certain morbid category; this is only a useful preliminary measure. Our object is to study the individual patient and discover what is wrong with his physiology (and psychology) and what has caused his individual disturbances. With this aim we study the history of the individual, the mode of function of his various organs and systems including the psyche, the immediate ætiological conditions which have brought about these disturbances, the special heredity, environment and constitution. To do all this, however, we must possess the science of the morbid phenomena as exhibited by human patients. We must possess Clinical Science, and Clinical Science cannot be taught, cannot develop, except in terms of morbid categories.

There are no diseases but only individual patients. This platitude has often been reiterated, and everybody agrees with it. We cannot, however, approach the individual patient without previous knowledge of diseases. Clinical Science is based on artificial constructions. This also is true, but all sciences are artificial. The important point is whether this artifice works. And history shows that it works. All physicians who have attempted to practise on the basis of Pathology alone, all those who have endeavoured to bypass Clinical Science, have failed. Such was the lot of the λογικοί (rationalists) who came after Hippocrates, of the pneumatists, the methodists and other dogmatists of Alexandrian and Roman times, of the scholastics of the Middle Ages, of the iatrochemists and iatrophysicists of the sixteenth, seventeenth and eighteenth centuries, the animists and vitalists and Brownians of the eighteenth century, of the disciples of Rasori, of Broussais and the early disciples of

Hahnemann in the early nineteenth century, and of the followers of the German so-called physiological school of the mid-nineteenth century. To enumerate all these schools, to remember all these names, is to give a list of the medical errors of the past. The practice of all these schools, based on purely pathological conceptions, resulted in one-sided, often violent and always ineffective treatments.

Nearer to our own times, what happened to the German school of physiological or rational medicine is a potent illustration. The Germans came late into medicine. They had not the advantage of the earlier infiltration of Hippocratic ideas enjoyed by Italy, Great Britain and France. The attempt of Schönlein to introduce the French and British Clinical Science failed in great part. The Germans were too prone to speculation and were too dominated by the principles of "Natural Philosophy" to understand clear clinical scientific thinking. When, in the middle of the nineteenth century, they decided to build up a German medicine, they did not adopt the principles of Clinical Science but were seduced by the empty speculations of the "Physiological Medicine" of Broussais. They rejected nosographical classifications and tried to build up their practice on Physio-pathology alone. This was the tendency of Traube, of Wunderlich, of Virchow. The result was a great physiological and pathological work, but from the practical point of view a chaos of empty speculations and theories. This was realized by men like Pfeuffer (himself at the beginning a follower of the Physiological School), Frerichs, Leyden and Naunyn, who brought German medicine back into the fold of British and French Nosology.

In knowledge of disease as well as in practice Clinical Science is as important as Pathology. The mistaken conceptions of tuberculosis and of diphtheria reached by the Germans on the sole basis of pathology illustrate this point.

Thus history shows that it is not true to say that Pathology is a science and Clinical Medicine an art. Clinical Medicine is a science, Clinical Science, the natural history of diseases, a science indispensable in the theory and practice of medicine, a great science which introduced the first two real scientific methods, observation and typology.

ISOLATION AND CLASSIFICATION OF DISEASES

From the days of the Hippocratists and the Cnidians to the beginning of the nineteenth century, morbid categories or "diseases" were isolated on the basis of their clinical manifestations. Diseases were symptom complexes or, to use the term of the Empiricists, clinical syndromes. With the advent of the anatomo-clinical schools of the early nineteenth century many diseases were isolated on the basis of their clinical manifestations connected with particular anatomical lesions. These diseases were thus clinico-anatomical syndromes. Later, some diseases were isolated on the basis of clinical manifestations connected with a particular physio-pathological disturbance or with a specific causal factor.

A mode of classification of diseases was necessary for scientific progress. Apart from a rudimentary attempt at classification found in the Cnidian work and based on the localization of diseases, the first real attempt at classification was made by François Boissier de Sauvages of Montpellier in 1731. Sauvages was influenced by the work of Sydenham, and essayed a classification of diseases on the principle of classification of natural history. He was not only a physician, but also a botanist and a friend of Charles Linné. He based his classification exclusively on symptomatological pictures and grouped diseases in classes, orders and genera just as natural scientists at that time were arranging plants and animals. The classification of Sauvages was cumbersome but it represented a first attempt at putting knowledge in order. William Cullen gave a better classification in his Nosology (1769). Whereas Sauvages often labelled isolated symptoms as "diseases", Cullen grouped symptoms into symptom complexes. This was more on the lines of the Hippocratists, the Cnidians and of Sydenham. Nosology was thus simplified, and the number of species of diseases or morbid categories was reduced. However, Cullen's nosological divisions, like those of Sauvages, were based only on symptoms. A further advance was marked by Philippe Pinel, whose *Nosographie Philosophique* was published in 1798. His classification was based on anatomical and physiological considerations.

Since Pinel nosologies, that is, systematic expositions of diseases, have developed better systems of classification but a perfect classification has not been found and is in fact impossible. We have to catalogue and group morbid categories constructed on various principles. Some diseases are isolated on the basis of their clinico-anatomical picture, others on the basis of their particular ætiology, others on the basis of their special physio-pathology, others on the basis of the purely clinical picture. Thus each arrangement has its defects and exhibits only some forced approximation. We have to consider it as a repertory lacking complete exactitude, and select that which brings together the greatest number of analogous diseases. We have also to remember that the classification of diseases is secondary, the most inportant thing being the isolation of diseases, the accurate description of their specific combination of symptoms and of their specific course.

The systematic exposition of diseases, thus the systematic exposition of Clinical Science, would have been designated "Natural History of Diseases" by Sydenham. Sauvages, Cullen, Pinel and the French clinicians of the first half of the nineteenth century termed their expositions Nosologies, a term maintained in modern Greek medical terminology. In contemporary France and in German-speaking countries the term "special pathology" is current, a term which may cause confusion with Pathology, which is a branch of Physiology. In English-speaking countries the term Practice of Medicine is used, meaning "Introduction" in the Oslerian sense to the practice of medicine. The term Clinical Science would be more appropriate.

THE CLINICAL DESCRIPTIVE CHAPTER IN THE NATURAL HISTORY OF DISEASES

The clinical descriptive chapter is the basic chapter in the natural history of diseases. It allows isolation of the particular disease and forms the frame for pathogenic, ætiological, prognostic and therapeutic considerations.

(1) The first clinical scientists described the signs and symptoms in diseases. Endowed with great powers of observation and the directness of vision characteristic of the ancient Greeks, they often gave descriptions which have never been surpassed. The Hippocratists dwelt on general symptoms. The Cnidians endeavoured to study local symptoms pointing to disease of a particular organ. With the Empiricists study of the symptoms of particular "disease types" reached its zenith. A great contribution to the symptomatological picture of diseases was made by the Neo-Hippocratists of the first century of our era, Archigenes of Apamia, Aretaios and Soranos. Symptomatological and semiological description reached its peak in the work of Sydenham, whose observational and critical powers and searching vision appear to me as similar to those of Hippocrates.

Work has proceeded on these lines during the course of the centuries, and the symptomatological-semiological picture has been progressively completed. The ancient Greeks dwelt on symptoms, although signs elicited by auscultation, percussion and palpation were mentioned in the Hippocratic writings. With the advent of the anatomo-clinical school, signs were much more developed and helped to complete the clinical pictures of known diseases and to isolate new ones. Recently signs elicited by special explorations such as the various endoscopies and radiology have been added.

(2) A further step in the descriptive chapter of the natural history of diseases was completion of the disease picture through consideration of the anatomical lesions connected with the symptoms and signs.

The first clinical scientist to connect a symptomatological picture with an anatomical lesion was Erasistratos, who flourished in the third century B.C. in Antioch as Court physician to the Selencidæ, and in Alexandria. He adopted the principles of the Cnidian school and looked for the " seats of diseases", *Οὐ μόνον τό πάθος ὁποῖον ἐστίν ἀλλά καί τόν πάσχοντα τόπον.* In the brilliant Alexandria of the first two Ptolemies dissection of humans was permitted, and Erasistratos availed himself of these opportunities. He found that in dropsical patients the liver was hard as stone. He described lesions of the liver and intestine in a form of snakebite, and deduced from his post-mortem examinations the seat of pleuritis.

During the Renaissance Francis Bacon in his *Advancement of Learning* pointed out the two chief ways in which he thought medicine might advance: In the first place he advocated revival of the Hippocratic method of recording cases in order that through such observations the description of diseases which had been undertaken in ancient Greek medicine might be amplified and extended. In the second place, he held that through anatomical investigation the pathological changes, "the footsteps of diseases", should be studied, and findings compared with the symptoms during life. But on the latter point neither the lead of Erasistratos nor the opinion of Bacon was followed for centuries. It is true that physicians made post-mortems, and a few of them like the Dane, Thomas Bartholin (1616-1680), and Theophilus Bonetus (1621-1689) published collections of anatomo-clinical observations, but they did not endeavour to apply the anatomical findings to complete the pictures of diseases.

In 1761 Morgagni published his *De Sedibus et Causis Morborum per Anatome Indagati*, in which he followed the Hippocratic lines of describing diseases but added anatomical findings to the Hippocratic symptoms and signs. He thus showed that disease pictures can gain in completeness and precision by addition to the symptomatological-semiological picture of the corresponding anatomical lesion.

Xavier Bichat in 1801 went a step further. Whereas Morgagni emphasized the lesions of whole organs Bichat showed that the morbid changes in an organ can be dissociated in various tissues each of which follows a different course. Later Rudolf Virchow (1821-1902), availing himself of modern techniques, discovered the importance of cellular lesions. Following the lead of the Morgagni-Bichat-Virchow triumvirate, clinical scientists completed their disease pictures by linking their symptomatological-semiological pictures with the macroscopic and microscopic anatomical pictures. Thus known diseases were more completely described and many new ones were isolated. Morbid anatomy gave to Clinical Science and thus to medicine a greater scientific status.

The first work following the lead of Morgagni was, I think, that of Mathew Baillie, who in 1793 published the first book describing the anatomical lesions in various diseases. Unfortunately Baillie, submerged by his enormous practice, lacked the time to give a powerful impetus to this new method of Clinical Science. This was reserved for Napoleon's famous physician, Corvisart. In his *Essai sur les Maladies et les Lésions Organiques du Cœur* (1806) he maintained that disease could not bc considered as a mere grouping of symptoms, but that the study of anatomical lesions should complete the picture.

The new method of Clinical Science was followed by great clinicians in France and England whose names are familiar to all of us. Laennec, Bayle, Charcot, Bright, Hodgkin, Addison, Graves and many others worked on the Coan-Cnidian lines, and the British in particular considered pathological anatomy as merely an aid to clinical medicine and subordinated anatomical findings to the general clinical picture of disease. Robert Graves (1796-1853) said in his clinical lectures that anatomical lesions had the rank of symptoms.

The Vienna school also adopted pathological anatomy, but not on Hippocratic lines. Skoda (1805-1881) and principally Rokitansky (1804-1878) subordinated pathological anatomy to clinical medicine. They placed anatomical alterations first in the classification and description of morbid processes and considered that the task diseases or morbid categories was reduced. However, Cullen's nosological divisions, like those of Sauvages, were based only on symptoms. A further advance was marked by Philippe Pinel, whose *Nosographie Philosophique* was published in 1798. His classification was based on anatomical and physiological considerations.

Since Pinel nosologies, that is, systematic expositions of diseases, have developed better systems of classification but a perfect classification has not been found and is in fact impossible. We have to catalogue and group morbid categories constructed on various principles. Some diseases are isolated on the basis of their clinico-anatomical picture, others on the basis of their particular ætiology, others on the basis of their special physio-pathology, others on the basis of the purely clinical picture. Thus each arrangement has its defects and exhibits only some forced approximation. We have to consider it as a repertory lacking complete exactitude, and select that which brings together the greatest number of analogous diseases. We have also to remember that the classification of diseases is secondary, the most inportant thing being the isolation of diseases, the accurate description of their specific combination of symptoms and of their specific course.

The systematic exposition of diseases, thus the systematic exposition of Clinical Science, would have been designated "Natural History of Diseases" by Sydenham. Sauvages, Cullen, Pinel and the French clinicians of the first half of the nineteenth century termed their expositions Nosologies, a term maintained in modern Greek medical terminology. In contemporary France and in German-speaking countries the term "special pathology" is current, a term which may cause confusion with Pathology, which is a branch of Physiology. In English-speaking countries the term Practice of Medicine is used, meaning "Introduction" in the Oslerian sense to the practice of medicine. The term Clinical Science would be more appropriate.

THE CLINICAL DESCRIPTIVE CHAPTER IN THE NATURAL HISTORY OF DISEASES

The clinical descriptive chapter is the basic chapter in the natural history of diseases. It allows isolation of the particular disease and forms the frame for pathogenic, ætiological, prognostic and therapeutic considerations.

(1) The first clinical scientists described the signs and symptoms in diseases. Endowed with great powers of observation and the directness of vision characteristic of the ancient Greeks, they often gave descriptions which have never been surpassed. The Hippocratists dwelt on general symptoms. The Cnidians endeavoured to study local symptoms pointing to disease of a particular organ. With the Empiricists study of the symptoms of particular "disease types" reached its zenith. A great contribution to the symptomatological picture of diseases was made by the Neo-Hippocratists of the first century of our era, Archigenes of Apamia, Aretaios and Soranos. Symptomatological and semiological description reached its peak in the work of Sydenham, whose observational and critical powers and searching vision appear to me as similar to those of Hippocrates.

Work has proceeded on these lines during the course of the centuries, and the symptomatological-semiological picture has been progressively completed. The ancient Greeks dwelt on symptoms, although signs elicited by auscultation, percussion and palpation were mentioned in the Hippocratic writings. With the advent of the anatomo-clinical school, signs were much more developed and helped to complete the clinical pictures of known diseases and to isolate new ones. Recently signs elicited by special explorations such as the various endoscopies and radiology have been added.

(2) A further step in the descriptive chapter of the natural history of diseases was completion of the disease picture through consideration of the anatomical lesions connected with the symptoms and signs.

The first clinical scientist to connect a symptomatological picture with an anatomical lesion was Erasistratos, who flourished in the third century B.C. in Antioch as Court studied in the light of the whole clinical frame. This was effected chiefly by Albert Robin and by Fernand Widal.

Each disease thus represents a totality of symptoms, which are not only the subjective phenomena but include the so-called clinical signs and the signs given by special methods of exploration including laboratory exploration. Clinical observation means not only seeing but also arranging all these symptoms in their proper order of importance, and particularly in considering the course of this totality of symptoms. This descriptive chapter is the basis of Clinical Science. The description of a new disease and the rearrangement of the description of a known disease are of extremely great importance in practical medicine.

THE OTHER CHAPTERS OF THE NATURAL HISTORY OF DISEASES

The pathogenic chapter provides the answer to the question as to what kind of disturbances of body-mind function are the basis of the symptoms shown by a patient who enters into a particular disease type. The term physio-pathological chapter also is used, but I prefer the term pathogenic so as to avoid confusion with physio-pathology.

For construction of this chapter the clinical scientist has to take as main basis the data of Physio-pathology, but he has to consider these data in the light of his special method of clinical observation and, with the object of understanding the particular disease he is studying, he can resort to animal experimentation and to certain clinical tests. Thus, although related intimately with Physio-pathology, this chapter is not Physio-pathology. It is to Sir Thomas Lewis that we owe the codification of the method of constructing this particular chapter in the natural history of diseases. This chapter is not, however, as he tended to consider, the whole of Clinical Science but only a part, and as in Clinical Science in general the preponderant element is clinical observation, not experimentation.

The ætiological chapter describes the factors that have determined the disturbances in physiology manifested by symptoms in a patient showing a particular disease. The Hippocratists constructed this chapter on the basis of clinical observation, including a careful history, and described for every disease an interplay of external abnormal conditions—meteorological, traumatic, dietetic and psychological (the *κατάστασις* or external constitution), acting on a specially predisposed individual, on the *φύσις* or internal constitution. Sydenham developed this chapter on the same lines and had the intuition of specific infective ætiology. Physio-pathology helps clinical observation by its study of the various factors determining disease and of the mechanism of their action, but the last word remains with clinical observation. To the Hippocratic external factors physio-pathology has added the infective factors, and contemporary work as embodied in the teaching of Professor John Ryle, the social factors.

The therapeutic chapter was also introduced by the Hippocratists and the Cnidians on the basis of clinical observation. These clinicians applied medicines to patients entering into a special disease type on the basis of tradition or of certain theoretical physio-pathological considerations, and observed the effects of their remedies. A remedy which benefited a patient suffering from a known disease is likely to benefit another patient suffering from the same disease. This is the famous principle of *ἀπό τοῦ ὁμοίου ἀκολουθία*, the principle of the clinical empirical method. Sydenham worked on these lines to discover his specific remedies. Progress in Physio-pathology enabled clinicians to perfect this chapter. Study of therapeutic agents, pharmacology in its extended sense, is basically a branch of Physio-pathology, and further the more perfect conception of the pathogeny of various diseases attained by advances in general Physio-pathology allowed of more precise indications. However, the method of clinical observation has the last word. Whatever the physio-pathological conception, the clinical effect of remedies is over-riding in importance.

of clinical medicine was confined to demonstrating these anatomical changes in patients. Thus anatomical diagnosis became the sole object of the physician's efforts. They were far removed from the breadth of view of the natural history of diseases shown by Hippocrates and Sydenham. The medicine of Skoda and of Rokitansky was really a mortuary medicine. That the principle was wrong is shown by the therapeutic nihilism, the negation of medicine, to which the Vienna school was led. "Go to Vienna", people used to say in those days, "There everything is done for patients. They are diagnosed by Skoda and autopsied by Rokitansky."

A similar spirit pervaded German medicine in the Virchow era. Here also morbid anatomy and principally morbid histology dominated the clinical symptomatological-semiological picture of diseases. Virchow went even further and rejected the nosographical classifications of the British and French as "ontologies". That this principle too was wrong is shown by the chaos into which German medicine fell until its rescue by Frerichs, Leyden and others through introduction of the British and French nosology.

Morbid Anatomy and Histology as a branch of Pathology and thus of Physiopathology has its independence. The clinical scientist avails himself of the findings of this independent science but uses it to complete his disease pictures. This principle is being followed to-day.

(3). The introduction of the signs yielded by various laboratory methods marks a further step towards completion of the description of diseases. Urine, blood, vomit and fæces were examined macroscopically or by some rough methods by physicians of earlier ages, but it was only in the beginning of the nineteenth century that William Prout introduced more precise methods for various chemical examinations. In 1843 Gabriel Andral published his Essay on Hæmatology in which he studied the properties of the blood in various diseases.

Since then Pathology has given a great number of data on the biochemical, hæmatological and bacteriological aspects of disease in general. Clinical scientists avail themselves of these data to complete the description of each particular disease. The clinical scientist and the pathologist differ in their points of view. The pathologist uses biochemical, hæmatological and bacteriological data to study the general processes of disease. The clinical scientist uses the same data to complete his disease pictures. For him all these data are biochemical, hæmatological and bacteriological signs which he inserts in the frame of a particular disease picture, and thus all these pathological data are judged in the light of the general clinical picture.

The same can be said of the various functional tests. In 1866 Hutchinson investigated the functional capacity of the lungs with his spirometer. William Stokes, the Dublin clinician, described the "weakness or deficient muscular power of the heart" in 1856. Then, inspired by Claude Bernard and his stress on functional disturbances preceding anatomical lesions, the German school developed the study of functional tests. Adolf Kussmaul introduced gastric intubation in 1867, and with Leube he showed later the importance of this clinical method of exploration of gastric function. Similar functional tests were introduced for circulatory organs, for the liver and the kidneys. As usual, the technical developments made by the Germans were considerable, but the general idea underlying them was essentially wrong. With the exception of Kussmaul, who worked on British and French nosographical lines, most of them wanted to bypass nosology and to find tests presenting a physiological understanding of the individual patient. "We want to cure and not to classify", thundered Ottomar Rosenbach, the codifier of this line of research. However, the individual patient is not one or two tests but represents a totality of symptoms which can be understood only on the basis of previous knowledge of disease types, which represent totalities of symptoms. Thus these functional tests became useful only when connected with disease pictures, only when used to complete these pictures, and thus only when

Sclerodactylia with Œsophageal Lesion (3 Cases).—WILLIAM A. BOURNE, M.D., M.R.C.P.

Case I.—Mrs. A. B., aged 56. Raynaud-like symptoms from age 33. 1943: X-ray showed substernal thyroid with hiatus hernia. 1944: Burning of tongue on eating, with no obstruction. 1945: Blood-count—R.B.C. 4,480,000; Hb 68%; C.I. 0·68. 1946: Blood-count—R.B.C. 4,000,000; Hb 48%; C.I. 0·6.

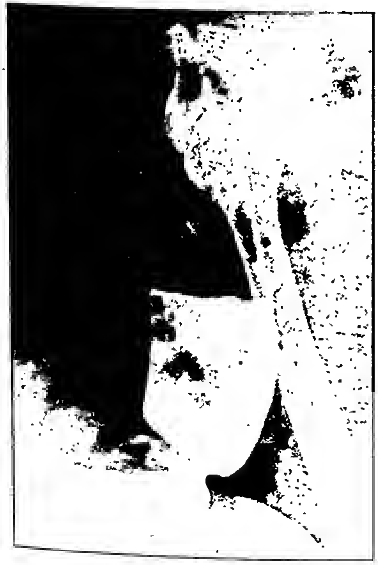

FIG. 1.—Case I. Œsophageal lesion associated with sclerodactylia. Atonic dilatation with hiatus hernia.

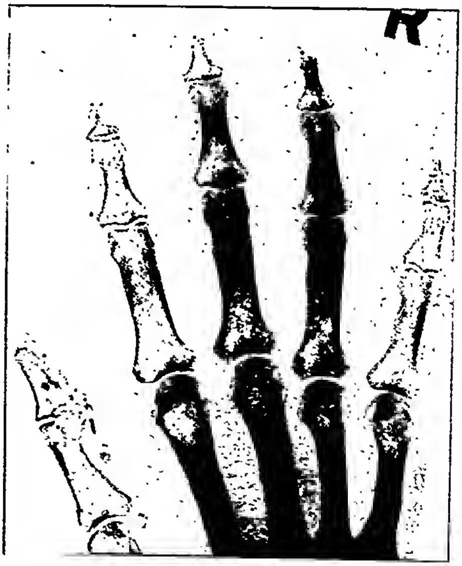

FIG. 2.—Case I. Sclerodactylia. Subcutaneous calcinosis with absorption of distal phalanges.

R.B.C. showed changes typical of severe hypochromic anæmia. Blood W.R. negative. Sputum negative for T.B. Stool negative for occult blood. Histamine test meal, achlorhydria. No flushing after 150 mg. nicotinic acid. X-rays showed dilated œsophagus with hiatal hernia (fig. 1). Lung fields showed slight basal fibrosis.

We take our remedies from any source, from old village women or from highly scientific laboratories. As Trousseau said, "La clinique prend son bien partout où elle le trouve". We can neither accept nor reject them on the basis of physiological and pathological considerations alone, but only on the basis of clinical observation. This principle should be applied to remedies whose physiological basis is debated, such as the homœopathic remedies, because their acceptance or rejection on the basis of *a priori* physiological thinking does not conform with our scientific method.

This chapter is based also on a special branch of Clinical Science, clinical pharmacology, which consists in study of the effects of remedies on healthy and diseased individuals. It is obvious that this branch is connected with pharmacology, mainly experimental, which is a branch of Pathology.

GENERAL CONCLUSIONS

There are three things in Medicine, the Art, Physio-pathology, and Clinical Science. These three are equally necessary but should not be confused, as is being done in most textbooks of History of Medicine.

The art of medicine consists in the application of scientific knowledge to the care of the sick. It demands special qualities of intuition and personality, but these qualities are useless without scientific knowledge. There has been a curious attempt in Germany—outside the universities—to build up a medicine without science, a medicine based only on intuition, personality, common sense and popular traditions. This movement originated with the physician of Bismarck, Ernst Schweninger (1850-1924), was adopted by the Nazis and was being developed in the Rudolf Hess Hospital of Dresden. Of course it failed. Medicine cannot be practised with "less science and more art" but needs "more science and more art".

Physio-pathology and Clinical Science are of equal importance. We cannot practise only on the basis of Physio-pathology, or even, as the Greek Empiricists and some early French nosologists of the Pinel type attempted to do, on the exclusive basis of Clinical Science.

Clinical Science is the natural history of diseases, a natural science comprising four chapters—the clinical descriptive, the pathogenic or physio-pathological, the ætiological and the therapeutic. The term should not be used in the restricted sense of clinical physio-pathology. It is a great and indispensable science, a branch of Biology.

Research physicians cultivate either Pathology or Clinical Science or both. They have, however, to keep their pathological and clinical scientific work in separate compartments.

The following quotation from an address by Sir James Paget in 1869 shows the real spirit of clinical science.

> "I am anxious to urge that all our work should be really clinical; all our chief studies among the living . . . I think there are even among ourselves signs of a want of faith in the power of clinical research; signs of too great readiness to reject results and suggestions which are not accordant with our belief in physiology or anatomical pathology; of too great readiness to accept and act upon deductions from any other sciences, though they are not approved by our own . . . We must believe and act on the belief that clinical science is as self-sufficient as any other. Self-sufficient indeed no science can be. All sciences are bound together by common facts and mutual illustrations and the same cardinal rules of study; yet each having its own subject-matter may claim a special range of knowledge, and within this range the highest right of judging what is true. This claim we must maintain for Clinical Science . . . I feel sure that Clinical Science has as good a claim to the rights and self-subsistence of science as any other department of biology; and that in it are the safest and best means of increasing the knowledge of diseases and their treatment."

Sclerodactylia with Œsophageal Lesion (3 Cases).—WILLIAM A. BOURNE, M.D., M.R.C.P.

Case I.—Mrs. A. B., aged 56. Raynaud-like symptoms from age 33. 1943: X-ray showed substernal thyroid with hiatus hernia. 1944: Burning of tongue on eating, with no obstruction. 1945: Blood-count—R.B.C. 4,480,000; Hb 68%; C.I. 0·68. 1946: Blood-count—R.B.C. 4,000,000; Hb 48%; C.I. 0·6.

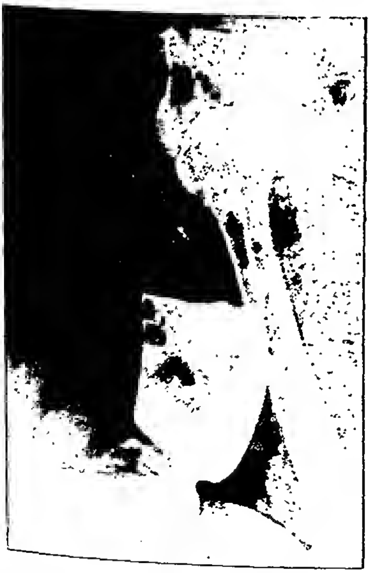

FIG. 1.—Case I. Œsophageal lesion associated with sclerodactylia. Atonic dilatation with hiatus hernia.

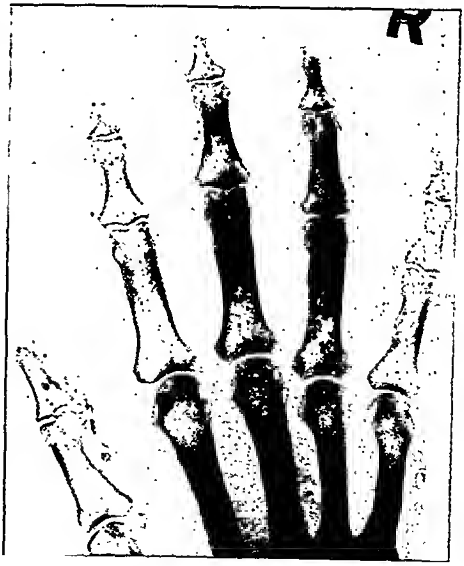

FIG. 2.—Case I. Sclerodactylia. Subcutaneous calcinosis with absorption of distal phalanges.

R.B.C. showed changes typical of severe hypochromic anæmia. Blood W.R. negative. Sputum negative for T.B. Stool negative for occult blood. Histamine test meal, achlorhydria. No flushing after 150 mg. nicotinic acid. X-rays showed dilated œsophagus with hiatal hernia (fig. 1). Lung fields showed slight basal fibrosis.

Hands showed calcinosis of subcutaneous tissues of digits with absorption of tips of terminal phalanges (fig. 2). Treatment with iron produced diarrhœa. Vitamin B complex relieved tongue symptoms. Transfusion raised Hb to 78% with relief of hand symptoms.

Case II (X-rays by courtesy of Professor J. McMichael).—Female, aged 60. Raynaud-like attacks since age 35. Dysphagia for thirteen years with repeated œsophageal dilatation. X-rays showed marked achalasia with traction deformity of upper œsophagus by fibroid changes in right lung apex, and shortening and absorption of distal ends of phalanges.

Case III (X-rays by courtesy of Professor Grey Turner and Professor McMichael). —Female, aged 56. Raynaud-like symptoms since age 54. Eighteen months' dysphagia and weight loss. Œsophageal dilatation gave only temporary relief. Following gastrostomy transferred to Hammersmith Hospital. X-ray showed obstructive lesion 2 in. above cardia with changes typical of new growth. Œsophagoplasty performed with relief of symptoms except for one bout of obstruction easily dilated. Histology of biopsied œsophageal wall: patchy hyperplasia and desquamation of the mucosa, œdema of the submucosa and infiltration with polymorphs, eosinophils, plasma cells and lymphocyte islets abutting on the muscularis suggesting lymphorrhages.

These three cases illustrate a relationship between sclerodactylia and œsophageal lesion recognized since 1903 (Ehrmann). From the Mayo Clinic Olsen, O'Leary and Kirklin report that 10% of cases of scleroderma seen between 1930 and 1943 had such a lesion, all the proved cases having sclerodactylia. English references are by Dowling, Lewis, and Prosser Thomas. The œsophageal involvement may simulate cardiospasm or carcinoma and may progress to marked atonic dilatation with hiatus hernia of short œsophagus type. Marked dilatation appears to produce few symptoms, but in cases showing less dilatation and more obstruction, Raynaud-like symptoms or frank sclerodactylia are important in diagnosis. (Two of the three cases reported were for a time regarded as carcinoma.) Case I presented several additional features. Hypochromic anæmia with glossitic symptoms suggested Plummer-Vinson syndrome, but X-ray findings were not characteristic. Length of history, absence of occult blood, and achlorhydria, rendered carcinoma, simple ulcer, or hæmorrhage from hiatus hernia unlikely. Bouts of severe diarrhœa were thought possibly due to sclerodermatous change in the small intestine, a suggestion supported by failure of nicotinic acid *per os* to produce cutaneous flushing. Notable improvement in hand condition followed elevation of hæmoglobin from 48% to 78% by transfusion. Wright and Duryee suggested the basis of symptoms in sclerodermia to be cutaneous ischæmia, and when appreciable anæmia is present transfusion should relieve ischæmic pain. The relation of thyroid disease to sclerodermia is doubtful (Banks, Bevans).

POSTSCRIPT (April 26, 1947).—The retrosternal goitre has since been successfully removed by Mr. Dickson Wright in spite of the rigidity of the head and neck.

Œsophageal Carcinoma Treated by Resection and Presternal Œsophago-Gastrostomy.—HERMON TAYLOR, F.R.C.S.

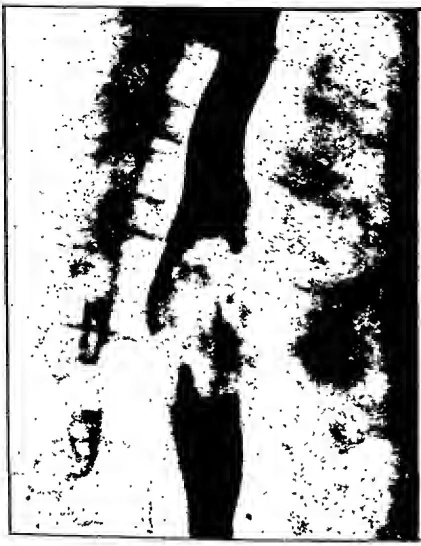

FIG. 1.—Mid-œsophageal growth before operation.

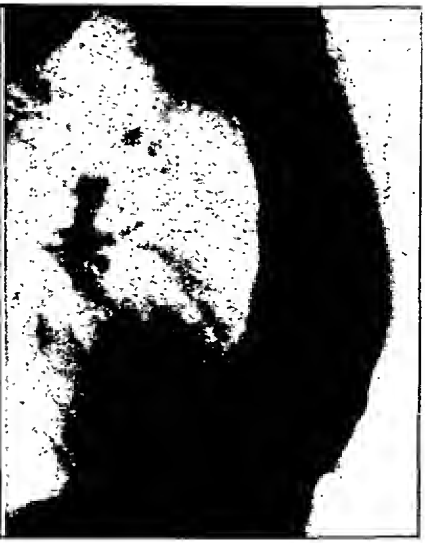

FIG. 2.—Lateral X-ray of presternal stomach with barium.

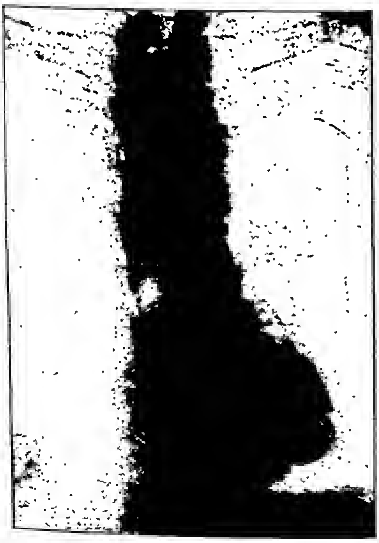

FIG. 3.—Antero-posterior X-ray of presternal stomach with barium.

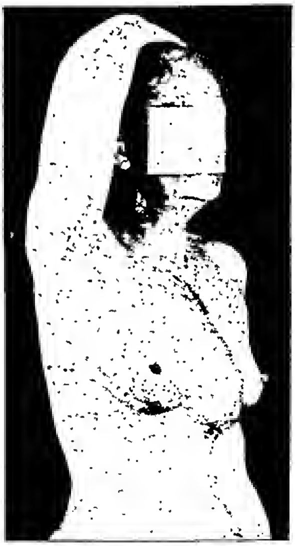

FIG. 4.–Patient 7 months after operation. Presternal stomach and the various incisions are well shown.

A. C., female, aged 53.

History of two months of dysphagia. X-ray showed cauliflower-like mass of growth in the œsophagus at the level of the sixth thoracic vertebra (fig. 1).

Stage I operation 11.7.46.—Right thoracotomy. Œsophagus mobilized. Growth $1\frac{1}{2}$ in. long. Œsophagus was divided 1 in. above the growth so that the upper stump just reached the suprasternal notch. Œsophagus was also divided below the growth and brought out into the epigastrium as an œsophagostomy, with an indwelling tube through the stomach into the duodenum, for feeding purposes.

Post-operative progress was uneventful with temporary exhibition of penicillin and aspiration of pleural fluid.

Stage II operation 8.8.46.—Stomach and lower œsophageal stump freed entirely from their proximal attachments. Lower œsophageal stump and upper half of the lesser curve together with lymphatic glands excised to complete the radical excision of area of possible extension of growth. Raw edge closed and infolded and the blind pear-shaped pouch of stomach, its stalk still attached as the pylorus with its vessels, now laid in a presternal subcutaneous position, the fundus reaching rather higher than the suprasternal notch where it lay under the upper œsophageal fistula.

No anastomosis was made at this stage.

The patient was fed by a tube through prepyloric gastrostomy via the pylorus to the duodenum. Post-operative progress was again uneventful.

Stage III minor operation 29.8.46.—Upper œsophageal stump was freed from the skin and anastomosed to the underlying pouch of stomach. Single layer anastomosis —no tension.

Post-operative progress was uneventful. The gastrostomy tube was withdrawn but the opening persisted.

Stage IV minor operation 6.10.46.—Closure of gastrostomy opening.

The patient is now able to eat an ordinary full meal. She is hungry for her food and is satisfied when she has eaten it. There has been no regurgitation into the mouth. She is conscious of the subcutaneous stomach which can be seen and palpated (fig. 4), but has no symptoms from its presence there. She lives a normal life and travels about the country in public transport at will.

Osteoporosis Circumscripta and Leontiasis Ossea Faciei Associated with Paget's Disease.—A. ELKELES, M.D.

A bus driver, A. J., aged 37, was transferred to the Manor House Hospital on 10.7.46, complaining of pain in his arms, shoulders, spine and knees.

History.—No previous serious illness. Six and a half years ago he noticed a swelling of his right cheek bone which gradually increased and was sometimes associated with severe neuralgic pain around his right eye.

Physical examination.—No abnormality except a diffuse hard swelling in region of his right upper jaw. Blood-count normal. W.R. negative.

Blood-chemistry.—Blood cholesterol 120 mg.; serum calcium 11·7 mg.; inorganic phosphorus 3·2 mg. per 100 c.c. Acid phosphatase 2·1 units; *alkaline phosphatase* 91 units (4 to 10 normal).

Radiological examination (24.7.46).—*Skull*: Enlargement and increased cloudy density of the right zygomatic bone in particular at the zygomatic arch. Thickening of the bony walls of the right maxillary antrum. Similar but less pronounced changes are visible on the left. Part of the maxillary antrum, the frontal sinus and the anterior ethmoidal cells on the right are obscured.

Large circumscribed rounded areas of osteoporosis are in the frontal and temporal regions near the base of the skull, through which the enlarged meningeal groove passes. These areas are surrounded by normal bone structures. Posterior half of the skull shows considerable osteoporosis interspersed with ill-defined nodular areas of bone condensation. Demarcation of this area from the anterior half of the skull is sharply defined but irregular in outline. There is marked thickening of the calvaria of the occipital and larger part of the parietal regions (two to three times that of normal thickness). Diploë can no longer be distinguished in the involved area and the lambdoid suture is obliterated (fig. 1). The remaining bones of the skeleton appear normal except the first lumbar vertebra, which shows early cotton-wool appearance, suggestive of Paget's disease. Diagnosis of osteitis deformans was confirmed by biopsy of the occipital portion of the skull by Professor Dorothy Russell.

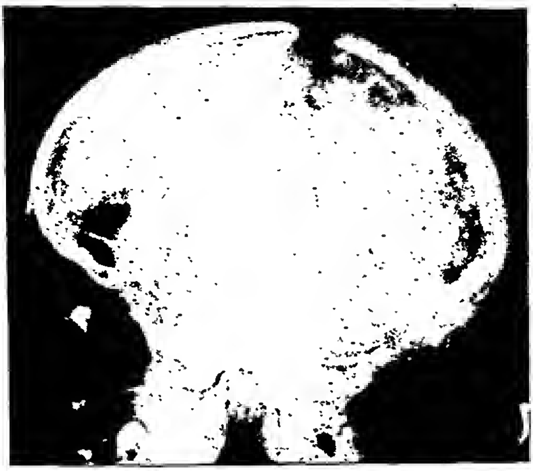

FIG. 1.

COMMENT

This case is an example of the difficulties which sometimes arise in the diagnosis and classification of bone diseases. The skull bones of this patient are the seat of apparently different pathological processes, and, unless the insidious forms in which Paget's disease may manifest itself in the skull bones are taken into consideration, the correct diagnosis may easily be missed. Osteoporosis circumscripta of the skull was first described by Schüller in 1926. But Sosman who re-examined one of Schüller's cases in 1927 established the relationship of osteoporosis circumscripta to Paget's disease for the first time, by examining trephined bone from the affected area. In his view osteoporosis circumscripta represents the absorptive-destructive phase of Paget's disease with the productive phase held in abeyance. Since then many reports have confirmed Sosman's observation and cases have been reported in which circumscribed osteoporosis of the skull was followed years later by typical Paget's disease.

The skull lesions in my patient represent different phases of Paget's disease simultaneously. The absorptive-destructive phase in its pure form is seen in the anterior half of the skull. The transition of the absorptive into the productive-repair stage with new but inferior bone formation is present in the posterior half, but has not yet the typical cotton-wool appearance of osteitis deformans. The new bone formation in this area points to marked osteoblastic activity, which finds confirmation in the much-raised alkaline phosphatase. The considerable thickening of the outer table and the diploë signifies typical Paget's disease. The findings provide strong evidence for the conception that osteoporosis circumscripta is a precursor of Paget's disease in the skull. The reason why circumscribed osteoporosis in osteitis deformans is met with solely in the skull bones may perhaps be explained by the pathological physiology of Paget's disease. According to Reifenstein and just reached the suprasternal notch. Œsophagus was also divided below the growth and brought out into the epigastrium as an œsophagostomy, with an indwelling tube through the stomach into the duodenum, for feeding purposes.

Post-operative progress was uneventful with temporary exhibition of penicillin and aspiration of pleural fluid.

Stage II operation 8.8.46.—Stomach and lower œsophageal stump freed entirely from their proximal attachments. Lower œsophageal stump and upper half of the lesser curve together with lymphatic glands excised to complete the radical excision of area of possible extension of growth. Raw edge closed and infolded and the blind pear-shaped pouch of stomach, its stalk still attached as the pylorus with its vessels, now laid in a presternal subcutaneous position, the fundus reaching rather higher than the suprasternal notch where it lay under the upper œsophageal fistula.

No anastomosis was made at this stage.

The patient was fed by a tube through prepyloric gastrostomy via the pylorus to the duodenum. Post-operative progress was again uneventful.

Stage III minor operation 29.8.46.—Upper œsophageal stump was freed from the skin and anastomosed to the underlying pouch of stomach. Single layer anastomosis —no tension.

Post-operative progress was uneventful. The gastrostomy tube was withdrawn but the opening persisted.

Stage IV minor operation 6.10.46.—Closure of gastrostomy opening.

The patient is now able to eat an ordinary full meal. She is hungry for her food and is satisfied when she has eaten it. There has been no regurgitation into the mouth. She is conscious of the subcutaneous stomach which can be seen and palpated (fig. 4), but has no symptoms from its presence there. She lives a normal life and travels about the country in public transport at will.

Osteoporosis Circumscripta and Leontiasis Ossea Faciei Associated with Paget's Disease.—A. ELKELES, M.D.

A bus driver, A. J., aged 37, was transferred to the Manor House Hospital on 10.7.46, complaining of pain in his arms, shoulders, spine and knees.

History.—No previous serious illness. Six and a half years ago he noticed a swelling of his right cheek bone which gradually increased and was sometimes associated with severe neuralgic pain around his right eye.

Physical examination.—No abnormality except a diffuse hard swelling in region of his right upper jaw. Blood-count normal. W.R. negative.

Blood-chemistry.—Blood cholesterol 120 mg.; serum calcium 11·7 mg.; inorganic phosphorus 3·2 mg. per 100 c.c. Acid phosphatase 2·1 units; *alkaline phosphatase* 91 units (4 to 10 normal).

Radiological examination (24.7.46).—*Skull*: Enlargement and increased cloudy density of the right zygomatic bone in particular at the zygomatic arch. Thickening of the bony walls of the right maxillary antrum. Similar but less pronounced changes are visible on the left. Part of the maxillary antrum, the frontal sinus and the anterior ethmoidal cells on the right are obscured.

Large circumscribed rounded areas of osteoporosis are in the frontal and temporal regions near the base of the skull, through which the enlarged meningeal groove passes. These areas are surrounded by normal bone structures. Posterior half of the skull shows considerable osteoporosis interspersed with ill-defined nodular areas of bone condensation. Demarcation of this area from the anterior half of the skull is sharply defined but irregular in outline. There is marked thickening of the calvaria of the occipital and larger part of the parietal regions (two to three times that of normal thickness). Diploë can no longer be distinguished in the involved area and the lambdoid suture is obliterated (fig. 1). The remaining bones of the skeleton appear normal except the first lumbar vertebra, which shows early cotton-wool appearance, suggestive of Paget's disease. Diagnosis of osteitis deformans was confirmed by biopsy of the occipital portion of the skull by Professor Dorothy Russell.

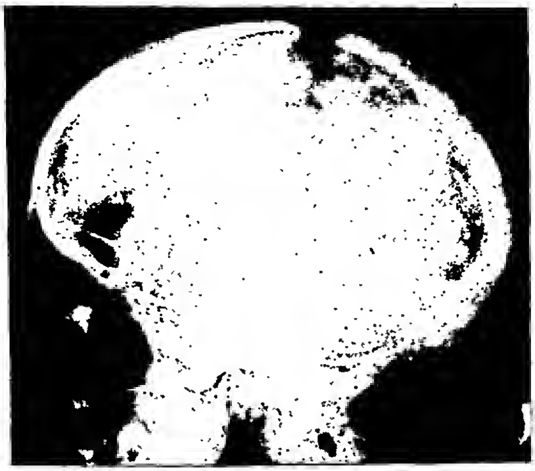

FIG. 1.

COMMENT

This case is an example of the difficulties which sometimes arise in the diagnosis and classification of bone diseases. The skull bones of this patient are the seat of apparently different pathological processes, and, unless the insidious forms in which Paget's disease may manifest itself in the skull bones are taken into consideration, the correct diagnosis may easily be missed. Osteoporosis circumscripta of the skull was first described by Schüller in 1926. But Sosman who re-examined one of Schüller's cases in 1927 established the relationship of osteoporosis circumscripta to Paget's disease for the first time, by examining trephined bone from the affected area. In his view osteoporosis circumscripta represents the absorptive-destructive phase of Paget's disease with the productive phase held in abeyance. Since then many reports have confirmed Sosman's observation and cases have been reported in which circumscribed osteoporosis of the skull was followed years later by typical Paget's disease.

The skull lesions in my patient represent different phases of Paget's disease simultaneously. The absorptive-destructive phase in its pure form is seen in the anterior half of the skull. The transition of the absorptive into the productive-repair stage with new but inferior bone formation is present in the posterior half, but has not yet the typical cotton-wool appearance of osteitis deformans. The new bone formation in this area points to marked osteoblastic activity, which finds confirmation in the much-raised alkaline phosphatase. The considerable thickening of the outer table and the diploë signifies typical Paget's disease. The findings provide strong evidence for the conception that osteoporosis circumscripta is a precursor of Paget's disease in the skull. The reason why circumscribed osteoporosis in osteitis deformans is met with solely in the skull bones may perhaps be explained by the pathological physiology of Paget's disease. According to Reifenstein and

Albright (1944) the initial lesion is a localized factor causing bone destruction. The affected bones are more susceptible to stresses and strains and as a compensatory mechanism increased osteoblastic activity sets in, laying down new matrix. It is therefore feasible that bones exposed to increased stresses, as spine, sacrum, pelvis and long bones, may fail to show the initial process of bone absorption, since the repair stage follows almost simultaneously. In the skull bones in which strain and stresses are minimal, bone repair may lag behind bone destruction.

The asymmetry of the patient's face, caused by a diffuse bony swelling of the zygoma and maxilla, calls for special comment. Kasabach and Gutman (1937) in their comprehensive paper on osteoporosis circumscripta of the skull and Paget's disease were able to collect 5 cases from the literature, to which they added 2 cases of their own with bony tumours of the maxillary region. In these cases it was invariably the upper jaw which showed the bony tumour and osteoporosis circumscripta was present in the adjacent frontal bone. The findings in my patient are almost identical with those described by Kasabach and Gutman. The bones of the face are only rarely involved in Paget's disease but, when affected, they produce the characteristic lion-like facies known as leontiasis ossea. It is doubtful whether leontiasis ossea represents a disease entity, since most of the reported cases are associated with Paget's disease and a smaller number with osteofibrosis generalisata Recklinghausen. The type Virchow, usually starting in childhood and hitherto considered an independent disease, may possibly be also part of a more or less generalized bone disease. This is suggested by recent reports of cases with Albright's disease (Pugh, 1945), in which involvement of the facial and skull bones showed the typical appearances of leontiasis ossea. The fact that in type Virchow the lesions are usually confined to facial and skull bones can perhaps be explained by their being the monostotic type of Albright's disease.

I should like to express my thanks to Lord Uvedale for kind permission to present the case and to Professor Dorothy Russell for the pathological report.

[*March* 14, 1947]

Lymphadenoma.—LEO RAU, M.D.

This patient was shown to the Clinical Section May 1946 (*Proc. R. Soc. Med.*, **39**, 707). The post-mortem held on 17.1.47 confirmed the diagnosis. At autopsy, there was a large mass involving the left lower lobe of the lung, which penetrated the left diaphragm and pressed upon the left kidney, without involving it. There was a mass in the lower part of the right upper lobe, similar in appearance to that in the left side, but only 2 cm. in diameter.

Histology (Dr. George Lumb).—Lung masses show diffuse infiltration with small cells of reticulum cell type. There are frequent giant cells of Sternberg-Reed variety. It is clearly a reticulosis, and Hodgkin's disease seems the most likely variety. No evidence of carcinoma.

Hypothyroidism With Macular Abiotrophy and Inner Ear Deafness.—LEO RAU, M.D.

Male, aged 38, an artist. First seen in October 1939, complaining of deafness. This had started in 1937, and was getting worse. There was no tinnitus. The right ear was more affected than the left. In 1939, the clinical examination did not reveal any abnormality. The radiograph of the sinuses showed a fluid level in the right antrum. On aspiration, this fluid was clear and full of cholesterol crystals. He was seen again in January 1941, when his hearing was worse. In addition to this, he had noticed a central scotoma of the right eye since the summer of 1940, which was followed at Christmas by slight distortion of the central vision of that eye, and "whirling" in the centre of the right field.

On examination in January 1941 his face was puffy and he looked pale. His B.P. was 95/65. He was of normal intelligence, with an average memory, but showed signs of slow cerebration. In all decisions he was dependent on his wife. At times he was melancholic, and depressed, and complained of claustrophobia and lack of power of concentration. There were no headaches, convulsions or faints.

He was investigated as follows: Radiograph of skull normal. Audiogram, bilateral inner ear deafness (Mr. F. C. Ormerod). Left eye amblyopic; right eye central region of fundus resembles that seen in familial macular abiotrophy (Best's disease) of the type (presenile) associated with the name of Behr (Mr. Arthur D. Griffiths).

Blood Wassermann reaction negative.

Blood sugar tolerance—

Minutes:	fasting	30	60	90	130	240
Mg. %:	83	140	120	85	90	65

Water dilution and concentration good. Excretion slow and insufficient.

Basal metabolic rate −12%.

Family history.—His father died of heart disease, his mother is suffering from hypertension and diabetes. A male cousin of his father's has catarrhal deafness, and his niece is suffering from epilepsy. There is no consanguinity. He is practically a non-smoker, and does not drink any alcohol.

Treatment (20.3.41).—Thyroid by mouth 1 grain b.d. This was increased to 1 grain t.d. on 17.4.41, after the B.M.R. on 15.4.41 was − 1%.

Progress.—Marked general improvement from May 1941, the scotoma became less marked and his hearing improved. In March 1943, re-examination: hearing of left ear was practically normal, right ear considerably improved. At the same time Mr. Griffith reported that "the macular retinitis was absorbed, leaving him with perfect vision, a happy result, if a somewhat unusual one".

Re-examination in 1944 and in 1946, and again in March 1947, did not reveal any abnormality. He is still taking thyroid in small quantities, 1 grain per week.

Comment.—This combination of inner ear deafness and central blindness was unusual. The investigations as described above in detail were necessary to find out the cause. All the tests showed an abnormally low result, as is found in certain glandular disturbances, e.g. thyroid deficiency and anterior lobe deficiency. Normal sexual functions were against a pituitary disturbance. Further, the knowledge of the presence of cholesterol crystals in his antrum, and the presumed deposit of cholesterol in his retina seemed to point to a thyroid deficiency. Psychological abnormalities which this patient showed from 1926 to 1941 until the commencement of the thyroid treatment have not been stressed. They too form part of this syndrome.

Large Chronic Rodent Ulcer Treated by Radiotherapy.—J. A. C. FLEMING, F.R.C.S.Ed.

H. C., male, aged 68.

History.—Bayonet wound involving skin of lumbar region in First World War which healed.

1929: Ulcer above left eyebrow treated with radium.

1931: Excision of this area reported as rodent ulcer, subsequent to which he

Large Chronic Rodent Ulcer Treated by Radiotherapy.—J. A. C. Fleming, F.R.C.S.Ed.

H. C., male, aged 68.

History.—Bayonet wound involving skin of lumbar region in First World War which healed.

1929: Ulcer above left eyebrow treated with radium.

1931: Excision of this area reported as rodent ulcer, subsequent to which he developed a soft subcutaneous swelling involving the underlying skin in this region.

1936: Wound in back began to ulcerate.

1937: Received treatment by radiotherapy to two lesions, believed to be rodent ulcers, involving the nose and forehead, did not draw attention to developing ulcer in lumbar region.

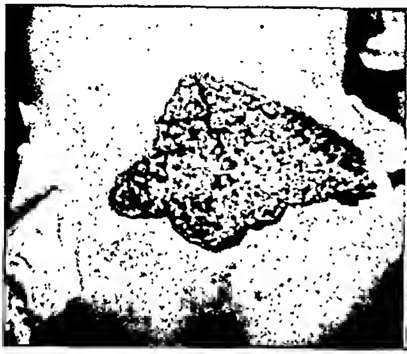

FIG. 1.—Before treatment, 24.6.45.

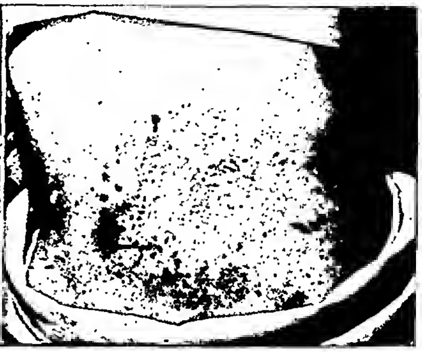

FIG. 2.—Six months after completion of treatment, 28.3.47.

24.6.46: Admitted to hospital with large ulcer involving skin of lumbar region measuring 11 cm. × 20 cm. No glandular involvement.

3.7.46: Biopsy from ulcer of back; report—basal-celled carcinoma with a tendency to squamous metaplasia.

15.7.46 to 23.9.46: X-ray therapy to back. 140 kV. Surface dose maximum. 5400 r (spaced) over 70 days.

Progress.—Involved area on back has healed slowly—has developed local recurrence at one corner [January 1947].

Arteriovenous Fistula Without a History of Trauma.—C. G. ROB, M.Ch., F.R.C.S.

Regular Sergeant R.A.F., aged 24. For six years he has noticed a vibration above his right clavicle. He has not taken any notice of this and has had good health up to the present time. Some ten years ago he had a blow on the back of the head but has had no other trauma to the neck and no penetrating wound.

He was admitted to hospital on 27.2.47 with a history of a sudden constriction in his chest at night which had been aggravated by deep breathing. He had "funny" feelings of the right leg and the whole of the right side with muscular spasms. The spasms lasted about half a minute. The pain in his chest persisted and spread to his throat where he had an aching feeling, and down the left arm on the inner side as far as the elbow. He was seen by a medical officer who heard a loud præcordial friction rub at the base and he was admitted as a case of pericarditis. An E.C.G. did not show changes suggestive of coronary thrombosis. His Wassermann was negative. His B.S.R. was 8 mm. in one hour (Westergren). His white count was 11,600, 81% polymorphs, falling in one week to 5,600, with 49% polymorphs. A throat swab grew hæmolytic streptococci.

He has a loud murmur occupying systole and diastole with a systolic accentuation below and above the right clavicle. This murmur is conducted up the line of the carotid vessels to the base of the skull, it is not conducted into the arm or below the third rib on the right side of the chest. There is a localized thrill above the right clavicle. His blood-pressure is equal in both arms 120/60. Occlusion of the fistula does not slow the pulse. No distended veins are visible, but a small soft pulsating mass is present at the site of the maximum murmur and thrill. An X-ray of chest shows no metallic foreign body, bony erosion or evidence of disease.

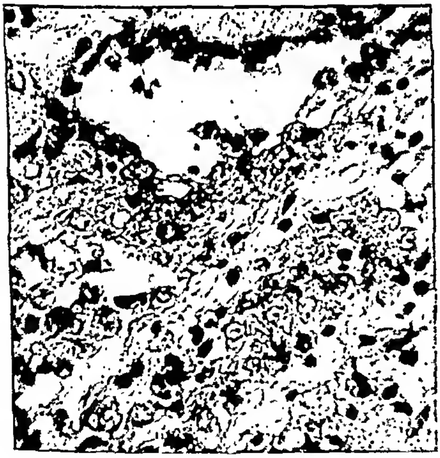
Diagnosis.—This is a small arteriovenous fistula probably on one of the branches of the thyreocervical artery. It is a single fistula, and therefore of an unusual type, for in the absence of a history of trauma it is probably congenital, whereas such arteriovenous fistulæ are usually multiple.

Malignant Lympho-endothelioma of Neck.—T. W. MIMPRISS, M.S.

Male, aged 46. Seen July 1946 with large, firm tumour right side of neck. Stated to have developed over two months.

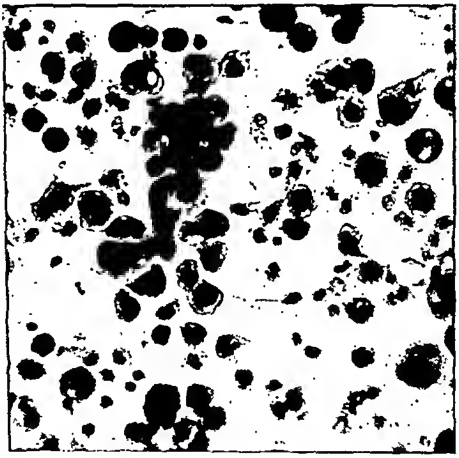
December 1946: Tumour in neck had grown considerably and there was a similar tumour in the right axilla. A pleural effusion on the right side and right recurrent laryngeal nerve paralysis had both occurred.

Following aspiration of pleural fluid the right upper lobe of lung was seen to be collapsed.



×300

FIG. 1.



×300

FIG. 2.

Section of the tumour shows malignant endothelioma; cells found in the pleural fluid are similar.

Diagnosis.—Malignant lympho-endothelioma of neck, infiltrating into axilla, pleura and mediastinum.

Treatment.—He is having a course of X-ray therapy.

Histological examination (Dr. J. Bamforth) shows that the tumour consists of spaces lined by large spheroidal cells showing a large pale vesicular nucleus and definite nucleolus. The spaces are separated by a loose stroma containing many cells of lymphocytic type. In addition, small aggregations of the large spheroidal cells are present in the stroma (fig. 1). Smears made from the pleural fluid, fixed in Schaudinn's fluid, showed large numbers of the large spneroidal cells found in the neoplasm (fig. 2). It is considered that this is a case of malignant lympho-endothelioma.

developed a soft subcutaneous swelling involving the underlying skin in this region.

1936: Wound in back began to ulcerate.

1937: Received treatment by radiotherapy to two lesions, believed to be rodent ulcers, involving the nose and forehead, did not draw attention to developing ulcer in lumbar region.

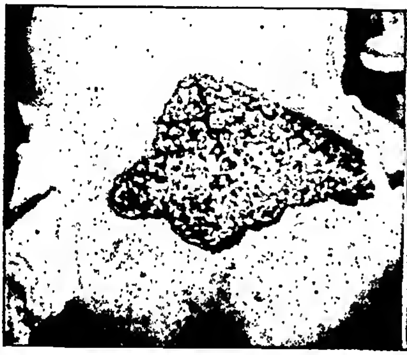


FIG. 1.—Before treatment, 24.6.45.

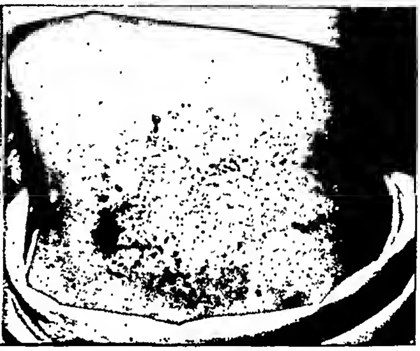

FIG. 2.—Six months after completion of treatment, 28.3.47.

24.6.46: Admitted to hospital with large ulcer involving skin of lumbar region measuring 11 cm. × 20 cm. No glandular involvement.

3.7.46: Biopsy from ulcer of back; report—basal-celled carcinoma with a tendency to squamous metaplasia.

15.7.46 to 23.9.46: X-ray therapy to back. 140 kV. Surface dose maximum. 5400 r (spaced) over 70 days.

He has a loud murmur occupying systole and diastole with a systolic accentuation below and above the right clavicle. This murmur is conducted up the line of the carotid vessels to the base of the skull, it is not conducted into the arm or below the third rib on the right side of the chest. There is a localized thrill above the

When seen again on 16.1.47, aged 21 months: Attacks had been controlled by diginutin, 4 drops daily. Satisfactory general development; no cyanosis; no clubbing; a systolic murmur over the whole heart, audible also over the aortic and pulmonary regions, the maximum in the 3rd left intercostal space near the left sternal border. The second sounds over the base were present. The exercise tolerance was good. Electrocardiogram: Wolff-Parkinson-White syndrome (fig. 2). A chest film showed the heart shadow to be enlarged and mainly globular in shape (fig. 3).

The first case of a short P-R interval with anomalous intraventricular conduction was published by Wilson in 1915 and a few isolated instances were reported subsequently. It was, however, not until Wolff, Parkinson and White published in 1930 a series of 11 cases that this syndrome was recognized as a clinical entity. A considerable number of explanations were put forward to account for this abnormality; they were listed in 1940 by Hunter, Papp and Parkinson. The hypothesis put forward independently by Holzmann and Scherf in 1932 and Wolferth and Wood in 1933 has now been accepted as affording the best explanation. According to this view the impulse originates normally in the sino-auricular node, but is conducted to the ventricles by an abnormal pathway, particularly the right lateral bundle, described by Kent in 1892 (often called the "bundle of Kent"). The assumption that the impulse is conducted through such an abnormal connexion as well as through the normal pathway via the atrioventricular node would account not only for the shortening of the P-R intervals and abnormal intraventricular conduction, but also for other features observed in this condition, viz. the abnormality in the Q-R-S complexes affects their first part either exclusively or predominantly whereas the appearance of the later parts of the Q-R-S complexes often is normal; moreover, if the features of the EC. revert to normal, either spontaneously or as a result of exercise or drugs, the interval between the beginning of the P waves and the end of the Q-R-S complexes (S-T junction) usually remains constant and is normal; lastly a high proportion of such cases have attacks of paroxysmal tachycardia, mostly of supraventricular origin.

The mechanism of the activation of the heart according to this view was well illustrated diagrammatically by Littmann and Tarnower (1946). Owing to the presence of an abnormal conducting bundle the normal impulse reaches abnormally quickly that part of a ventricle where the bundle terminates, since the physiological delay in the A-V node is absent; the result is a "pre-excitation" (Oehnell, 1944) of that particular part of one ventricle, which manifests itself in the EC. by an abnormally short P-R interval. From the area first activated the impulse spreads in the ventricles in an abnormal way, thereby giving rise to the abnormal shape of the first part of the Q-R-S complexes. Subsequently, however, as the normal conducting system is also functioning, the activation of the ventricles takes place in the normal way and it can thus be understood that the later parts of the Q-R-S complexes often have a normal appearance. This explanation also accounts for the transition of abnormal into normal forms and vice versa in the same patient and for the presence of transitional forms as well as for the fact that the P-ST junction interval remains the same with normal and abnormal complexes and is normal. The relative amounts of ventricular muscle activated through the abnormal connexion on the one hand and through the normal pathway on the other vary in different cases and in the same individual at different times. (Quite recently a case has been described by Kossmann and Goldberg (1947) in which the impulses seemed to have reached the ventricles exclusively by the abnormal connexion.) The frequent occurrence of attacks of paroxysmal tachycardia in such cases is accounted for by the presence of a circus movement, the impulse being conducted back to the auricles via the abnormal bundle.

This conception has been supported by more recent work in several ways. Glomset

Wolff-Parkinson-White Syndrome (Short P-R Intervals Associated With Disturbances of Intraventricular Conduction) With Attacks of Paroxysmal Tachycardia in an Infant Aged 8 Months Suffering From Probable Congenital Heart Disease.

—A. SCHOTT, M.D.

Cyanotic at birth; in an oxygen tent three days. Subsequently normal development until the age of 4½ months when frequent attacks of sickness and vomiting lasting from 24 to 36 hours started. Such attacks were heralded by a tachycardia of 220-260, starting and terminating suddenly.

On examination.—1.1.46, aged 8 months: Normally developed; no cyanosis; no clubbing. Electrocardiogram: Wolff-Parkinson-White syndrome (fig. 1). On screening the heart seemed to be enlarged and globular in shape.

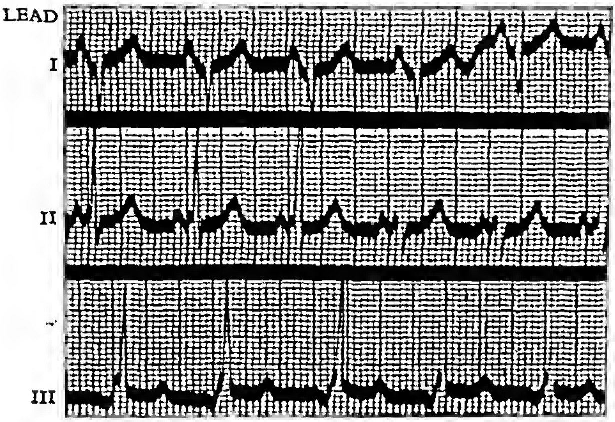

FIG. 1 (1.1.46).—Aged 8 months. Wolff-Parkinson-White syndrome. P-R intervals about 0·06 sec. (where measurable). Q-R-S complexes about 0·11 sec.

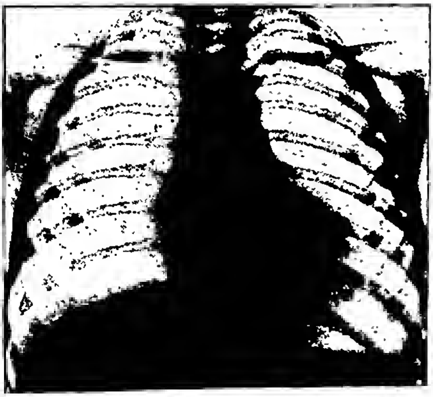

FIG. 3.

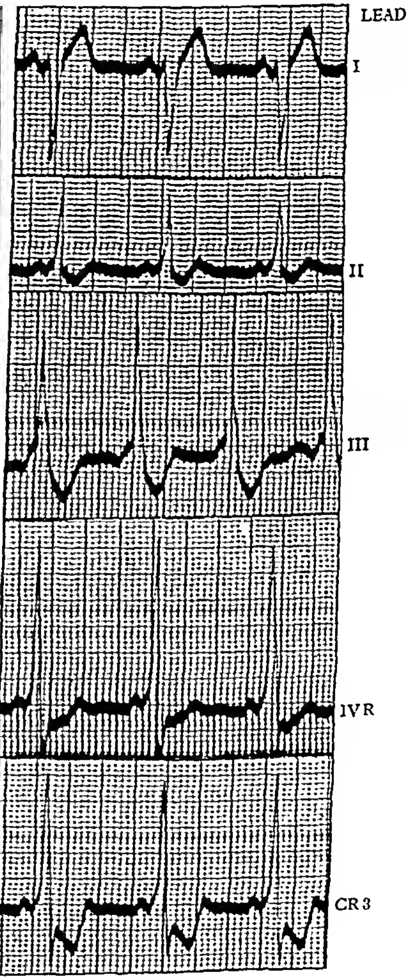

FIG. 2.

FIG. 2 (16.1.47).—Aged 21 months. Wolff-Parkinson-White syndrome. Note changes in the later portions of the Q-R-S complexes and in the T waves as compared with the previous record (*see also* text). P-R intervals about 0·08 sec. Q-R-S complexes about 0·12 sec. in the limb leads (where measurable), about 0·16 sec. in the chest leads.

FIG. 3 (16.1.47).—Aged 21 months. Chest film. Note enlarged heart shadow which is mainly globular in shape.

Dermatomyositis.—W. E. CLARKE, M.R.C.P. (for E. C. WARNER, F.R.C.P.).

M. E., female, unmarried, aged 43 years. Suffered from asthma for eighteen years prior to onset of present condition.

July 1945: Vivid erythema and burning sensation of skin of face, neck and front of chest to T.3; two months later swelling of left cheek spreading to involve whole face with weakness of facial muscles. January 1946: Marked general weakness and stiffness of whole body. November 1946: Erythema and irritation now both upper and lower limbs. Marked stiffness and general contracture of whole of musculature of body commenced and progressed. Slight dysphagia and dysarthria during past year not now present.

On admission (7.3.47).—Thinning of hair of scalp and eyebrows. Pigmented patches on scalp with some peeling of skin. Slight erythema of face. Patchy pigmentation of cheeks, neck and forearms and front of shins, also in axillæ. Muscles of face contracted and firm with œdema of subcutaneous tissue. Opening of mouth restricted; expressionless facies. Tongue protrudes poorly but palate and deglutition normal. Shoulder girdle, pelvic girdle and limb muscles all weak and sclerotic with some œdema of overlying tissue, most marked in distal parts of limbs.

Other systems normal: B.P. 130/78. Spleen not palpable.

Investigations.—Blood-count: R.B.C. 4,800,000; C.I. 1·0; Hb 96%; W.B.C. 7,000 (polys. 72%, lymphos. 21%, L. hyalines 4%, eosinos. 3%). Blood calcium 9·9 mg.%, B.S.R. 3 mm. in first hour, 9 mm. in second hour. Blood W.R. and Kahn negative. Blood phosphorus 3·1 mg.%. B.M.R. plus 15%. (Patient was rather apprehensive during tests.)

X-rays: Some osteoporosis of carpal bones, otherwise normal. No subcutaneous calcinosis. Lungs N.A.D. Teeth—two buried stumps in left lower molar region. Twenty-four hour creatine excretion estimations: 504, 460, 420 mg. daily.

Progress.—Rapid improvement while in hospital. Œdema much diminished in forearms and almost gone from face and legs. Muscles still extremely firm and contracted but now quite painless, even on stretching. Left lower molar roots removed under general anæsthesia with no flare-up in temperature. On culture grew a non-hæmolytic streptococcus.

Treatment so far has been symptomatic.

Comment.—The course of this case of dermatomyositis conforms to the usual description given of this condition. However, there was never any spontaneous pain, and at present even stretching the muscles causes no discomfort. The dysarthria and dysphagia were probably related to the weakness and stiffness of the tongue.

and Glomset (1940) not only confirmed Kent's findings of an abnormal connexion between auricle and ventricle, but found such connexions even more numerous than formerly assumed. Abnormal pathways were found histologically in one patient each, who had been known to have shown the W.P.W. syndrome, by Wood, Wolferth and Geckeler (1943), and by Oehnell (1944) respectively; in the former case, the connexion was found at the place where Kent had described it, in the latter it connected the left auricle with the left ventricle. The experimental work of Butterworth and Poindexter (1942) showed that the W.P.W. syndrome can be reproduced in dogs and cats by stimulating a ventricle with the normal auricular action current, amplified several thousand times; moreover, by reversing the direction of the current and stimulating the auricle by means of the amplified ventricular action currents, paroxysmal tachycardia could be produced. Lastly, Rosenbaum, Hecht, Wilson and Johnston (1945), by using unipolar leads from the œsophagus, præcordium and other parts of the thorax found that in cases showing the W.P.W. syndrome the dorsal wall of the ventricles is prematurely activated by impulses of supraventricular origin.

As late as 1946 it was stated that no cases had been reported in infancy (Littmann and Tarnower) although shortly before in the same year Bodlander published one case of this syndrome in an infant of 14 weeks; in view of the marked distortion of the tracing, however, caused by somatic tremor, it was not possible to make the diagnosis before the child was 2½ years old and the earlier tracing was misinterpreted; coarctation of the aorta also was present in Bodlander's patient. The present case seems to be the first one in which the diagnosis of this condition in an infant was made and the second one described of W.P.W. syndrome in infancy. The fact that congenital malformation of the heart also was present in both these cases may be of significance as congenital abnormalities of the heart often are multiple.

In regard to prognosis, this condition has generally been regarded as benign and any concomitant heart disease was usually considered to be coincidental. Some authors, however, have come to doubt whether this condition always is free from risk, and death in an attack of paroxysmal tachycardia has been reported (Oehnell). If the W.P.W. syndrome should be found to be a more frequent occurrence in infancy than hitherto assumed this would also have a bearing on the prognosis of paroxysmal tachycardia in infancy. It is usually stated that this arrhythmia is rare in infancy although according to Hubbard (1941) it is likely to be overlooked. If it is diagnosed the possible presence of a W.P.W. syndrome should be considered and in that event the prognosis would certainly be considerably better than when it is associated with severe infection, particularly diphtheria (Neubauer, 1945).

In the present case the prognosis will essentially depend on the associated structural malformation, the exact nature of which could not be diagnosed with any certainty at this patient's age. In trying to assess the marked changes in the EC. which have occurred between the ages of 8 and 21 months the fact has to be considered that the later tracing was obtained while the patient was having digitalis treatment; the marked alterations in the second part of the Q-R-S complexes and in the T waves need not necessarily be due to additional structural changes, but may, at least to a considerable extent, be an effect of the drug. It has been stated by Movitt (1945) that digitalis may not exert any influence on the aberrant bundle, whereas it would have the usual effect on the normal conduction path and this discrepancy would tend to aggravate the EC. signs of disturbances of intraventricular conduction.

Treatment by means of diginutin, 4 drops daily, was successful in preventing the attacks of paroxysmal tachycardia, but the dose had to be slightly increased when the patient was just over two years of age.

Section of Dermatology

President—SYDNEY THOMSON, M.D.

[*January* 16, 1947]

Lichen Planus in a Boy Aged 8 Years.—H. CORSI, F.R.C.S.

Duration two months. Eruption typical lichen planus.

There are no symptoms other than some itching after a bath.

Dr. H. W. Barber: Some years ago the children's nurse of a well-known surgeon consulted me for a severe and very widespread lichen planus. She asked me whether there was any risk of contagion to the infant she was tending. I replied that, although I believed the disease to be due to a virus infection, I had not met with an instance of apparent contagion. A few months later I saw the infant in question and it had quite typical lichen planus from which it made a spontaneous recovery. Considering the rarity of lichen planus in infants, I think this was probably a genuine example of contagion.

Hyperkeratotic Systematized Nævus with ? Bromide Eruption.—A. HARGREAVES, M.B. (for W. N. GOLDSMITH, M.D.).

Miss E. F., aged 52.

History.—At the age of 3 months, red patches were noticed on the skin, attributed at first to teething or vaccination. Generalized thickening and dark scaling of the skin were noted at about 1 year of age. The face, at first affected with the rest of the body, became clearer, while the legs got progressively worse and became painful; from time to time great lumps of skin separated from them. The pain was worse when she was lying than when sitting.

She attended school up to the age of 15, and apparently made average progress. Menstruation began at 16, and was normal until two or three years ago. Apart from self-administered aspirin, she had had no treatment, and washing had been minimal. On November 25, 1946, she was admitted to University College Hospital.

On admission.—The whole of her skin except the face and scalp was dry and rough. In many areas, especially the lower limbs and feet and hands, it was warty, the papilliform projections being in some parts acuminate and in others more rounded (mammillated). The palms and soles were greatly thickened, but smooth. On the upper limbs there was hypertrichosis (fig. 1). On the legs the papillomatous overgrowth reached an extreme degree, large fleshy red vegetations being covered by

The ætiology is still obscure. There was no preceding event or infection that could be associated with its onset. Her present progress is towards improvement, and any causative infective process seems to have subsided. There was no leucocytosis, the differential white cell count was normal, and the B.S.R. was not raised. There was no increase either in monocytes or in eosinophils, as has been described. There was no reaction to the removal of buried roots: these grew a non-hæmolytic streptococcus on culture. No consistent bacteriological findings have been described in the literature, and the muscle histology is not that of an acute infection. Griffiths and Dowling draw a close parallelism between the symptomatology, histology and biochemical findings in thyrotoxicosis and dermatomyositis. This case clinically is not thyrotoxic; her B.M.R. was raised, but she was apprehensive during repeated tests, and this presumably does not give a true indication of her B.M.R. Nor was there any undue sweating, which is often stressed as a finding. In this case too, the peripheral insulin test, used by Griffiths in these cases, was within normal limits. The blood calcium and phosphorus were normal, and there was no subcutaneous calcinosis or general osteoporosis. French writers have implicated the parathyroid glands, and claim good results after parathyroidectomy. The creatinuria is associated with the myopathy in these cases and in thyrotoxicosis, and cannot be used to relate them to a common ætiology.

Dr. F. Parkes Weber agreed that this was a remarkable example of subacute or chronic dermatomyositis (or "poikilodermatomyositis"), to be differentiated from mere symmetrical sclerodermia by the excess of the residual cutaneous pigmentation and the history of the striking facial erythema at the commencement. It was, however, now a case of "symptomatic scleroderma" (cf. F. P. Weber, "Rare Diseases," London, 2nd edition, 1947, p. 180) and should be treated by physical methods, such as massage, passive movements, "short waves," &c., with every chance of gradual, though slow, improvement, now that the most active and dangerous part of the disease was apparently over. He (Dr. Weber) did not think that the disease was of hormonal (endocrine) origin. He believed, however, that it represented an allergic manifestation towards some unknown kind of infection, the infection probably having little effect excepting in certain predisposed (hypersensitive or allergic) individuals. He stressed the analogy with the allergic theory of the manifestations of acute articular rheumatism.

patches. (2) The exuberant vegetating condition on her legs. (3) The pain in the legs. For the pain, which was intense and prevented sleep, analgesics and sedatives, including bromide, were given at first, but did not help. The three features above mentioned then aroused the suspicion of a drug eruption, especially bromide, superimposed on the nævus, and all sedatives were stopped.

Her blood bromide was found on December 5, 1946, to be 80 mg%, and a week later, 70 mg.%. This was calculated to be a much higher concentration than was likely to have been brought about by the amount we had given her. To help eliminate the bromide she was given sodium chloride by mouth.

Local measures consisted of Cyllin-M baths and varying strengths of salicylic acid ointment for the legs. Twelve days after starting the sodium chloride treatment, she became increasingly irrational, with visual and auditory hallucinations, and then drowsy. Ketones, but no sugar, were found in the urine. Treatment with sodium bicarbonate and glucose led to recovery of the ketosis, but she remained confused. Three weeks later Professor Himsworth advised a high-protein diet and big doses of vitamin-B complex. This was followed almost immediately by a striking improvement in her mentality.

The pain in her legs gradually got less from the time that sedatives were stopped and local treatment instituted. The offensive discharge steadily diminished and the warty masses were gradually reduced.

Inunction of an ointment containing potassium bromide 30% in soft paraffin on a relatively unaffected part of the skin caused no reaction.

Present condition.—The appearances have not changed except on the legs, where sepsis has been greatly reduced, and a good deal of the horny covering removed.

Comment.—The case is shown as an unusual systematized nævus of the ichthyosis hystrix group, and the question is raised whether the vegetating painful condition of her legs has been the result of prolonged bromide medication (of which there is no positive evidence), or whether it is just an exaggerated manifestation of the nævus. In either case, it is aggravated by sepsis and neglect.

Pityriasis Rubra Pilaris.—G. B. MITCHELL-HEGGS, O.B.E., F.R.C.P., and M. FEIWEL, M.B.

Miss J. F., aged 20.

At age of 12 sustained a compound fracture of the right arm. It was noticed that the scar when healed always remained red and had a tendency to scale. Two years later the skin below both eyebrows became red and scaly and showed no tendency to heal with local applications. The legs next became affected, showing a bluish-red discoloration followed by the appearance of horny rough papules, a condition which has persisted. Gradually other parts became affected, the arms, the upper part of the trunk and the face becoming red and scaly. The backs of the hands and fingers were involved four years ago but the changes are less obvious now. The scalp, the palms and the soles have always been clear. There has been little irritation throughout except during the past month, but there has been a feeling of tightness and constriction of the face, back and arms especially when the weather is cold. Desquamation has been severe at times. Local application of salicylic acid ointment and ung. aquosum, medication with vitamins, arsenic and thyroid, and calcium injections have merely reduced the amount of scaling. The patient has been receiving Grenz rays since September 1946 (Dr. Leitner).

Past history.—Measles, scarlet fever and chicken pox. Had urticaria and dermographism as a child.

thick masses of horny material mixed with debris and offensive pus (fig. 2). On the chest and upper limbs were some irregular flat red patches with sharp outlines.

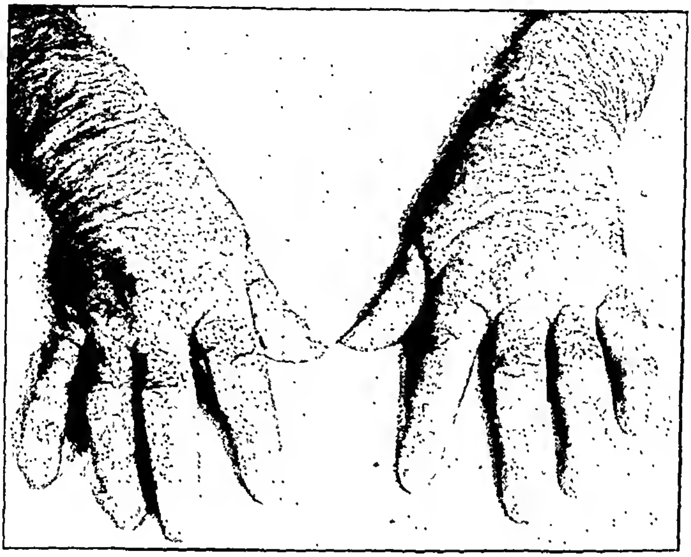

FIG. 1.

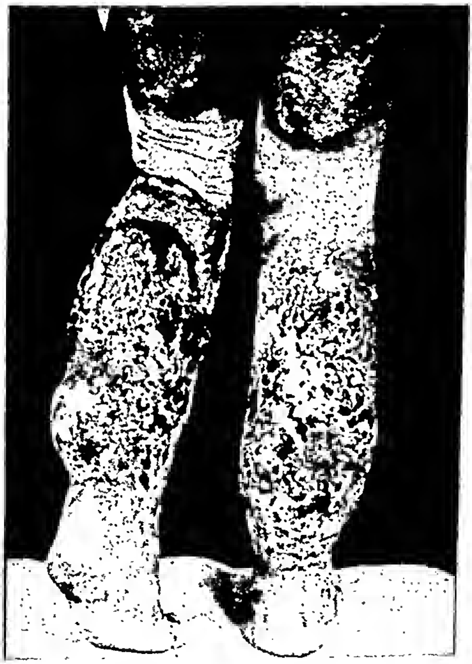

FIG. 2.
Condition on admission November 1946.

Course and treatment.—It was obvious that the essential trouble was a systematized warty and hairy nævus. Three unusual points attracted attention: (1) The flat red the right wrist and neck with very fine papules. The patches on the back, chest and thigh have a circumscribed but irregular and rather indefinite edge.

Blood examination.—Absolute count: R.B.C. 5,100,000; Hb (Sahli) 86%; C.I. 0·85; W.B.C. 5,900. Differential count: Polys. 61, lymphos. 28, monos. 5, eosinos. 4, basos. 2%.

Remarks.—Blood films show no anisocytosis, poikilocytosis or polychromasia. No nucleated red cells were seen.

Dr. W. Freudenthal: Dr. Mitchell-Heggs very kindly sent me the sections of his biopsies from back, chest and thigh for examination. They present the picture that one expects to find in poikilodermia vascularis, and in addition they all show a permeation of mesenchymal cells into the epidermis where they form small "cell nests". These cell nests are found in mycosis fungoides, and also in other reticuloses. The sections resemble those of Dr. Mitchell-Heggs's case of ? poikilodermia—? parapsoriasis—? premycosis, shown at the last B.A.D.S. meeting in which our French colleagues took great interest. The present case shows also clinically some resemblance to premycosis.

Pili Torti.—G. B. MITCHELL-HEGGS, O.B.E., F.R.C.P., and W. R. MAY, M.B., B.S.

Barbara, aged 4. Her mother states that she had very little hair at birth, and it never grew very much. She has had no serious illness, accidents or operations.

Family history.—No relatives are known to have had any unusual skin or scalp trouble.

On examination of the head the whole of the occipital area looks almost bald. Over the back and sides of the scalp the hair is now short and curly; it has never grown to a length of more than ½ in. in this region. The hair in the parietal and frontal area, where it is not subject to trauma, is between 2 and 3 in. long, but straight and brittle, and sticking out in an unruly fashion, as the hair will not stay in position after brushing. The hair has never required cutting. The eyebrows are also affected, but the eyelashes are normal. The nails and skin are normal. The child is healthy in all other respects. A brother aged 6 has normal hair.

On examination of the hair, there is apparent irregularity in the diameter of the hair. On microscopical examination, the irregularities are seen to be due to a twist of 180° at certain points; these points look like little nodes on direct examination, without lens. Histological examination of the hair follicles suggests that this twist in the hair is taking place in the follicles.

Dermatomyositis in a Child.—DOYNE BELL, D.M.

I first saw this child with Dr. Ungar in my Out-patients Dept. at the age of 2½ years. At the invitation of Dr. Wigley I now show him here, partly because I believe this to be an unusually early age at which to see so striking a case of dermatomyositis and partly in order to ask for suggestions as to treatment.

Male child, now aged 3 years. Birth-weight: 6 lb. 15 oz. Age of mother and father at birth—26. Breast fed for two months. Development normal. No previous illnesses. Vaccinated. Diphtheria immunization at usual times.

Well until one year ago, when lassitude and poor appetite were noted, red scaly areas of skin appeared on his nose and the back of the neck. Shortly afterwards red areas on the fingers and backs of his hands; these areas coalesced and the mother described them as looking like chilblains. These faded gradually when the area of skin began to stiffen. Stiffness spread to the forearms and to the elbows. Within two months stiffness developed in the feet and legs.

July 1946: Weight 1 st. 12 lb. 2 oz. Apyrexial during four weeks under observation in hospital, except for two peaks of temperature between 102° and 101° associated with a cold.

Family history.—No familial incidence of pityriasis rubra pilaris.

Present condition.—Face and neck have a uniform red discoloration. The upper part of the trunk, front and back, shows widespread red areas, with scaling more pronounced in some than in others. The breasts have a streaky dusky telangiectasia. The skin of the affected areas appears thickened. The "shoulder-strap" areas are curiously spared. The skin of the arms is almost uniformly covered with thickened, dusky red areas with some scaling. The dorsal surface of the proximal phalanges have very small indistinct discrete papules. The legs are covered with bright red areas and rough grating yellowish red papules centred round the follicles. The upper margin of the eruption is fairly sharply defined in the lower part of the thighs. Over each tendo Achillis and on the outer margin of the foot are rough, thick hyperkeratotic areas. The toes are red and smooth.

Biopsy from the skin at the back of the right arm: The epidermis varies in thickness due to varying depth of stratum granulosum. There is no hyperkeratosis but small areas of parakeratosis are present not related to the orifice of the sweat or sebaceous glands. Round-cell infiltration of superficial portion of the corium (Dr. Pike). Dr. W. Freudenthal confirmed the diagnosis of "Pityriasis Rubra Pilaris".

In the hope that vitamin-A therapy might help this case, estimations were carried out by Dr. Leitner and found to be normal.

	Blood carotene	*Vitamin A*
26.8.46	161 I.U.	113 I.U.
9.9.46	156 I.U.	103 I.U.

? Poikiloderma ? Premycosis.—G. B. MITCHELL-HEGGS, O.B.E., F.R.C.P.

Mrs. B. was referred to me on account of irritation on the back, chest and thighs for two months.

Past history.—Married, 3 children. All alive and well, no miscarriages.

Family history.—Father had gouty eczema, and one brother had alcoholic cirrhosis. No history of blood disease or of unusual skin condition.

Previous health.—In 1928 metrorrhagia and menorrhagia were treated by inducing an artificial menopause by treatment of the body of the uterus with radium (? 2250 mg. hr.) Mixed endocrine deficiencies following this procedure are likely to be a factor in the ætiology of this case.

History of present condition.—The patient, now aged 63, thinks she has had a rough patch on the lower part of her back, and on her chest and thighs since 1938, and that its appearance followed a type of sciatica which started with acute pain in the right calf followed by pain in the big toe and later in the other toes and ankle, ultimately causing dropped foot: this was supported by a garter-spring-toe-lift. The foot-drop is of uncertain origin and may have been due to a drug given for the sciatica.

The skin irritation commenced after a wasp sting in October 1946 and has gradually become more and more intense.

On examination.—General medical investigation showed no abnormality. The patient looks and feels quite well. Hair on the scalp is present, but there is no hair in the armpits. Her skin, generally, is unusually smooth. The surface of the skin on the back and chest shows a fine bran-like scaling with a diminution in thickness, atrophy in certain areas and infiltration in others.

On the deltoid region there is a rough red area; on both thighs, a reddish-brown area. The patch on the left thigh has a mottled appearance. There are areas of pallor with a network of vascularity. An erythematous patch is also present on

In recent times there have been rather more ulcers which have appeared higher on the legs around the knees.

The lesions are purplish nodules, palpably deep in the subcutis, and some of them break down into indolent ulcers. Healed lesions show marked scarring. There is no apparent disease of the veins.

There was no apparent response to treatment with calciferol over three months.

The lesions here resemble those of erythema induratum, but there is no evidence of tuberculosis, and the disease has been present for twenty years.

Dr. C. H. Whittle: I was wondering if this could possibly be a case of epidermolysis bullosa. That may seem a somewhat fantastic suggestion but I saw a case a month ago presenting chronic ulceration for many years of the legs and also of the back in a man about whom we were very puzzled. I took him into hospital for investigation and found he had been in several years ago, and I had then with confidence and without difficulty diagnosed epidermolysis bullosa. Under observation for a few weeks he produced typical bullæ on prominent parts. The histology might settle the question in this case.

Dr. J. E. M. Wigley: Would the President say whether he thinks this case would come into the category described by Dr. Arthur Whitfield as erythema induratum—not of tubercular origin?

The President: It is true that in most of Whitfield's cases the lesions were in the thighs and did not break down. He was convinced that they were the result of septic foci elsewhere; and it is also true that the number of his cases which I saw at that time did clear up. Unfortunately, I did not see the particular case Dr. Wigley has in mind.

Dr. C. H. Whittle: Were not Whitfield's cases occurring in middle-aged women? The patient Dr. Wells refers to is about thirty years of age.

Dr. G. C. Wells: I believe the cases Whitfield described occurred in women of about forty years of age, in which the lesions were more painful and in which no tuberculous ætiology was found. At about the same time Galloway described the histology in which he emphasized the sclerosis in small vessels and fat necrosis, but again none of the cases was tuberculous and I gather that he got no closer to the true ætiology.

I should question an epidermolysis bullosa. The lesions in this case are too deep and they appear as nodules which in many instances do not break down. The lesions around the knees have broken down. They were explored for micro-aerophilic streptococci, but no organisms grew either aerobically or anaerobically.

Leukæmia Cutis ? Myeloid Leukæmia.—E. Colin Jones, M.B.

Mrs. K. P., aged 47. Was referred to me on December 30, 1946, giving the history that she had developed a sore throat two to three weeks ago, followed two weeks later by the widespread rash now evident.

Careful questioning at a later date revealed that she had had swelling of her ankles off and on for one year, and been markedly dyspnœic.

Previous history.—Hysterectomy eighteen months ago (bleeding fibroids). No blood examination.

On examination.—An ill-looking woman. Fever and tonsillar remnants, with ulceration and necrosis, left more than right. Recent bleeding from the gums, but for the most part not affecting the buccal mucosa. Generalized glandular enlargement, most marked in the cervical triangles, and less so in the axillary and inguinal regions. Spleen and liver easily palpable, two f.b. Œdema of legs, no obvious cause.

She has a widespread nodular and infiltrated eruption, most marked on the abdomen (when originally seen limited to this area, but now affecting the trunk and limbs). The lesions on the breasts are petechial, hæmorrhagic, and indurated, but for the main part tumour-like infiltrated nodules covered by normal skin.

Investigations.—Wassermann negative. R.B.C. 2,900,000/c.mm.; Hb 56% Haldane; C.I. 0·9; W.B.C. 56,000/c.mm. Differential: Myelos. 88, premyelos. 2, At this time there were scaling red areas on nose and on the right side of the back of the neck. The whole of the extensor aspect of the forearms and legs was pigmented as if sunburned.

The movements of the wrists were restricted, and also of the ankles, and the skin covering the fingers was atrophied and inelastic.

Investigations (July 1946).—Tuberculin jelly test negative; blood-count within normal limits; urine normal; E.S.R. (Westergren) 6 mm. in 1 hr. to 16 mm. in 2 hr.; X-rays of limbs, chest and skull normal (Dr. F. Tierney).

Chemical investigations (Dr. J. Paterson).—Blood urea 22%, blood uric acid 4·2, blood cholesterol 210, serum sodium 375, serum potassium 20, plasma chloride 270 mg.%. Daily urinary excretions total: Nitrogen 5·89 grammes; creatine 157 mg.; creatinine 327 mg.

Insulin resistance test (*see* Griffiths, *Brit. J. Derm.*, 1940, **52**, p. 295). Using 2·5 units of soluble insulin intravenously and 25 grammes of glucose p.o. results are: *Capillary*: Fasting 107, 30 minutes 130, 60 minutes 146. *Venous*: Fasting 77, 30 minutes 99, 60 minutes 125.

There has been a gradual progression during the past few months. He now shows scleroderma of the hands and feet with myositis of the legs and forearms and areas of de-pigmentation of these areas and also of the back of the neck.

There are small discrete glands in the back of the neck, left axilla and groins. No splenomegaly.

Dr. H. Corsi: I think benefit might result to the child from treatment with short-wave therapy; I suggest that one limb be so treated and the effect observed.

Dr. G. B. Mitchell-Heggs: I suggest a sympathectomy as a trial on one side, because the adults we see with similar conditions are often relieved by sympathectomy.

Dr. J. E. M. Wigley: I think any question of sympathectomy should be approached with extreme caution.

The President: Recently I had occasion to see a middle-aged sea captain with what was, apparently, an acute scleroderma of the chest. From the clinical point of view I had no doubt about that. The disease progressed rapidly and became much more obviously a dermatomyositis. The patient died within two or three months. The histological picture of the skin and of the subcutaneous tissues was that of scleroderma, while that of the muscles showed a sclerodermatous infiltration plus large amounts of what were undoubtedly typical myositic degeneration, &c. That was the most striking case of the type that I have seen. I confess that I have been dubious, formerly, as to the connexion between the two diseases.

There is one feature about this particular child which undoubtedly suggests dermatomyositis; the classical mode of onset is so well described. From the purely clinical point of view to-day one would have to think of the third group of scleroderma in which changes start in the deeper tissues and spread towards the surface and into the muscles. In this particular case it seems wise to have a biopsy to see if there are any pathognomonic changes in the muscle.

Recurrent Ulcers of the Legs.—G. C. WELLS, M.R.C.P.

Miss B., aged 35. School teacher.

This patient first noticed lumps about the ankles at the age of 14 years. Some of the lesions went on to ulcerate, and she has had trouble with these indurated lesions and ulcers over the last twenty years. At times she has been free of trouble for as long as six months, and the lesions tend to clear with rest or while she is on holiday.

The lesions do not appear to vary with the seasons, although she has the tendency to acrocyanosis and coldness of the extremities which usually accompanies Bazin's disease.

General health has been good, apart from migrainous headache. There has never been anything to suggest tuberculosis, and X-ray of the chest is negative.

Section of Orthopædics

President—V. H. ELLIS, F.R.C.S.

[*December* 3, 1946]

Diaphyseal Aclasis.—G. O. TIPPETT, F.R.C.S.

Man, aged 32. Neuritis of the left arm together with an increasing swelling below the outer end of the left clavicle which he had noted for three months. No history of injury. An X-ray showed an osteoma growing from the outer end of the left clavicle which was no doubt pressing upon the inner part of the brachial plexus (see fig. 1). Further X-rays showed osteomata growing from the scapulæ and the lower ends of both femora.

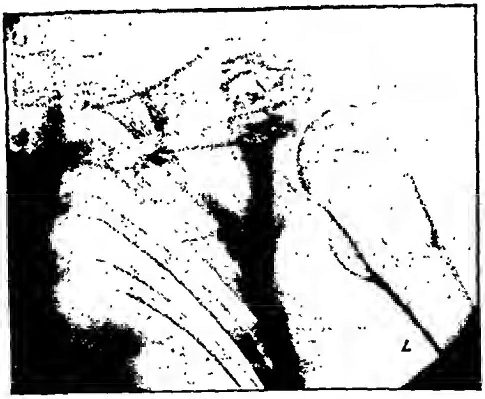

FIG. 1.—Case of diaphyseal aclasis. Osteoma of clavicle.

Cyst in the Femur.—G. O. TIPPETT, F.R.C.S.

Child, aged 8, was knocked over by a dog in January 1945. Admitted to hospital suffering from a fracture through the outer end of the neck of left femur. An X-ray showed that the fracture had taken place through a solitary cyst in the outer end of neck and upper part of shaft of femur. The fracture was immobilized in a plaster spica for three months at the end of which time the cyst appeared to have grown larger. During the next eight months the child was allowed to walk on a weight-relieving caliper. During this time the X-ray taken shows that the appearance of the cyst is greatly enlarged with much periostitis.

neutrophil myelos. 2, neutrophil metamyelos. 1, neutrophil polys. 3, lymphos. 0·5, promonos. 2·5, monos. 1%.

Dr. M. O. Skelton reports appearance is that of a myeloid leukæmia in a myeloblastic phase—i.e. with many circulating blast cells.

It may be an acute myeloid leukæmia *ab initio*, or an acute phase in a chronic leukæmia.

Biopsy.—There is a zone of large mononuclear cells lying beneath the epidermis. This zone of infiltrating cells lies in the most superficial part of the cutis, for the most part, with some tendency to show deeper aggregations in small areas. These cells appear to be of the same type as the blast cells in the circulating blood, and the condition to be a leukæmic infiltration of the skin.

Dr. W. A. Bourne saw this case three days ago, and considered it was probably a monocytic leukæmia, passing into a myeloid leukæmia (Naegeli type). The only points against it are the prominent spleen and absence of lesions in the buccal mucosa.

Lupus Vulgaris with Epithelioma and Mutilations.—G. B. MITCHELL-HEGGS, O.B.E., F.R.C.P., and J. R. OWEN, M.R.C.P.

Housewife, married, aged 52. History of red scaly patches developing on the face at the age of 24. Subsequent appearance of similar lesions on body and hands, which later spread to the arms. Attended for treatment at the Royal Berkshire Hospital, Reading, when lesions had already been present for over a year. No notes of early treatment available, but X-rays said to have been used in several areas. After receiving this, and other forms of treatment over a period of several years, she ceased attending, but returned again in August 1946, on one occasion only.

There is no history of any other illness save laryngitis a few weeks before the onset of the skin condition, and this was not considered at the time to be tuberculous, although it took some months to clear up, nor is there any record of tuberculous disease, or disease of the skin, amongst relatives.

The case presents very numerous patches of typical lupus vulgaris over the face, trunk, and upper limbs. The hands are grossly affected, with scarring, atrophy, swelling, necrosis, loss of phalanges, and ulceration. The face is extensively infiltrated with lupus in its later stages, and the left maxillary region presents an enormous, deep, foul-smelling ulcer which has eroded the antrum and nares.

It has been impossible to investigate or treat, owing to the patient's failure to attend. Her very good reasons for not attending were that no treatment had ever helped her, and that she was unable to bear the remarks made by her fellow out-patients in her hearing.

Dr. Whittle: How are the mutilations which produce the curious horny changes on the tips of the fingers explained?

Dr. Owen: I think endarteritis due to the tuberculous process may have caused the changes at the finger-tips.

monthly intervals according to the amelioration of symptoms and tendency to relapse. After six doses the patient is instructed to return for an injection when required.

The joint can be injected from the side, from the back, or from the front. Of these the anterior approach seems to be the easiest, the least painful and also the more certain. The surface marking which was drawn on the thigh of the case shown is simple in the extreme. The femoral artery is marked on a line joining the symphysis pubis with the upper edge of the great trochanter. The needle is inserted vertically on this line an inch or so outside the artery. A local anæsthetic is not really necessary but the use of a fine procaine needle as a probe to test the thickness of the capsule of the joint, and whether the point meets with bone, cartilage or tender synovial membrane, is a help.

When bone is encountered the injection can still be given provided that the needle has a sufficiently short bevel to drive the solution in between the closely apposed layers of the synovial membrane.

In a small proportion of cases, fluid is present in the joint so that it is as well to try aspirating with an empty syringe before attaching the syringe containing the solution.

Grant Waugh advises infiltrating the tissues in the neighbourhood of the joint. I do not do this intentionally, though the effect seems to be quite satisfactory as long as the point of the needle is inside the capsule. No surgical accidents have occurred.

We have now carried out many hundreds of these intra-articular injections of the hip-joint at the Clinic and I can therefore speak with some confidence of their value. I cannot claim that these alone will arrest the progress of osteo-arthritis of the hip-joint, because all cases are given vaccine therapy as a routine. In addition, special exercises are given for stretching the adductors of the thigh, counteracting flexion and eversion deformities and strengthening atrophied muscles.

Over the last twenty-five years comparative skiagrams have demonstrated arrest of the disease process in a high proportion of cases, but since the introduction of acid phosphate injections, some joints seem positively to have improved as in the case of the patient shown to the meeting.

[Lantern slides were put on the screen, and skiagrams shown of a joint injected with a contrast medium.]

Osteoid-Osteoma of Upper End of Ulna.—D. WAINWRIGHT, F.R.C.S.Ed.

Early in February 1944, Jessie E., an unmarried girl of 18, employed in a pottery, was referred with a history of pain and increasing stiffness of the left elbow, which she first noticed fourteen months previously. She had been treated as a case of monarticular arthritis, with myocrysin, following an X-ray examination in April 1943 which did not show any bone abnormality.

She was complaining of intermittent pain in the left elbow-joint, which had been gradually getting worse and which troubled her at night and was aggravated by use of the joint. There was no history of injury.

Examination revealed an appreciable thickening of the upper end of the ulna with some tenderness on deep pressure; no local redness or heat. Movements of the elbow-joint were limited to about 45 degrees of extension and 30 degrees of flexion. W.R. was negative. B.S.R. 4 mm. in first hour. Blood-count normal.

X-rays: Considerable thickening and sclerosis of the upper end of the ulna with a well-defined lesion involving the articular surface, showing considerable mottled calcification and surrounded by a faint translucent line of demarcation.

The possibility of this being an example of an osteoid-osteoma was considered, but the tumour—if such it was—appeared to be very inaccessible, and she was

The case was shown for confirmation as to the nature of the condition though it is probable that the condition remains one of simple cystic disease. The appearances might also suggest that the condition was a myeloma. At the meeting it was pointed out that the age of patient was against the diagnosis of myeloma and in favour of a loculated cystic condition.

The treatment advised by several members was exploration of the area with, probably, scraping out the abnormal tissue and packing the cavity with bone chips.

Typhoid Osteitis of the Long Bones.—E. T. BAILEY, F.R.C.S.

A. S., merchant seaman, aged 20. 31.10.45: While serving in Hospital Carrier running between Southampton and Ostend he contracted severe typhoid fever with positive Widal reaction and positive culture typhoid bacilli in the blood and fæces. Gradual recovery followed, but, whilst still convalescing five months later, he developed nodes on both tibiæ, right fibula and left radius and ulna. These caused general bone aching and local tenderness. He was treated conservatively for the first three months by physiotherapy and local applications without improvement, until definite subperiosteal abscesses formed, for which local aspiration with penicillin replacement was carried out and combined with systemic penicillin. Culture of aspirated pus was sterile, but the condition progressed.

25.6.46: The affected areas of the left tibia and left radius were excised and the area of the right fibula curetted. Operation findings showed small, clean-cut cavities containing gelatinous material enclosed in dense sclerotic bone. Following the operation, subsequent progress was uneventful apart from some delayed skin healing at site of previous abscess formation. Bone symptoms were completely relieved.

Histological report of bone and adjacent tissue excised at operation: Chronic purulent inflammation including some large cells of "typhoid" type in fragments of fibrous tissue with a few trabeculæ of new bone formation in two specimens.

All blood tests, including blood-count, W.R., Kahn, G.F.T. and agglutination tests were normal. B.S.R.: Fall in one hour 5 mm. The characteristic features of the case were the selection of the cortex for the site of bone infection, the chronicity with bone sclerosis and failure to respond to conservative measures.

Osteo-arthritis of the Hip-joint treated by Intra-articular Injections.—H. WARREN CROWE, D.M.

Male, aged 56. Began to feel pain in 1940. No trauma. No family history of arthritis.

This case is a good example of the effect of intra-articular injection of the hip-joint.

A few months ago at a meeting of the Section on the surgery of the hip-joint, Grant Waugh described his results in some twenty-five cases. I should like here to pay my tribute to his originality and to express my thanks to him for having been the initiator of such an exceedingly helpful method of treatment. Grant Waugh uses a solution of procaine and lactic acid. At the Charterhouse Rheumatism Clinic we have substituted for this two preparations of acid-buffered salts: acid potassium phosphate (A.P.P.) and acid magnesium phosphate (A.M.P.). Whether procaine is added or not the effect is the same but it does delay reaction so that out-patients can get home in comfort. A.P.P. is less drastic, can be given in larger amounts, being much less liable to provoke reaction, but its effect is less prolonged. The first dose is 20 c.c. of A.P.P. followed a fortnight later, if no reaction, by 10 c.c. of A.M.P.[1] Thereafter A.M.P. can be repeated at about monthly intervals according to the amelioration of symptoms and tendency to relapse. After six doses the patient is instructed to return for an injection when required.

---

[1] Both preparations are put up by Messrs. Allen and Hanburys in 100 c.c. rubber-capped bottles with 0·5% phenol, ready for use.

The joint can be injected from the side, from the back, or from the front. Of these the anterior approach seems to be the easiest, the least painful and also the more certain. The surface marking which was drawn on the thigh of the case shown is simple in the extreme. The femoral artery is marked on a line joining the symphysis pubis with the upper edge of the great trochanter. The needle is inserted vertically on this line an inch or so outside the artery. A local anæsthetic is not really necessary but the use of a fine procaine needle as a probe to test the thickness of the capsule of the joint, and whether the point meets with bone, cartilage or tender synovial membrane, is a help.

When bone is encountered the injection can still be given provided that the needle has a sufficiently short bevel to drive the solution in between the closely apposed layers of the synovial membrane.

In a small proportion of cases, fluid is present in the joint so that it is as well to try aspirating with an empty syringe before attaching the syringe containing the solution.

Grant Waugh advises infiltrating the tissues in the neighbourhood of the joint. I do not do this intentionally, though the effect seems to be quite satisfactory as long as the point of the needle is inside the capsule. No surgical accidents have occurred.

We have now carried out many hundreds of these intra-articular injections of the hip-joint at the Clinic and I can therefore speak with some confidence of their value. I cannot claim that these alone will arrest the progress of osteo-arthritis of the hip-joint, because all cases arc given vaccine therapy as a routine. In addition, special exercises are given for stretching the adductors of the thigh, counteracting flexion and eversion deformities and strengthening atrophied muscles.

Over the last twenty-five years comparative skiagrams have demonstrated arrest of the disease process in a high proportion of cases, but since the introduction of acid phosphate injections, some joints seem positively to have improved as in the case of the patient shown to the meeting.

[Lantern slides were put on the screen, and skiagrams shown of a joint injected with a contrast medium.]

Osteoid-Osteoma of Upper End of Ulna.—D. Wainwright, F.R.C.S.Ed.

Early in February 1944, Jessie E., an unmarried girl of 18, employed in a pottery, was referred with a history of pain and increasing stiffness of the left elbow, which she first noticed fourteen months previously. She had been treated as a case of monarticular arthritis, with myocrysin, following an X-ray examination in April 1943 which did not show any bone abnormality.

She was complaining of intermittent pain in the left elbow-joint, which had been gradually getting worse and which troubled her at night and was aggravated by use of the joint. There was no history of injury.

Examination revealed an appreciable thickening of the upper end of the ulna with some tenderness on deep pressure; no local redness or heat. Movements of the elbow-joint were limited to about 45 degrees of extension and 30 degrees of flexion. W.R. was negative. B.S.R. 4 mm. in first hour. Blood-count normal.

X-rays: Considerable thickening and sclerosis of the upper end of the ulna with a well-defined lesion involving the articular surface, showing considerable mottled calcification and surrounded by a faint translucent line of demarcation.

The possibility of this being an example of an osteoid-osteoma was considered, but the tumour—if such it was—appeared to be very inaccessible, and she was kept under observation for some time. Her pain, however, persisted, and in an effort to relieve this a simple linear osteotomy of the upper end of the ulna was performed.

In spite of some temporary relief her pain returned and she was slowly becoming more disabled; she had to give up her work and was constantly losing sleep because of the pain at night. Movements of the joint were also more limited and, in July 1945, she had only about 10 degrees of extension and 20 degrees flexion of the joint.

In view of the inaccessible position of the lesion, the only prospect of cure appeared to be excision of the upper end of the ulna and reattachment of the triceps tendon to the shaft of the ulna. It was realized that removal of such an amount of the joint surface would give rise to some permanent weakness of the arm; but, in view of the persistent pain and increasing stiffness of the elbow—and also because as a result of such treatment a tumour, the nature of which was uncertain, would be removed—this treatment was decided upon.

On 27.9.45 a subperiosteal excision of the upper end of the ulna was performed, with some difficulty owing to the sclerotic nature of the bone, and the triceps tendon was firmly reattached to the upper end of the ulna.

Her progress was satisfactory but restoration of movement was rather slow; subsequent X-rays showed some forward subluxation of the head of the radius, and this was excised about ten weeks later. With active exercises the movement slowly increased and she now has only occasional aching in the joint after using it a good deal. The range of movement has continued to increase and, at the moment, she has about 80 degrees extension, 30 degrees flexion, full supination and 50 degrees pronation. Three months ago she resumed her old job for the first time for about twelve months.

Dr. McCall (Pathologist to North Staffordshire Royal Infirmary) reported that the tumour corresponded very closely to Jaffe's osteoid-osteoma, and his opinion was supported by Professor Turnbull of London Hospital.

The sections show the tumour to be well demarcated from the surrounding spongiosa and separated from it by a characteristic narrow zone of delicate fibrous marrow. The tumour itself consists of very atypical osteoid tissue and bone and corresponds in every way with the tumour described by Jaffe and Lichtenstein in their article in the *Journal of Bone & Joint Surgery*, 1940, **22,** 645.

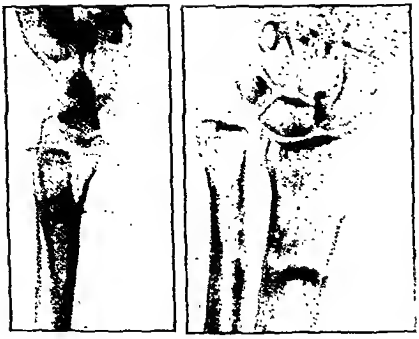
Treatment of Displacements of the Distal Radio-ulnar Joint.—F. P. FITZGERALD, F.R.C.S.

Forward, backward and upward displacements of the radio-ulnar joint have been described. The following cases demonstrate methods of treating backward and upward displacements.

Backward displacement.—CASE I.—The patient, a female, aged 23, came to hospital in 1942 complaining of marked weakness of the right wrist. She had fallen on to the outstretched hand two years previously. On examination she had an obvious backward displacement of the distal radio-ulnar joint, which was confirmed by X-ray (fig. 1).

Treatment.—The dislocation was reduced by simple supination of the fore-arm, and this was verified by X-ray (fig. 2). The elbow and wrist were then immobilized in plaster of Paris in the supine position (*see* fig. 197, McNeill Love's "Minor Surgery," London, p. 374).

Some years previously I had treated a similar case in this fashion, which I had kept immobilized for three months. The result was good, but some backward displacement of the joint recurred some time later. The case being described was, therefore, kept in plaster for nearly six months. It was many months before full



A B

FIG. 1.

A—shows the backward displacement of the head of the ulna. B—demonstrates the wide gap in the distal radio-ulnar joint.

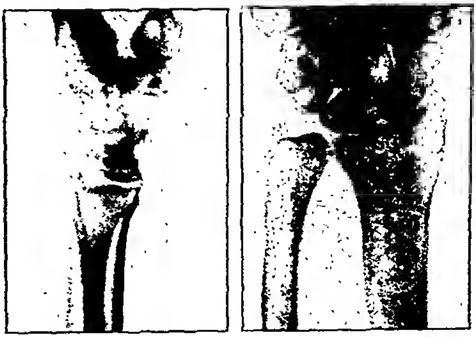


FIG. 2.

Both views show that the dislocation has been reduced.

pronation was recovered. Now the patient has a full range of movement, and the function is normal.

Upward displacement.—CASE II.—A female, aged 18, sustained in 1943 a compound fracture of the radius as the result of enemy action. There was extensive laceration of the soft tissues. The wound became infected and a large fragment of the radius sequestrated. When seen one year later there was a large gap between the fragments of the radius, and the distal radio-ulnar joint was dislocated upwards (fig. 3). Instead of excising the lower end of the ulna it was decided to attempt a closed reduction. Consequently, Kirschner wires were passed through the metacarpals and olecranon, and Cuendet's distraction apparatus fixed to the Kirschner wires. The distraction on the radial side was then increased by means of the

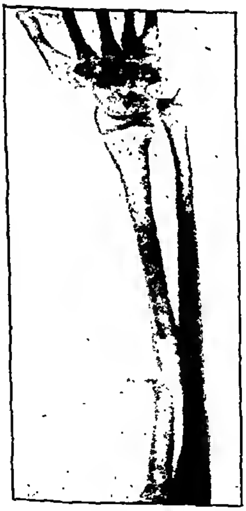

FIG. 3.

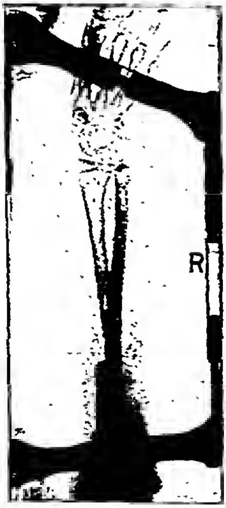

FIG. 4.

FIG. 5.

FIG. 3.—Ununited fracture of radius with upward displacement at the radio-ulnar joint.

FIG. 4.—Cuendet's apparatus fixed to Kirschner wires in olecranon and metacarpals. The dislocation has been corrected.

FIG. 5.—The grafts are firm. The length has been maintained.

turnbuckle and the dislocation thus reduced (fig. 4). The distraction apparatus was left in place and the radius grafted by means of onlay and chip grafts through a posterior approach. When the plaster was removed the grafts were found to be firmly united (fig. 5).

Present condition.—The patient is doing full work as a clothes presser and her forearm and wrist are normal in every way.

CASE III.—A bricklayer, aged 36, sustained in 1945 a compound fracture of the radius and ulna. The wound became infected, and, as in the previous case, a large sequestrum was extruded. When seen one year after the injury, there was non-union of the radius and a distal radio-ulnar dislocation (fig. 6). Cuendet's apparatus was again applied and the dislocation gradually reduced (fig. 7). As before the radius was exposed through a posterior approach and it was fixed by chip and onlay grafts (fig. 8). The ulna was found to have united. Now three months after removal of the plaster he has 15 degrees limitation of pronation and 15 degrees limitation of extension of the elbow-joint. Flexion is full. The grip is not yet quite normal. He is back at light work and he says that the function of the limb is gradually improving. The bones have united and the dislocation has been reduced (fig. 9).

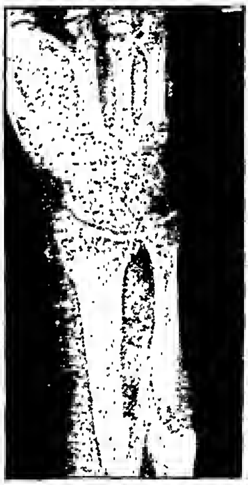

FIG. 6.

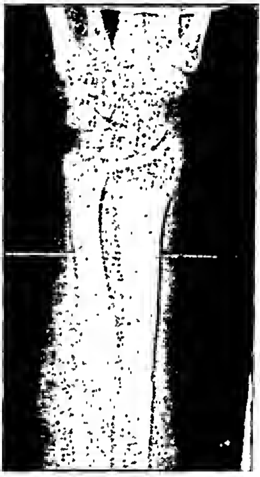

FIG. 7.

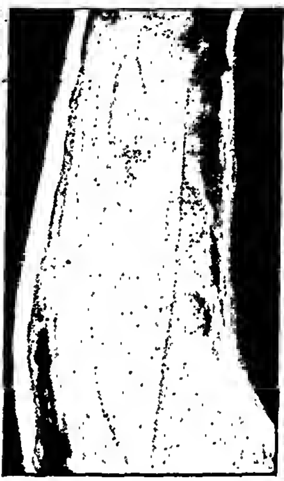

FIG. 8.

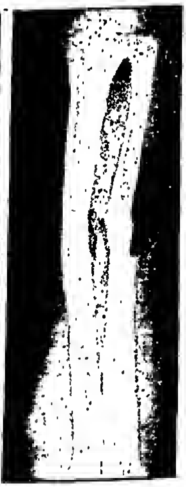

FIG. 9.

FIG. 6.—The radius is displaced upwards at the distal radio-ulnar joint.

FIG. 7.—The dislocation is being gradually corrected by the distraction apparatus.

FIG. 8.—The dislocation has been corrected. The radius has been grafted. The limb is still in plaster.

FIG. 9.—Three months after operation. The graft is firm; the length has been maintained.

CASE IV.—A schoolgirl, aged 14, sustained in 1942 a fracture of the lower end of the radius. When seen a few months ago there was marked radial deviation of the hand (fig. 10), and the head of the ulna was very prominent. She complained of marked weakness of the hand. In this case an osteotomy was performed on the lateral side of the radius, and the lower end of the ulna was excised. The line of the osteotomy was then "opened out" (fig. 11), and the excised piece of the ulna was used as a buttress graft (fig. 12).

POSTSCRIPT.—Function is now normal, seven months after operation.

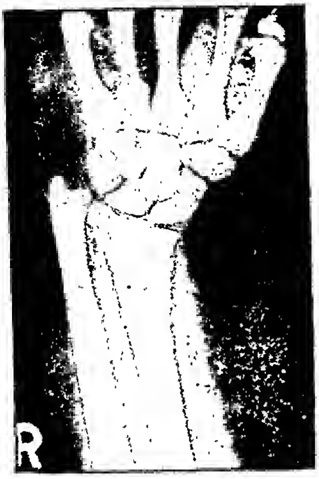

FIG. 10.

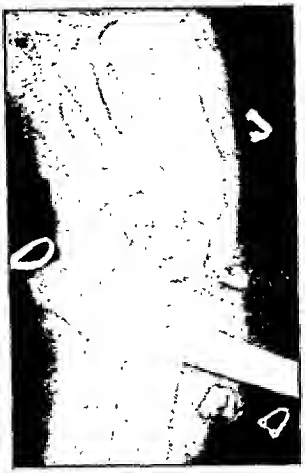

FIG. 11.

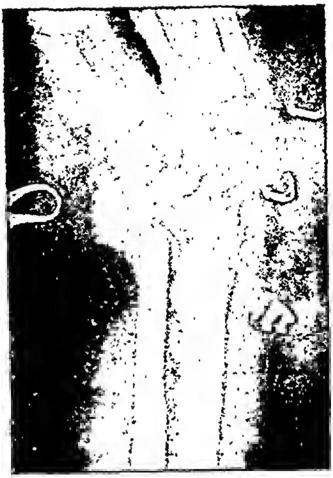

FIG. 12.

FIG. 10.—Displaced joint; deformed radius; no manipulative correction possible.

FIG. 11.—The lower end of the ulna has been divided. An osteotomy has been performed on the radius and "opened out" by the width of the osteotome.

FIG. 12.—The lower end of the ulna has been shaped to fit the osteotomy gap. The alignment of the joint has been restored.

Chondro-osteodystrophy. ? Morquio.—J. A. CHOLMELEY, F.R.C.S.

J. B., born 17.10.44.

10.11.44: Noticed to have mild talipes equinovarus; treated by manipulation and application of Denis Browne splints. Good correction obtained.

10.9.45: Noticed to have lumbar kyphos.

1.10.45: Admitted to Royal National Orthopædic Hospital, Stanmore.

On admission.—Head: Anterior fontanelle widely open. Face: Suggests gargoyle type. Spine: Dorsolumbar kyphos. Feet: Satisfactory correction of equinovarus.

Treatment.—Spinal frame, followed by spinal support.

Investigations.—Mantoux: 1/10,000 and 1/1,000 negative. B.S.R.: 2 mm. in first hour. W.R. negative. Blood cholesterol: 130 mg. per 100 c.c. W.B.C.: 6,100 per c.mm., polys. 59%, lymphos. 40%, monos. 1%.

X-rays.—Spine: Anterior "dislocation" of D.12 on L.1 with "bite" out of antero-superior surface of body of L.1. Several of the dorsal vertebral bodies are pear shaped but show none of the anterior tongue typical of Morquio's chondro-osteodystrophy. Intervertebral spaces normal. Hips: Acetabular roofs very sloping; femoral necks broad and almost vertical. Slight upward displacement both femoral heads. Forearms: Radii thick and "shapeless". Humeri: Broad and straight.

Epiphyses.—Dates of appearance: Lower end humerus, capitellum usually appears at 2 years, in this case present at 1 year. Lower end radius normally appears at 2 years, in this case present at 1 year. Carpal ossification normal in this case at 1 year. Tibia and fibula lower ends usually appear at 2 years, in this case present at 1 year. Tarsal ossification, normally four centres at 1 year, in this case five centres present.

Osteo-arthritis of the Trapezio-metacarpal Joint treated by Excision of the Trapezium.—W. H. GERVIS, F.R.C.S.

Osteo-arthritis of the trapezio-metacarpal joint is fairly common, and when at all severe is a painful and crippling condition. I have been treating this condition by excision of the trapezium for a number of years.

CASE I.—Female, aged 53. Complained of pain in the base of both thumbs on use. X-ray showed osteo-arthritis of trapezio-metacarpal joints, right and left.

Operation November 1945, excision of right and left trapezium.

She is very satisfied with the result. There is no apparent deformity and she can use her hands normally, but with a very slight loss of power in the thumbs.

CASE II.—Cowman, aged 48. Complained of pain in base of right thumb and was unable to work. X-ray showed osteo-arthritis of trapezio-metacarpal joint.

Operation September 1946, excision of right trapezium.

Was able to start milking within a month of operation and is now milking 20 cows a day.

The following cases were also shown:

(1) **Multiple Disseminated Calcinosis.** (2) **Congenital Deformity of Lumbar Vertebræ with Sciatic Nerve Lesion.**—W. D. COLTART, F.R.C.S.

(1) **Degloving Accident to Right Fore-arm, Followed By Necrosis of Skin Flaps, &c.** (2) **Degloving Accident to Left Lower Leg, Treated By Immediate Full-Thickness Grafts Obtained from the Skin Flaps.**—K. I. NISSEN, F.R.C.S.

DISCUSSION ON PAIN IN THE UPPER LIMB, EXCLUDING SHOULDER LESIONS

Dr. Wilfred Harris: I propose to limit my remarks to lesions of various kinds affecting the nerves and nerve roots supplying the hand, arm, and shoulder girdle.

Median nerve.—Atrophy of the thenar eminence, abductor and opponens pollicis, without interosseal atrophy, may occur in rheumatoid arthritis of the trapezio-metacarpal joint. This may be a source of considerable pain on the outer side of the wrist, with obvious swelling of the joint, and weakness and pain on movement of the thumb. R.D. on electrical tests may then be found in these muscles. When the interossei, especially the first dorsal interosseous, show wasting in addition, the lesion may be rib pressure on the first dorsal nerve, or it may indicate an acute or chronic anterior poliomyelitis, or syringomyelia, or an intramedullary tumour at the first dorsal level. Pain is sometimes a feature in acute poliomyelitis, especially in older subjects. In syringomyelia and intramedullary tumours pain may be a marked feature, while sensory changes will be distinctive, especially loss to pain and temperature.

Even without noticeable heavy use of the hand the lower portion of the median nerve may suffer severely from a pressure neuritis in the carpal tunnel, where it lies between the palmaris longus and the flexor carpi radialis. Russell Brain (*Proc. R. Soc. Med.*, 1946, **40**, 83) described this syndrome fully and its treatment. Pain like "electricity" in front of the wrist and outer half of the hand is complained of, and wasting of the thenar eminence and median nerve anæsthesia are found.

Injuries of the median nerve in the region of the elbow are becoming increasingly common with the more frequent use of parenteral injections, and especially in intravenous injections. Using the median basilic vein the needle may pierce the median nerve beneath the vein, and injections of drugs and of dyes used in renal and gall-bladder investigations have caused irreparable damage from severe median neuritis. Even worse is the result of injecting the brachial artery instead of the vein, when injecting a dye, as gangrene of the hand has been caused in this way. These dangers can be almost wholly avoided by choosing the median cephalic or the cephalic vein for intravenous medication.

Gunshot and stab wounds involving the median nerve, if clean, may give rise to no pain, but septic wounds involving the nerve cause prolonged pain in the hand, with median type of wasting and anæsthesia and glossy skin. Median *causalgia,* very common in the first World War, usually resulted from slight wounds of the median above the elbow. Mostly the muscular wasting and anæsthesia were slight, though the subjective burning pain and hyperæsthesia which might be started by the slightest stimuli, such as vibration of the floor, were often intense.

A not uncommon form of chronic *ulnar neuritis* is associated with frequent subluxation of the ulnar nerve from the groove at the back of the inner condyle, or from progressive filling up of this groove, causing pressure on the nerve, so that flexion of the elbow becomes increasingly uncomfortable and painful as the years go by. This may ultimately become so troublesome that surgical intervention may be necessary to bring the nerve forward to the front of the elbow by dividing the inner head of the flexor carpi ulnaris. Perineuritis of the *radial nerve* may result from a heavy muscular strain, as from lifting a patient from a trolley on to an operating table. Aching pain in the arm and back of forearm results, which is aggravated by such movements as stooping with arms extended, as in lacing the shoes. Massage should be avoided in these cases, and usually there is no detectable wasting or anæsthesia, though the triceps-jerk may be lost.

General *brachial neuritis* from chill, exposure to draught, rheumatism or influenza, may cause the most acute pain in the limb, with resulting sleeplessness, lasting for several weeks. There is considerable tenderness above the clavicle and over the nerve trunks in the arm, with hyperæsthesia, the slightest movement being extremely painful. Partial immobilization is essential, though patients cannot bear plaster splinting as in sciatica, and adhesions in the shoulder-joint are a frequent sequel, and may require wrenching afterwards under an anæsthetic. These are probably due partly to the lack of movement, and partly to the trophic effects of the neuritis. Usually complete recovery takes place, though management and nursing of the patient may be most difficult. Sometimes periarticular adhesions in the wrist and finger joints, and glossy skin may result. These complications are more likely to occur in extension of inflammation upwards from the apex of the lung and pleura in tuberculosis or from involvement of the cervical roots by growths in the neighbourhood of the spinal foramina.

Of recent years symptoms of brachial neuritis have been recognized as produced by rupture or dislocation of an intervertebral disc, usually the sixth or seventh cervical. The onset of the pain may be gradual or sudden, and may be so severe as to require continuous treatment with morphia for a few days. It may be mistaken for tennis elbow, and the condition may become more or less chronic, with varying symptoms for years, the pain being aggravated by use of the arm, or by lying on that side. Occasionally the slipped disc may press upon the spinal cord and cause paraplegia, temporary or permanent.

In spite of the enthusiasts for the newer teaching not all cases with brachial neuritis are due to disc lesions.

Posterior or long thoracic neuritis may result from direct chill, as from a down draught from a window close to the bed, causing typical winged scapula, with aching pain in side of neck and over scapula, and down outer upper arm. Similar results may follow toxic neuritis after influenza or paratyphoid. Excessive muscular action of the scalenus medius may damage the nerve as it passes through the muscle on its way to the serratus, as I have seen in a man who developed serratus palsy immediately after a swimming race, in which he used the side stroke. The winging of the scapula is characteristic, with inability to raise the arm beyond the horizontal.

Trapezius palsy may be easily mistaken for serratus palsy, owing to the partial winging of the scapula. This is seen best with the arm at rest and the hand resting on the hip. The winged appearance disappears at once on holding up the arm by the undamaged serratus (*see* figs. 4 and 5). In trapezius palsy the vertebral border of the scapula lies further from the mid-line than its fellow, and the action of the serratus is normal.

Posterior scapular neuritis (the nerve to the rhomboids) may result from direct wounding, or from excessive muscular action of the scalenus medius and levator anguli scapulæ. I have seen it produced by heavy heaving efforts in digging a deep grave. Sudden pain at the back of the neck and shoulder, with weakness of the arm, produced typical palsy of the rhomboids and levator anguli scapulæ. As a result the scapula hangs lower than its fellow, with the inferior angle everted (*see* fig. 7). [The figures referred to may be seen on pp. 69 and 71 of Dr. Harris's book "Neuritis and Neuralgia," London, 1926.]

Mr. David Le Vay: When pain is referred from a lesion in the posterior triangle or cervical spine there is an obvious analogy with low back pain and sciatica. In both regions we have to consider congenital bony anomalies; intrinsic neuritis; spastic muscles (piriformis or scaleni); and prolapsed intervertebral discs. The sciatica problem has been solved almost exclusively in terms of the prolapsed disc. But a simple solution is impossible in the upper limb because of the several factors involved—the mobile shoulder girdle, the dependent arm, and the overriding clavicle. The diagnosis of brachial neuritis, however, appears increasingly ill-founded as the importance of mechanical factors emerges.

(1) POSTERIOR TRIANGLE SYNDROMES

These are essentially postural in origin, and in nearly every case there is more than one postural mechanism at work. As Professor H. A. Harris says of the ulnar nerve, the neurovascular bundle of the arm "lives dangerously" in its passage from thoracic outlet to axilla, and this is due to imperfect adaptation to the erect position. It is subject to a normal variation in anatomical relationships which easily verges on the pathological. Thus, Falconer and Weddell (1943) have shown in connexion with costoclavicular compression that many normal individuals can obliterate their radial pulse by backward bracing of the shoulders.

(*i*) *Syndrome of the "normal" first rib.*—"Normal" is often a misnomer as developmental asymmetry is common. As gravity drags on the dependent arm the bundle is stretched over the outer border of the bone, a movement which can be visibly reproduced at operation. The tendency is increased by carrying heavy burdens, hence the preponderance of right-sided symptoms. Symptoms appear when the tone of shoulder-girdle musculature is reduced by fatigue, and the scapula gradually descends. This descent is the most important and constant of all mechanical factors at work, and also forms the background to the other, possibly more striking, posterior triangle syndromes, e.g. costoclavicular compression. Clinical features at their most severe are those classically ascribed to cervical rib; at their mildest they are those known as acroparæsthesiæ.

It must be recognized that *acute* descent of the shoulder girdle may be caused by trauma, with intense pain and swelling in the whole limb, and I have seen this in two patients whose right arms were trapped and forcibly depressed. Severe persistent pain and paresis followed, with gross œdema, and sagging of the right scapula. Both were completely relieved of pain and swelling by resection of the first rib, and in one an abundance of new venous channels in the posterior triangle made it clear that thrombosis of the subclavian vein had occurred. Such cases link up on the one hand with "strain thrombosis of the axillary vein", and on the other with traction injuries of the brachial plexus.

(*ii*) *Syndrome of costoclavicular compression.*—Though the clinical picture is often striking, there is usually some associated sagging of the shoulder girdle. The narrow costoclavicular gap is further closed in abduction and elevation of the arm. Pain is elicited by raising the arm, or bracing the shoulders in the attention position, or at night when the clavicles fall backward. The distinctive features are due to clavicular pressure on the *whole* plexus, with possible sensory disturbance over the entire limb surface, and on the subclavian vein. The position of exacerbation may produce venous stasis, œdema, distension of pectoral collaterals, and widening of the axillary venous trunk which may be visualized by contrast media.

Walshe, Harvey Jackson and Wyburn-Mason discuss the constant movement of the costoclavicular vice with every respiration and change of position, and the diffuse fibrosis of intervening connective tissue which may result. This mass of scar tissue may be seen at operation and is capable in itself of maintaining symptoms by its constricting action.

(*iii*) *Scalene syndrome.*—Leriche (1946) believes that the artery and plexus may be compressed in the gap between scalenus medius and anterior. It is certainly better to think in terms of this gap than of a probably hypothetical scalenus anterior syndrome. Walshe and his colleagues (1944) pointed out that isolated spasm of this latter muscle is not only improbable, but would not compress the bundle against the first rib even if it did occur. Clinical tests designed to elicit and isolate this muscle's action are unsatisfactory since they also alter the relationships of clavicle, bundle and first rib. Though benefit often follows anterior scalenotomy, this is because of relaxation of one limb of the scalene gap and possibly because of some change in costoclavicular apposition; in some cases the operation causes severe exacerbation. There is much more evidence compromising the scalenus *medius*, against the knifelike anterior edge of which the clavicle can certainly squeeze the neurovascular bundle. Therefore it seems advisable to discard the term "scalenus anterior syndrome", and to refrain from dividing this muscle without clear indication just because the operative procedure is simple.

Cervical rib.—The problem of cervical rib is largely solved in terms of the three syndromes already discussed. Though one agrees with Eden (1939) that a large rib thrusting itself into the scalene gap must be removed, these cases are rare. The often severe clinical disturbance associated with the usual rudimentary ossicles can hardly be due to the ribs themselves or to any fibrous band. X-ray usually reveals a general asymmetry in which the cervical rib is important only as an index that the first thoracic rib is abnormal in position and in its relation to the clavicle. Symptoms are still due to drag over the first rib, or compression between first rib and clavicle or in the scalene gap. Leriche points out that cervical rib affords an additional origin to the scalenus medius which enables that muscle to encroach still further on the scalene interval.

Treatment.—Conservative measures are adequate for most cases; but, if operation has been performed, physiotherapy and muscular re-education must be continued as the bundle is liable to drag even when the first rib fulcrum has been removed. Operation should not be delayed too long in presence of severe pain. Not only do neurotic complications appear, but, once established, well-marked wasting and hypoæsthesia are only slowly reversible. Partial resection of the first rib is advocated as a routine for severe cases. Since this procedure necessarily entails division of the scalenus anterior, erasion of the insertion of scalenus medius backwards, and removal of the bony ledge of rib behind the neurovascular bundle, it deals with all the factors in the complex pathology. General anæsthesia is desirable, and most of the bone can be removed through a straight incision paralleling the clavicle. The operation is tedious and may be difficult, and it is fortunate that the thoracic duct is a left-sided structure.

(2) Prolapse of Cervical Intervertebral Discs

Once the clinical picture becomes familiar this condition is found to be not much less common than the posterior triangle syndromes as a cause of pain in the arm. There is a combination of orthopædic signs in the neck—pain and restriction of extremes of motion—with radicular neurological features in the arm, in which pain is often more of the nature of unpleasant paræsthesiæ.

The disc at C.5-6 irritates the sixth cervical root, causing wasting of the biceps and pain over the dorsum of thumb and index. The disc at C. 6-7 compresses the seventh root with triceps wasting and more extensive sensory disturbance spreading to the back of the middle finger. The picture is not always so clear-cut; severe wasting of the deltoid is sometimes seen. Patients are often most unhappy at night, for the pillow presses on the back of the head, which they prefer to allow to hang backwards. Unlike the situation with lumbar prolapses, the X-ray here is of constant value. One expects to see the narrowed intervertebral space, with bony proliferation at the anterior margins of the bodies and in the region of the foramen.

Conservative treatment deals with most cases, and operation is usually left to the neurosurgeon, but I should like to stress the value of manipulation. The long-term results of manipulation of the spine for sciatica are disappointing because of the continued action of body-weight. This is much less important here, and manipulation of the neck under anæsthesia often gives gratifyingly persistent improvement. As with lumbar manipulation, there is little risk of exacerbation if the spine is not flexed but subjected only to rotation and hyperextension.

Dr. Frank A. Elliott: I shall say nothing about the better-known inflammatory, neoplastic, and traumatic causes of pain in the arm, but will deal briefly with the more controversial aspects of the subject.

Herniation of the fifth and sixth cervical discs is a common cause of pain in the arm and upper chest. It radiates from the back of the shoulder girdle, down the back of the arm, and along the radial border of the forearm to the wrist, and is often felt in the upper part of the pectoralis major and over the scapula. It is aggravated by movements of the head, by pressure on the head, and sometimes by certain movements of the arms. Tingling is felt in the thumb (sixth root) or index and middle finger (seventh root), and slight sensory loss may be present in these situations. Weakness and slight wasting may occur in triceps and the extensors of wrist and fingers. "Trigger" points are often present in the shoulder girdle and pectoralis major; when pressed upon, pain and tingling shoot down the arm, and if these points are infiltrated with novocain, relief from pain is obtained. Depression of biceps and triceps reflexes occurs in lesions affecting the sixth and seventh roots respectively. In doubtful cases, contrast myelography will demonstrate the level of the lesion.

The costoclavicular syndrome is also common. Drooping of the shoulder, or elevation of the uppermost rib (as in scoliosis), causes pressure on the lower cord of the plexus as it passes over the rib into the axilla, and exposes the subclavian artery to nipping between the clavicle and the first rib in certain positions of the shoulder.

Attrition at this site may lead to a reactive fibrosis around the plexus and aneurysmal dilatation of the artery, with or without thrombosis. Six types of sensory symptoms are encountered, in varying combinations: "Pins-and-needles" of ulnar distribution, due to irritation of the lower cord of the plexus; "pins-and-needles" in the entire hand, due to compression of the plexus as a whole; an unpleasant sense of numbness in the limb, due to compression of the subclavian artery, when the arm is maintained in positions which cause compression of the artery; ischæmic muscle pain, sometimes severe, from subclavian thrombosis; pain in the trapezius associated with the postural strain of a drooping shoulder; and finally, pain behind the clavicle and down the inner aspect of the arm and forearm from pressure on the plexus. Objective neurological and vascular signs are too well known to require recapitulation here.

Extramedullary spinal tumours can give rise to root pain in the arm for months before sensory, motor, or reflex abnormalities appear. The pain is sometimes abrupt in onset, remittent in course, and apparently relieved by manipulation, physiotherapy, and peripheral injections of novocain—misleading features which may suggest other diagnoses. Paræsthesiæ in the hand indicate that the lesion is somewhere along the afferent pathways, and the simultaneous presence of tingling, coldness, and "heaviness" of the legs suggests that the lesion is intraspinal. Neurological examination and lumbar puncture should be repeated from time to time, and contrast myelography is needed for suspicious cases.

Syringomyelia, infective radiculitis, and post-herpetic neuralgia are not uncommon sources of pain in the arm, but to remember them is to recognize them.

Cervical osteo-arthritis sometimes gives rise to root pains in the limbs. In some, an osteophyte is radiologically demonstrable in the intervertebral foramen corresponding to the affected root. In others, there is no such evidence, but there is reason to suppose that the root sheath is involved by inflammation from the adjacent intervertebral joint. Symptoms differ from those of a prolapsed disc in four respects. Pain has often a burning quality. Pain and paræsthesiæ are often more widespread, indicating simultaneous affection of more than one root. Objective neurological signs of root compression are seldom present. Finally, there are, or have been, symptoms elsewhere from osteo-arthritis at other levels of the spine and in the proximal joints of the limbs.

Subacute muscular rheumatism following rheumatic fever or its equivalents can give rise to transient pain in the arm. There is always a history of similar pain having occurred in other parts of the body in previous attacks, and objective neurological signs do not occur. Pain limited to one part of the body in successive attacks should not lightly be attributed to this condition. Spondylitis ankylopoietica is a rare cause of pain in the neck and arm; in the course of time, rigidity of the spine, a raised sedimentation rate, and the characteristic radiological changes in the spine and sacro-iliac joint will disclose the nature of the disease.

Fibrositis and brachial neuritis are often diagnosed, but there is as yet no pathological proof of their existence, and it has been my experience that cases so labelled usually turn out to be something else if they are followed up long enough. Moreover, so many cases of prolapsed discs, spinal tumours and spinal osteo-arthritis give a history of having been treated for fibrositis in the early stages of the disease, that it may be inferred that the clinical features of fibrositis and neuritis are not free from ambiguity.

Dr. J. W. Aldren Turner: The name "thoracic inlet syndrome" is a poor one to comprise the various conditions which cause compression of the brachial plexus and great vessels as they pass out from the neck into the axilla; a more correct name anatomically would be "cervical outlet syndrome", or better "axillary inlet syndrome", as the compression is not directly related to the thoracic inlet.

Surgical treatment is very rarely necessary for lateral prolapse of the C.6-7 intervertebral disc, the great majority of patients become free of symptoms with rest in bed, with three or four pillows to keep the neck flexed and a sling on the affected arm and analgesics in the early stages. The usual course is for the pain to be completely relieved in three to four weeks, though paræsthesia in the index finger may persist for several months and the triceps-jerk remain absent. This prognosis is based on 35 cases with the typical clinical picture, though the diagnosis was not proved by myelography in any of the cases.

The condition variously described as "infective neuritis of the shoulder girdle" (Spillane, 1943) and "acute brachial radiculitis" (Aldren Turner, 1944) may cause severe pain in the shoulder and upper arm before a flaccid palsy suddenly appears. The palsy usually comes on three to four days after the pain subsides, but in a few cases pain has persisted for several weeks before the onset of paralysis. The paralysis is a lower motor neurone one and at times sensory impairment is present in addition. There is no constitutional disturbance and the C.S.F. was normal in the cases where it has been examined.

TURNER, J. W. ALDREN (1944) *Brit. med. J.* (ii), 592.

Mr. W. E. Tucker: It is difficult in some cases of acroparæsthesia to be certain whether the symptoms start in the shoulder and move down the arm, or in the hand and work up the arm to the shoulder and neck muscles. Often two main groups are seen, one in younger patients with drooping shoulders, the other type in older patients with a raised shoulder and contracted cervical muscles, especially the trapezii. Often this latter type are found to have osteo-arthritis of the cervical spine, and owing to a jarring injury such as may occur in taking a divot on hard ground while playing golf, the lower cervical joints are traumatized and symptoms start. If the symptoms start in the hand, the forearm flexors are found contracted, there is pain referred to the intrinsic muscles of the hand and a tender point appears in the extensor origin of the wrist from the external humeral epicondyle and radio-humeral collateral ligament. Often this type shows itself in young girls starting employment such as nursing, or housewives, who are continually lifting or carrying articles. As one writer has said: "Life is now one continual grip for the housewife." Most cases improve with rest from strain, remedial exercises, combined with gentle manipulation of the neck and faradic contractions of the muscles of the arm, shoulder and neck. The patient should be given advice with regard to carrying parcels and shopping bags, relaxing the hands while sleeping and arrangement of four pillows at night, so as to support the head and neck.

Section of Dermatology

President—SYDNEY THOMSON, M.D.

[*February* 20, 1947]

Granulosis Rubra Nasi.—D. I. WILLIAMS, M.B. (for SYDNEY THOMSON, M.D.).

J. P., aged 9 years 11 months.

His mother complains of his red, sweating nose. He himself is little concerned about it or inconvenienced by it. The red area on the nose is said to have been present since birth. The sweating is more marked in hot weather. The peripheral circulation elsewhere seems to be normal. There is no excess sweating elsewhere on the face or body. He has one sister, aged 3, with a normal nose. There is no family history of any similar condition.

The tip of the nose, the alæ nasi and a projection in the mid-line up to the bridge of the nose are symmetrically red; the edge of the lesion fades off into normal skin. On diascopy a brownish-yellow colour is seen diffusely throughout the affected area. There is a certain amount of telangiectasia and a few pinhead brownish macules.

Prominent over the tip of the nose are small, tense, round vesicular lesions of a bluish tint with central dark areas; these hidrocystomata are about half a dozen in number and were far more numerous when he was first seen in the Out-patient Department of King's College Hospital in the autumn of 1946. Small beads of sweat can be seen collecting in the affected areas. These turn red litmus paper blue.

X-ray of chest and antra: No abnormality.. E.N.T. report: Normal, no signs of infection in ear, nose or throat. Mantoux reaction: 1/10,000 negative. Gastric residuum: *Before histamine.*—Reaction acid; free HCl 31 c.c. N/10; total acid 42 c.c. N/10. *After histamine.*—Reaction acid; free HCl 67 c.c. N/10; total acid 77 c.c. N/10.

Dr. F. Parkes Weber: If this is really a specimen of what is usually termed granulosis rubra nasi, is it right to call it a granulosis? It makes me think of a nævoid condition. This is suggested by the position and by the fact that it has remained since birth always the same. "Granulosis" would seem to imply some granulomatous condition or some growth of granular tissue. The history and the position in the middle line make one think of some form of nævoid (chiefly vascular) developmental abnormality.

The President: The name, of course, was given to the condition by Jadassohn in 1901 when he wrote his monograph. Granulomatous lesions have not been found histologically except in one case where a certain number of giant cells were found.

Poikiloderma Congenitale (Thomson). Two Cases.—C. H. WHITTLE, M.D.

CASE I.—N. S., a boy, aged 12 years.

History of discoloration since birth of the skin of face, forearms, hands, legs and feet. The face shows a telangiectatic reticular vermilion pattern, with pale skin between the meshwork. Both cheeks and ears are involved. The condition is similar though less marked on the forearms and lower legs. There is scattered brown pigmentation also. Scars present are the result of numerous boils. In addition there is a marked tendency to warty hyperkeratoses on the knuckles and on prominences such as the elbows, knees, malleoli and heels. He has sandy hair, brown eyes and a triangular-shaped head with the apex corresponding to the chin. He is thin and rather small for his age but intelligence appears normal. *Family history* shows no others affected, but the mother's father had eczema. Two siblings (girls) aged 7 and 9 are unaffected.

Remarks.—The condition corresponds in many respects to Thomson's description of 3 cases all in girls (Thomson, S., 1935, *Brit. J. Derm. and Syph.*, **48**, 222), notably in appearance, shape of head and history of early onset, but differs in the tendency to hyperkeratosis on prominences. The buttocks are not affected.

Vitamin-A content of plasma (by courtesy of Dr. T. Moore).—45 I.U. per 100 c.c. (25.11.46); 65 I.U. per 100 c.c. (14.1.47). Carotene 76 I.U. per 100 c.c. (25.11.46); 47 I.U. per 100 c.c. (14.1.47). (Normal vitamin A 70—120 I.U.) This low vitamin-A level may be significant.

CASE II.—G. S., a girl, aged 4 years.

The child was brought to the clinic because of the discoloration of the cheeks noticed soon after birth. There had been no previous swelling. The cheeks are the only parts which show the bright red (bluish-red in cold weather) reticular pattern, with circular islands between of normal pale skin. There is a tendency to scale and possibly slight superficial atrophy, like a glaze. There is a hint of similar discoloration of the skin of the upper lip. The buttocks are not affected.

The only noticeable abnormality elsewhere is a fairly general dryness of the skin amounting to mild xerodermia, affecting chiefly the outer aspects of the upper arms and of the thighs, with some follicular hyperkeratosis. She is chubby, and inclined to a bluish complexion when cold. Hair dark.

When first seen at the age of 1 year she showed well-marked koilonychia, an unusual feature in an infant. The nails are now normal.

The family history shows no hereditary features. Two siblings, a brother aged 6 months and a sister aged 13, are unaffected; nor is there any consanguinity.

Vitamin-A content of plasma (by courtesy of Dr. T. Moore).—Vitamin A 85 I.U. per 100 c.c. Carotene 131 I.U. per 100 c.c. (12.2.47).

Dr. F. Parkes Weber: I should like to know whether Dr. Whittle regards these cases of poikiloderma congenitale of Dr. Thomson as a kind of congenital or developmental dysplasia chiefly affecting the superficial blood-vessels. It seems to me that cases of this kind are in fact what I have suggested in regard to the previous case (granulosis rubra nasi), examples of congenital or developmental dysplasia mainly affecting the blood-vessels. This idea would, of course, fit in with occasional association of other developmental abnormalities.

The President: With regard to Dr. Whittle's first case (the boy aged 12), I was, of course, very delighted to see him as it is a classical picture, with a history since birth, or very soon after birth, of the development of a network of vessels and the atrophy over the vessels. As the child grows older the changes become more marked, and warty lesions develop later. One of my cases started to show that only at the age of 12. Dr. Dowling has shown one or two older cases, with the warty change very marked. I think that in the cases I have seen bone changes have always been present; the striking thing is the shape of the head; in one case there was maldevelopment of radius and ulna.

On the question of vitamin-A estimations: we were, of course, not doing these twelve or fifteen years ago when I first saw the cases. There seems to be no doubt it is a developmental defect; but it has certain peculiar features of its own. There are numerous instances in the literature of gross endocrine disturbances of varying types accompanying poikiloderma. I have not seen any obvious endocrine disturbances in these children; the only other abnormalities have been in the bones. I would like to have an opportunity of examining Dr. Whittle's second case (the girl aged 4) much more thoroughly and over a much longer period than the few minutes available at this meeting, but certainly the pattern, &c , of the cheek lesions strongly supports his diagnosis.

Dr. A. C. Roxburgh: I saw a case of Dr. Dowling's two years ago. The patient, an adult, was covered with warty growths and atrophic patches and was altogether in a most miserable state.

The President: Dr. Whittle has asked for suggestions as to treatment but I do not know of anything very satisfactory. We tried many treatments, and ended up with local electrolysis of the more obvious vessels on the face, but it was a very tedious business and obliterated only small areas.

Raynaud's Phenomenon, with Paroxysmal Hæmoglobinuria, Caused By Cold Hæmagglutination.—C. H. WHITTLE, M.D., A. LYELL, M.B., and M. GATMAN, M.B.

C. M., a married woman aged 56. History of attacks of blueness, tingling and numbness of the hands in cold weather for two years with occasional blood-stained urine. Anæmia present for five years.

The patient is a well-covered, pale, anæmic, slightly icteric, nervous woman. She has two children alive and well. Family history shows nothing of note. She does not smoke. Central nervous system normal. Heart slightly enlarged with apical presystolic and systolic murmurs. Arteries good. B.P. 150/90. No splenic or hepatic enlargement detected.

The lesions which appear only when extremities are chilled consist of bluish-red macules and blotches chiefly on the tips of thumbs, backs of fingers, and dorsa of hands, varying in diameter from 1 cm. to 2 or 3 cm. Tips of ears and nose are also slightly affected.

Diascopy suggests extravasation of blood, as colour does not disappear on pressure.

Laboratory findings.—Macrocytic anæmia of moderate degree which has not responded to iron or liver therapy. Platelets were increased and reticulocytes have averaged 5%. Sternal bone marrow shows a hyperplastic marrow essentially of the normoblastic type though nests of megaloblastic activity are present. Lymphocytes are definitely increased. Plasma bilirubin averages 1·8 mg. per 100 ml. and is of the indirect type. Cold hæmagglutinin titre 1 : 2,000,000. Erythrocyte fragility: (*a*) *saline*—normal at 39° C. and 23° C.; (*b*) *traumatic*—normal at 39° C.; increases in intensity at temperatures below 26° C.; very marked at 4° C. Sedimentation rate —6 mm. per hour at 39° C.; 44 mm. per hour at 23° C. Urine contained red cell ghosts and methæmoglobin after exposure of patient to cold. Urobilin increased: bile pigment negative: Bence-Jones protein negative. Histamine-test meal showed active hydrochloric acid production. Wassermann and Kahn (repeated) negative. Donath-Landsteiner reaction negative.

Dr. A. Lyell: The explanation of the colour changes in the extremities seems to be that the cooling gives rise to intravascular hæmagglutination, the blood flow in the capillaries ceases, the hæmoglobin becomes reduced: the colour remains on diascopy not because the corpuscles are extravasated but because they cannot be shifted in their clumped state within the capillaries.

Since, however, the hæmagglutination is reversible the flow starts again when the part is warmed: but at low temperatures owing to the increased mechanical fragility of the corpuscles some are hæmolysed, and this explains the slight icterus with raised serum bilirubin. It also explains the occasional attacks of hæmoglobinuria.

Treatment with liver injections has been followed by great improvement in symptoms, and she can withstand longer exposure and lower temperature without ill-effect. Though immersion of her hands in ice-cold water for half an hour will provoke an attack, recovery takes place now in twenty minutes. But a severe attack of hæmoglobinuria has been brought on to-day by the cold train journey to London.

Dr. M. Gatman showed on the micro-projector the clumping of the red corpuscles, and the ease with which they are broken up by slight injury such as tapping the microscope slide. The red cells embedded in the adsorbed protein complex are readily ruptured, and their rupture can be observed within the skin capillaries of the patient under the capillary microscope.

Dr. C. H. Whittle: Cases like this may be seen by dermatologists because of the purpura-like lesions. Though not very uncommon the diagnosis may be missed if a blood-count is not made, i.e. if they show no gross anæmia. The condition is to be distinguished from others with Raynaud's syndrome, e.g. acrosclerosis and sclerodactyly, arteriosclerosis, syphilitic arteritis, thrombo-angiitis obliterans and Raynaud's disease, in all of which permanent damage such as atrophy or gangrene is sooner or later found in the extremities (Hunt, 1936). No angiospasm, and no reaction to over-cooling, mark off the clinical condition from the rest of the group. If blood is taken for a count, the diagnosis will be made immediately after a glance at the corpuscles in the counting chamber at room temperature.

Dr. Parkes Weber: Is there any local pain associated with the attacks?

Dr. Whittle: Tingling and numbness, the usual symptoms associated with Raynaud's phenomenon.

Dr. F. Parkes Weber: I suppose that the degree of pain varies with the degree of the angiospastic part of this "syndrome"—for, of course, it is a syndrome. Extreme pain I have seen only once, and that was in the case of a girl 12 months old (F. Parkes Weber, *Brit. J. Child. Dis.*, 1923, 20, 25). I do not know which of the various types of Raynaud's syndrome has a special right to be termed Raynaud's disease. The Raynaud's syndrome often associated with sclerodactylia I regard as a most important constituent part of the sclerodactylia or acrosclerosis, whichever one likes to call it.

Dr. Whittle: I would refer Dr. Parkes Weber to John Hunt's paper. In his view the most important point about Raynaud's phenomenon is that it is not followed by permanent change in the part. It is a paroxysmal condition which is due to cold, and clears up as soon as the stimulus of cold is removed. On the question of angiospasm, there does not appear to be any here. As far as we know, the picture is made by the clumped red cells in the capillaries of the extremities where the blocking occurs.

Dr. Gatman: Work has been done on this type of Raynaud's syndrome by irrigating the conjunctival sac with ice-cold saline and only agglutinated red cells are to be seen in the small vessels. No angiospasm at all has been seen.

Tropical Lichenoid Dermatitis.—H. J. Wallace, M.D.

G. W., aged 37. This man's dermatitis began in September 1943 three months after his arrival in West Africa. He states that he had no trouble with his skin previously. The skin around the ankles was first affected by a prickly-heat type of eruption. This was followed after a few days by a widespread eruption all over the body, accompanied by marked œdema of the ankles and ulceration of the mouth. Except for a little oozing in the small patches, which became septic, the eruption was dry. The scalp was covered by a crust and shortly afterwards most of the hair fell out. Irritation was minimal but malaise, fever and mental depression marked. After three weeks desquamation began and persisted for months. This was accompanied by areas of pigmentation. Apart from taking mepacrine in suppressive dosage for three months previously, he gave no relevant past history including other drugs or malaria. His diet appears to have been adequate. He continued to take mepacrine for three months after the onset of the dermatitis until he went home.

Recovery to the present state took place slowly over the next few months whilst in England, leaving the sequels which he now shows. In particular, recurrent soreness of the tongue began and has persisted.

He has widespread atrophic areas in the scalp, indistinguishable from pseudopelade. There are gross lichenoid changes in the mouth and tongue and some of the changes are suggestive of early leukoplakia. He has the remains of warty growths on the forehead which have recurred after destruction with cautery. On the whole body there are scattered areas of atrophic lichenoid changes with some scaling.

Comment.—This condition has been widely studied and has been reported from many different parts of the world. There is little doubt that it bears a close, but not fully defined, relation to mepacrine. The clinical features of the patient conform to the normal description of the condition. In particular, however, the leukoplakic changes in the tongue and the widespread atrophy in the scalp are apparently unusual. The continued administration of the mepacrine for three months after the onset of the dermatitis is to be noted.

Dr. R. M. B. MacKenna: I have seen a certain number of these cases, and I consider that the case shown is a true example of the so-called tropical lichen planus. From the military point of view the case belongs to the older age-group of individuals at risk, and it seemed to me that there were mild atrophic changes in the skin of the lower legs; both of these points, which have not been made by previous speakers, are of minor importance but are consistent with the diagnosis.

Dr. Brian Russell: I saw a patient recently who, about nine months previously, had started taking mepacrine, 3·1 grammes in the first week and 0·7 g. in subsequent weeks, but with two periods of 1·7 g. a week interposed. About six months after starting to take the drug he developed lichenized patches, psoriasiform lesions, follicular hyperkeratoses, and a purulent condition of the scalp, with intense itching. The doses recommended for mepacrine are a maximum of 2·8 g. in the first week and

0·7 g. as a maintenance dose in subsequent weeks. This case supported the suggestion that mepacrine eruptions may be the result of high dosage and cumulative action, rather than of idiosyncrasy.

Mycosis Fungoides—Treated with Thorium X.—BERNARD GREEN, M.R.C.S., L.R.C.P.

E. S., male, aged 56. The case was shown at this Section by Dr. Corsi in March 1945 (*Proc. R. Soc. Med.*, **38**, 505).

Duration about thirty-five years. A scaly erythema first commenced on his legs and now is all over the body, including face and scalp. At first it was non-irritating, now it is extremely so. He has a generalized exfoliating erythrodermia with areas of tumefaction, lichenification and many channels of normal-looking skin fairly sharply demarcated. In addition there is loss of hair from the usual areas on the body, together with patches of alopecia on the scalp. There are enlarged lymphatic glands in the inguinal region. The intensity of the rash and the irritation varies, quiescent periods alternating with periods of exacerbation. X-ray treatment had little effect.

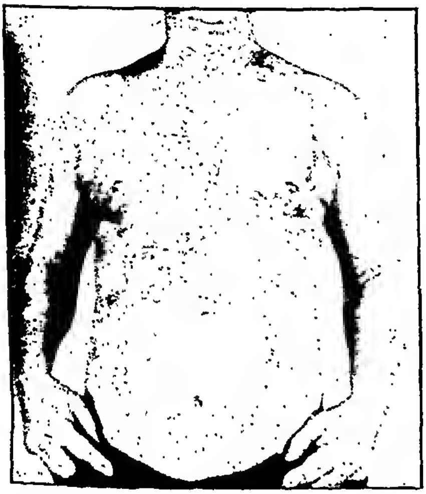

FIG. 1.

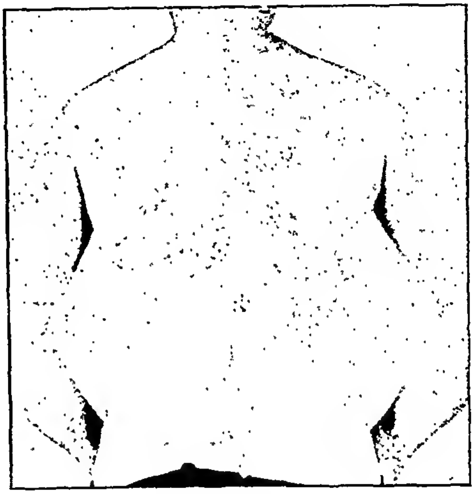

FIG. 2.

Thorium X 2,000 units in iso-propyl alcohol was painted on a small affected area of the skin. This was done once a week six times. This appears to clear the erythema for a time, the effect following the first application; the itching is completely relieved and continues in abeyance, even after some relapse of the erythema. After many weeks without treatment the scaly erythema and the itching return.

It was decided to try a course of intravenous injections of thorium X. 100 units in saline were given once a week twelve times. At first there was some relief of the irritation and some of the erythema diminished. However, I was reluctant to continue with this line of treatment although a differential blood-count taken before, during and after the treatment showed no abnormality.

It was then decided to treat him again with applications of thorium X 2,000 units in iso-propyl alcohol, and this was done once a week twelve times on the whole of the left half of his back and on two square patches on the front of the trunk. The result was again very satisfactory. The erythema and the irritation disappeared and the skin returned to a normal appearance. It is four weeks since the last application and the two squares on the front of the trunk show no return of the erythema (fig. 1) and the itching is completely relieved. On the half of the back painted there is a slight return of the erythema (fig. 2), but the irritation still remains in abeyance.

Mycosis Fungoides.—BERNARD GREEN, M.R.C.S., L.R.C.P.

A. B., female, aged 56. Duration of skin trouble four years. A premycotic eruption of scaly erythema for about one year. Now has in addition multiple tomato-like sessile, rounded, circumscribed tumours all over the trunk, limbs and face. Some of the tumours are ulcerating, causing irritation and discomfort. On the scalp there are areas of cicatricial alopecia with scaly erythema.

Biopsy showed a typical pleomorphic appearance of mycosis fungoides. She has had many X-ray treatments, together with penicillin, T.A.B., &c. X-ray therapy was successful in some degree, some of the tumours treated having disappeared. At other times no results were noted. A course of intravenous injections of thorium X was tried. 100 units in saline were given once a week twelve times. At first the patient reported there was much less irritation for the first few days following each injection, but the appearance of the rash and tumours remained more or less the same. A blood-count done before and after the course of injections showed no abnormality. Nevertheless I was reluctant to continue this form of treatment and thorium X 2,000 units in iso-propyl alcohol was painted on controlled areas of the body once a week twelve times. On the areas painted the exfoliation and the erythema is considerably diminished and the skin has regained a more normal appearance. The irritation remains in abeyance. Some of the tumours were also painted with thorium X in the same strength and these have considerably flattened and become less red. Those which were ulcerating and weeping have dried, become crusted over and diminished in size. On the chin and nasolabial fold, where there was some fissuring, erythema and some loss of the normal elasticity of the skin, considerable improvement has taken place, the fissures having healed and the erythema subsided.

Dr. P. J. Feeny: This is the first time that thorium X has been used parenterally in dermatology, although it has been available since 1912. In the 1920s radio-active thorium injections were used extensively abroad with poor results. In the years just before the late war a case of necrosis of bone after injection of thorium X [1], another case of late bone necrosis seven years after subcutaneous injection [2], a case of radiodermatitis [3], and a case of late radiodermatitis as well as other skin lesions were reported from parenteral use of thorium X [4]. Necrosis of bone both early and late, and radiodermatitis both early and late, have therefore been seen. About two years ago a case of cellular activation and autoradiography was published [5].

Almost all reports have been bad, save in one group, namely, rheumatic conditions [6]. In rheumatism, except gonorrhœal rheumatism [7, 8], the reports have been good. There have been several accidents, however, even with the treatment of rheumatism [9]. At the moment thorium X is being used at the Charterhouse Clinic. Hernaman-Johnson last year published a report on spondylitis favourably treated, and he cited a previous French report [10]. The dose given at the Charterhouse Clinic was 30–100 electrostatic units per c.c. subcutaneously.

We must make up our minds about using thorium X and other radio-active substances internally. I do not think that in dermatology we should start using 100 unit injections of thorium X—it may be found that we should not use it at all internally.

Dr. Green: I quite agree that thorium given intravenously might be dangerous, but in cases of this kind with a grim outlook I felt some justification in trying desperate measures.

Dr. F. F. Hellier: I would like to know if anyone has any experience with nitrogen mustard in mycosis fungoides. This is a new line of attack on certain types of malignant disease. It is a selective method like X-rays, and it affects some cells more than others. The results are only temporary, but it has been useful in certain conditions, and it may have some sort of future in those cases which are resistant to X-rays.

Dr. MacKenna: I have no experience of this particular treatment myself, but reports say that it does relieve the very severe generalized itching which may occur in Hodgkin's disease.

Mycosis Fungoides.—J. R. Owen, M.R.C.P.

M. A., female, aged 61. Cook. 14.10.46: Admitted to hospital, complaining of "lumps on the skin". Condition first noticed in February 1946, following "influenza". At first the lesions very irritable; subsequently less so.

Past history.—Varicose veins nine years ago. Scarlet fever and arthritis, thirty-two years ago. *Family history* not relevant.

Condition on admission.—Good colour and nutrition. C.V.S. Systolic bruit at pulmonary area. B.P. 240/130. Lungs: Diminished breath sounds at left base. C.N.S. normal. Abdomen: Spleen just palpable below costal margin.

Regional lymph nodes not enlarged. Skin: Studded with raised red nodules and irregularly shaped patches of erythema; scaling and superficial ulceration at some points.

X-ray chest: Cardiac shadow enlarged on left with unfolding of aortic arch. Hypertensive heart.

Blood-count (16.10.46): R.B.C. 4,080,000 per c.mm.; Hb 73%; C.I. 0·89; W.B.C. 6,200. Polys. 62·5%, lymphos. 30·5%, monos. 5%, eosinos. 2%. 31.12.46: R.B.C. 4,200,000 per c.mm.; Hb 80%; W.B.C. 3,000. Polys. 64, lymphos. 32, monos. 4%.

Treatment.—Low-voltage therapy. 140 kV. to three small areas (*a*) Right arm 4 cm. field. Max. 2,400 r, min. 1,900 r in twenty-eight days; (*b*) left forearm 4 cm. field. Max. 2,400 r, min. 1,900 r in twenty-eight days; (*c*) left thigh 10 cm. field. Single dose 400 r. 22.10.46 to 25.10.46, daily inclusive: Nitrogen mustard 6 to 7 cc. I.V. 12.11.46 to 15.11.46, daily inclusive: I.V. injections of nitrogen mustard. 1.1.47: Discharged, improved.

Section shows picture characteristic of mycosis fungoides.

Blue Nævus in a Mongolian Patch.—C. L. Collins, M.B.

Mrs. J. M., aged 28, a dairy worker. A dark patch was first noticed on the chest, just below the left clavicle, ten years ago. The area has gradually increased in size and has recently spread upwards on to the left side of the neck. The patient's father came from Barbados, but she does not know of any coloured relation in the family.

On examination.—There is a blue-grey area of skin on the left shoulder and left side of the neck, showing many white striæ. A blue nævus present in the area was removed for biopsy. The rest of the skin is clear.

Report on section.—In the mid-corium there is a zone of very pigmented, ribbon-shaped cells and these can also be seen, though sparsely distributed, in the corium generally.

Ashmead, A. S. (1905) *J. Cutan. Dis.*, 23, 203; (1934) *Bull. Soc. obst. Gynéc.*, 23, 442.
Cockayne, E. A. (1933) Inherited Abnormalities of the Skin and Its Appendages, p. 69. London.

Dr. F. R. Bettley: This case seems identical with one I recorded in the *British Journal of Dermatology* in 1938, 50, 151. The distribution is the same and it has almost the same linear dimensions to the area. My patient was of about the same age as the patient now presented. The nævus had been present for about fifteen years and was slowly increasing in size. There was the same slaty pigmentation and biopsy gave results which seem to be identical with those given in this case; some of the pigmented cells were Dopa-positive and some negative. I saw my patient again about a year ago, after eight years had elapsed. I had photographs and accurate measurements made, and I found that during the eight years when I had not been observing her there was no increase whatever in the size of the lesions. Apparently they get to a certain size and then stop.

As to the nature of the condition, the only cases I was able to find of the same kind were those described by Darier under the name of melanosis or melanosarcoma. When the term "nævus" is applied to them it is almost begging the question. Treatment presented rather a hopeless prospect. Radium treatment and CO_2 snow made no difference whatever.

Morphœa Guttata.—BRIAN RUSSELL, M.D.

Miss G. G., aged 66. *History.*—1944: Dryness and scaling of skin of the forearms, sacral region, shoulders, and sides of neck. December 1946: A large red patch developed beneath right breast, with intense irritation.

On examination.—A well-nourished woman, of healthy appearance. Mucosæ normal. Skin: Many figurate, slate-coloured plaques with very slightly raised edges, and scaling and atrophy in the centre. Some of the small lesions are polygonal but all show central atrophic changes. These lesions are present under breasts, where they are moist and superficially ulcerated, on front and back of chest and over sacrum, with other smaller lesions near elbows. Supple symmetrical atrophic oval scars above the clavicles. There is an angiomatous papule in a telangiectatic atrophy of vulva.

Biopsy.—Shows hyperkeratosis, with some follicular plugging, thinning of epidermis with absence of rete pegs, and pale, rather structureless collagen in dermis, in which there is slight perivascular round-cell infiltration. The collagen bundles are thickened but pale in the subpapillary region and there is marked disruption of the elastic fibres in this area.

Leucoderma and Leucotrichia.—BRIAN RUSSELL, M.D.

L. W., aged 25. Electrician.

History.—Two to three months: Left eyelashes gradually became white. Two months: Alveolar abscess—tooth extracted under nitrous oxide. One month: Some of left eyebrow hairs became white. *Family history.*—Nothing relevant.

Wassermann and Kahn reactions negative.

On examination (20.11.46).—Apparently healthy man, of placid temperament. Left eyelashes are white. Two small patches of the left eyebrow hairs are white. The skin of the eyelid and orbital region is pale. There is marked acne vulgaris of the back.

? Lupus Vulgaris.—E. COLIN JONES, M.B.

G. W., female, aged 36. Skin trouble began early in 1943 with evanescent reddish areas over the cheeks. In the past she has been variously described as suffering from lupus vulgaris and lupus erythematosus. She had treatment with calciferol 100,000 units daily, with but little benefit.

On examination.—Her condition consists of scattered, indistinctly infiltrated patches on the pre-auricular and cheek areas, the pigmented patch on the right cheek representing the oldest lesion. Although there is a superficial resemblance to erythematoides, the cheek lesions are more those of a lupus vulgaris. W.R. negative. Blood-count normal. No history of drugs. Biopsy suggests a diagnosis of erythematoides.

Dr. Dowling: I would suggest the diagnosis of sarcoid as a possibility in this case—the very superficial type—though with quite perceptible infiltration. The resemblance of that type of sarcoid to lupus disseminatus can be very close.

Favus.—E. COLIN JONES, M.B.

F. T., boy, aged 11. Onset of condition approximately ten years ago while in Egypt. Never previously diagnosed. Scalp is covered by coalescent, dirty, yellowish, adherent crusts, with a typical mousy odour. No typical scutula. The central area shows a somewhat irregular, atrophic, hairless patch. On the body are scars of old patches of favus. Examination of hair shows a typical mycelium, and culture confirms.

The Sterilization of Dental Handpieces

By Warren Harvey, C. H. LeMay and C. W. Shuttleworth

THE PROBLEM

During the war when one had to inspect hundreds of men and women in about a quarter of the number of minutes, the dish of disinfectant into which the mirrors and probes were dipped was really little but a pretence at sterilization, but I am sure that the personnel would have been more disgusted at its absence than they were at the taste of the fluid. And yet, how often do we sterilize our handpieces? It is not merely the risk of cross-infection but the thought of unhygienic technique which has stimulated this communication.

PREVIOUS METHODS

Hot-air sterilization has been recommended by Parfitt and Herbert (1939) but it is likely from the report of the M.R.C. War Memorandum No. 15 (1945) that a temperature of 160° C. for at least one hour is necessary, with of course special apparatus. Relubrication is then necessary. Autoclaving at 120° C. at 15 to 20 lb. pressure for twenty minutes is recommended by Mead (1940), and by Parfitt and Herbert, but again the apparatus is expensive. Lysol or Bard-Parker solution have been suggested by the same authorities, but there are several disadvantages to these and other chemical methods such as length of time needed (e.g. eighteen hours), corrosion and ineffectiveness, and these have been pointed out in the M.R.C. War Memorandum No. 15 and by Foster, LeMay and Johnstone (1945).

Hot oil has been recommended by Parfitt and Herbert, but has been found unreliable for sterilizing syringes. Oil with a chemical germicide has been suggested more recently by Loretz (1944) and even at 100° C. this is stated to render handpieces sterile after ten minutes; there is a sterilizer on the market with the necessary separate compartment for the oil.

SUGGESTED NEW METHOD

My attention was first concentrated on this problem when during wartime storage conditions, handpieces (which had not been opened since package by the manufacturers) were found to be so corroded that they could not be used. Before the fall of Japan it was necessary to devise a method of storage and lubrication under very unfavourable tropical conditions. After degreasing, all handpieces were soaked in an anticorrosion fluid used by the R.A.F. in gyros; after draining they were sealed in polyvinylchloride envelopes.

Then it was ascertained that a team consisting of an ophthalmic surgeon, a consultant chemist, and a steel technician had overcome the problem of corrosion and is applied to them it is almost begging the question. Treatment presented rather a hopeless prospect. Radium treatment and CO_2 snow made no difference whatever.

Morphœa Guttata.—BRIAN RUSSELL, M.D.

Miss G. G., aged 66. *History.*—1944: Dryness and scaling of skin of the forearms, sacral region, shoulders, and sides of neck. December 1946: A large red patch developed beneath right breast, with intense irritation.

On examination.—A well-nourished woman, of healthy appearance. Mucosæ normal. Skin: Many figurate, slate-coloured plaques with very slightly raised edges, and scaling and atrophy in the centre. Some of the small lesions are polygonal but all show central atrophic changes. These lesions are present under breasts, where they are moist and superficially ulcerated, on front and back of chest and over sacrum, with other smaller lesions near elbows. Supple symmetrical atrophic oval scars above the clavicles. There is an angiomatous papule in a telangiectatic atrophy of vulva.

Biopsy.—Shows hyperkeratosis, with some follicular plugging, thinning of epidermis with absence of rete pegs, and pale, rather structureless collagen in dermis, in which there is slight perivascular round-cell infiltration. The collagen bundles are thickened but pale in the subpapillary region and there is marked disruption of the elastic fibres in this area.

Leucoderma and Leucotrichia.—BRIAN RUSSELL, M.D.

L. W., aged 25. Electrician.

History.—Two to three months: Left eyelashes gradually became white. Two months: Alveolar abscess—tooth extracted under nitrous oxide. One month: Some of left eyebrow hairs became white. *Family history.*—Nothing relevant.

Wassermann and Kahn reactions negative.

On examination (20.11.46).—Apparently healthy man, of placid temperament. Left eyelashes are white. Two small patches of the left eyebrow hairs are white. The skin of the eyelid and orbital region is pale. There is marked acne vulgaris of the back.

? Lupus Vulgaris.—E. COLIN JONES, M.B.

G. W., female, aged 36. Skin trouble began early in 1943 with evanescent reddish areas over the cheeks. In the past she has been variously described as suffering from lupus vulgaris and lupus erythematosus. She had treatment with calciferol 100,000 units daily, with but little benefit.

On examination.—Her condition consists of scattered, indistinctly infiltrated patches on the pre-auricular and cheek areas, the pigmented patch on the right cheek representing the oldest lesion. Although there is a superficial resemblance to erythematoides, the cheek lesions are more those of a lupus vulgaris. W.R. negative. Blood-count normal. No history of drugs. Biopsy suggests a diagnosis of erythematoides.

Dr. Dowling: I would suggest the diagnosis of sarcoid as a possibility in this case—the very superficial type—though with quite perceptible infiltration. The resemblance of that type of sarcoid to lupus disseminatus can be very close.

Favus.—E. COLIN JONES, M.B.

F. T., boy, aged 11. Onset of condition approximately ten years ago while in Egypt. Never previously diagnosed. Scalp is covered by coalescent, dirty, yellowish, adherent crusts, with a typical mousy odour. No typical scutula. The central area shows a somewhat irregular, atrophic, hairless patch. On the body are scars of old patches of favus. Examination of hair shows a typical mycelium, and culture confirms.

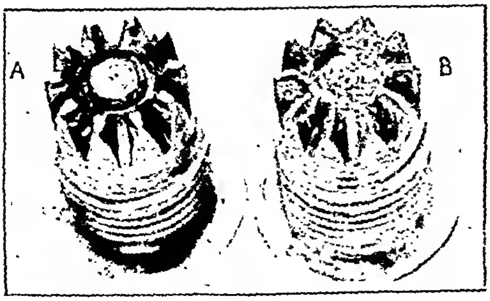

FIG. 2.—The gear from a right-angled handpiece A, lubricated with AC. 10 (Surgical) and boiled in AC. 10 soda is unaffected, whereas gear B from a handpiece lubricated with "dental engine oil" and boiled in water is heavily rusted.

(*b*) *Sterilization.*—Four handpieces, two right-angled and two straight, were sterilized in the usual manner in the hot-air oven. Each handpiece was then immersed in a large tube filled with nutrient broth. The handpieces were completely covered with fluid. The broth was inoculated with *Strep. hæmolyticus* (Group C) and the tubes incubated for twenty-four hours.

The infected handpieces were then transferred to a bath of boiling AC. 10 soda solution for five minutes. They were then taken out and dipped into sterile distilled water and immediately placed in tubes of nutrient broth and incubated for seventy-two hours.

TABLE I.—TEST INCUBATION AFTER FIVE MINUTES IN AC. 10 SOLUTION

	24 hours	48 hours	72 hours at 37°C.
Right-angled handpiece 1 ..	—	—	—
Right-angled handpiece 2 ..	—	—	—
Straight handpiece 1 ..	—	—	—
Straight handpiece 2 ..	—	—	—

The above experiment was repeated, this time boiling in the AC. 10 was continued for ten minutes, with similar results.

Repeat experiments were performed using a highly resistant sporing organism as the infecting agent. Three experiments were performed, boiling the handpieces in the AC. 10 soda solution for ten, twenty and thirty minutes respectively.

TABLE II

Results	10 *min. in AC.* 10 *sol.*			20 *min. in AC.* 10 *sol.*			30 *min. in AC.* 10 *sol.*		
Hours at 37° C.	24	48	72	24	48	72	24	48	72
Right-angled handpiece 1	+	+	+	—	+	+	—	—	+
Right-angled handpiece 2	—	—	+	—	+	+	—	—	—
Straight handpiece 1	+	+	+	—	—	+	—	—	—
Straight handpiece 2	—	+	+	—	—	—	—	—	—

N.B.—The organism used to infect the handpieces in the above series of experiments was *B. subtilis.*

From these results it will be seen that five minutes' boiling of the infected handpieces in the experimental solution rendered them free from organisms as shown by the test incubations. It would appear that this time is sufficient for the destruction of the ordinary non-resistant type of organism infecting dental handpieces.

Ten minutes' boiling failed to sterilize any of the handpieces. Only one was free from infection after twenty minutes' boiling and even after thirty minutes one handpiece gave a growth of infecting organisms after seventy-two hours' test incubation.

From these tests it appears that in order to be absolutely certain of complete destruction of all forms of bacteria it is necessary to boil dental handpieces for over thirty minutes in AC. 10 soda solution. Although it has been reported by Garrod and in the *Brit. Med. J.*, 1941, that five minutes' boiling in 2% sodium carbonate solution kills all organisms including spores, yet it would appear that for instruments the larger subsequent blunting of fine cataract knives by adding sodium carbonate and a fluid known as "AC. 10 (Surgical)" to the sterilizer. It was therefore most gratifying to find that there was a connexion between AC. 10 (Surgical) and the R.A.F. fluid we used to protect our handpieces (Foster *et al.*, 1945).

Exhaustive *ad hoc* experiments, previously reported to the Section of Ophthalmology of this Society (Foster *et al.*, 1945, and Kayser and Foster, 1946), proved that addition of 1% to 2% v/v of AC. 10 (Surgical) to the alkaline aqueous sterilizing solution provided complete protection against corrosion without interfering with sterilizing efficiency (if anything, it helped) and that it was biologically inert and without effect on the metabolic processes of healing. AC. 10 (Surgical) differs from the original AC. 10 only in that it has been modified to obviate "oily" odour when boiling in the sterilizer. It consists of 95% of a light petroleum neutral oil (containing, approximately, 64% paraffins, 31% naphthenes, 5% aromatics) and 5% of a complex of metallic petroleum sulphonates of molecular weights between 400 and 500 and average composition of the order $C_{24}H_{37}SO_3X$—$C_{30}H_{50}SO_3X$.

As this work had demonstrated a means, without alteration to existing equipment, of positively preventing corrosion during, and subsequent to, such a simple and completely effective (Garrod, 1941, &c.) method of sterilization as boiling in 2% soda solution, and as moreover the remnant film was of an oily nature promising lubricant value, it was decided to apply this technique to dental handpieces.

EXPERIMENTAL JUSTIFICATION

(*a*) *Corrosion.*—Two new straight and two new right-angled handpieces were degreased in benzene and dried in an oven. One pair of handpieces was soaked in the AC. 10 (Surgical) fluid for fifteen minutes, while the control pair was soaked in a proprietary dental engine oil; the test handpieces were then put in a sterilizer containing a solution of 2% w/v of crystalline sodium carbonate (decahydrate) and 2% v/v of AC. 10 (Surgical) fluid in water; the control handpieces were then placed in a sterilizer containing water only. All handpieces were boiled for an hour and then dried in an oven at 51° C. overnight. Rust was found on the gears of the right-angled handpiece. The sequence was repeated three more times and then photographs were taken. Figs. 1 and 2 show corrosion of the handpieces (B) which were the controls.

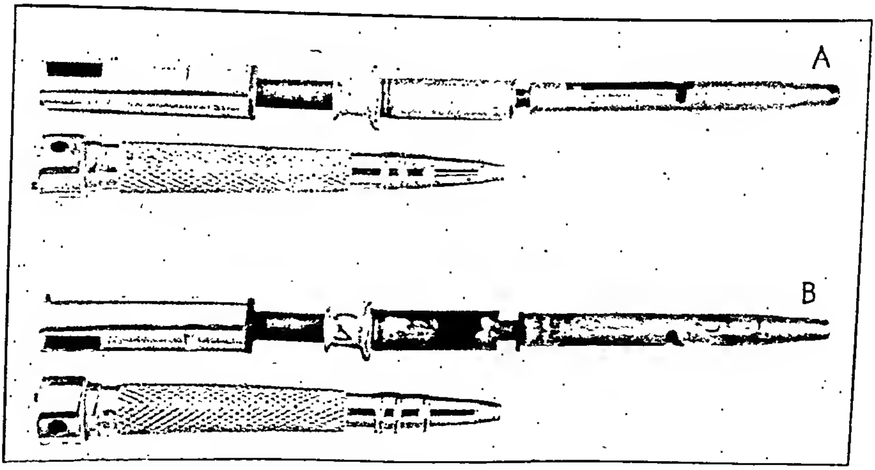

FIG. 1.—Handpiece A, lubricated with AC. 10 (Surgical) fluid, and boiled in AC. 10 soda solution is quite clean; handpiece B, lubricated with a proprietary dental engine oil, and boiled in water, shows considerable corrosion. New handpieces were used.

The "Three-Ply" Structure in Facial Bones

By W. WARWICK JAMES, O.B.E., F.R.C.S., M.Ch.

When war was declared in 1914 no preparation for the special treatment of injuries of the jaws and face had been made. Gradually a definite scheme was evolved and later this was formulated in a War Office Report (1935) leading to the present development of Maxillo-Facial Centres.

The treatment of mandibular lesions was our chief concern at first but those of the upper part of the face became more important and increasingly so with the development of aeroplanes and the increased speed of motor traffic. To-day these injuries have become still more significant and extend to civil life.

My communication is concerned with some features influencing these injuries. Emphasis cannot be made too often upon the great difference between the structure of the dense movable mandible and that part of the face which is fixed to the cranium and provides a base upon which the mandible acts.

The contrast between the dense bone and the thin laminæ of the upper part of the face is particularly noticeable in the macerated skull. The strength of the dense bones is obvious. The thin bones with the mucous membrane attached, possess elasticity as well as strength, whilst lightness is also attained. They provide a powerfully resisting structure.

These characteristics are well demonstrated by anatomical studies and by the experimental investigations carried out by Le Fort (1901) on the cadaver. These studies together with the experience gained from the treatment of jaw injuries showed that the strength and elasticity of thin bones, particularly when supported on either side by the mucoperiosteum with its penetrating fibres, is truly remarkable. Mr. Fickling and I compared their flexibility and strength with three-ply preparations of wood (James and Fickling, 1940, 1941, *a*, *b*).

The force of mastication upon the post-canine teeth of the maxilla is directed through the compact bones of the zygoma of the wall of the orbit to the frontal. Anteriorly the resistance is through the premaxillæ and maxillæ whilst considerable strength is added by the arrangement of the delicate laminæ of bone underlying them. The dense structure of the external surface, on account of the curvature, is not readily recognized in sections.

My own experience led me to think we had more knowledge of details than of a co-ordinated anatomical picture, and that an examination of serial sections through the face would provide a beginning for further study.

I have been greatly helped by Dr. Smout at Birmingham and Professor Lockhart at Aberdeen who have obtained photographs of sections for me. The actual specimens may be seen in the museums of Birmingham or Aberdeen. In addition to these, illusthe mass of metal and the greater the complexity of internal mechanisms, the longer would be the time needed for sterilization.

When necessary AC. 10 (Surgical) fluid can be sterilized by autoclaving as for liquid paraffin.

(*c*) *Lubrication.*—A comparison is shown in Table III of some of the properties of some proprietary dental engine oils and AC. 10 (Surgical).

TABLE III

Oils	A	B	C	D	AC. 10 (Surgical)
Sp. Gr. at 60° F.	0·882	0·882	0·846	0·862	0·879
Fl. Pt (P.M.) Cl. .. °F.	405	430	375	315	310
Visc. R.I. at 70° F. .. secs.	724	919	140	122	120
Visc. R.I. at 140° F. .. secs.	102	119	48	45	43
Visc. R.I. at 200 ° F. .. secs.	49	52	37	35	33

So far as one can judge from criteria of this sort, it is likely that AC. 10 (Surgical) is equally efficient as a lubricant.

(*d*) *Side effects.*—Animal experiments have shown that AC. 10 (Surgical) is biologically inert; remnant traces from sterilization neither have irritant effect nor interfere with metabolic processes.

Silk, glass and natural rubber are not significantly affected (Speakman, 1946), whereas ivory, insulating varnish and synthetic rubber are unaffected.

It is to be expected that the AC. 10 soda solution is, if anything, beneficial to local anæsthetic solutions; for example, when a syringe is boiled in the solution and stored in Smith's solution,[1] drained and filled with Waites Cobefrin local anæsthetic solution the change of pH is as follows:

TABLE IV

AC. 10 (Surgical) soda →	Smith's solution[1] →	Waites Cobefrin in syringe	← Waites Cobefrin in container
pH 9·0-10·0	6·8-7·2	4·6-5·2	2·8-3·6

Thus an alkalizing effect is produced. Professor Berry of the College of the Pharmaceutical Society has concurred in the view that the slight residual alkalinity is likely to be an advantage as far as local anæsthetics are concerned.

I have used this method of sterilizing my handpieces for the last year. The method is very cheap, needing no special apparatus. My sterilizer is emptied and cleaned only once a month and a tenth of a pint of the fluid and six teaspoonfuls of sodium carbonate are added. When evaporation takes place the solution is made up with water only. I soak all the handpieces in neat AC. 10 (Surgical), boil and allow to drain overnight, and boil each after use in AC. 10 soda solution. As with all instruments they are dried in a clean linen towel so that the oiliness is no worry. When cold the AC. 10 fluid separates but re-forms an emulsion on boiling. Occasionally handpieces appear to squeak after several boilings and this is overcome by soaking in neat AC. 10 (Surgical) for a few minutes and reboiling. Local anæsthetic solutions are certainly unimpaired.

Finally, I can keep surgical burrs, reamers, needles and scalpel blades *continuously* in a burr-tray in my sterilizer completely free from corrosion.

I would like to pay tribute to Air Commodore Ballantyne, Director of Dental Services of the R.A.F., who originally gave permission for this work to be carried out, and to thank the Metallurgical Division of the Royal Aircraft Establishment for the photographs.

W. WARWICK JAMES: The "Three-Ply" Structure in Facial Bones.

trations were shown from a paper by Professor Reid (1904); tracings modified by Mr. Fickling and me from Eycleshymer and Shoemaker (1911) and an illustration of a disarticulated skull from Schaeffer (1920).

Some explanation is needed of the specially prepared photographs by Dr. Smout. I quote his own words. "I got my artist to photopaque the bones and you may take it that these are accurate and have been most carefully drawn from the specimens. The specimens, from which the photographs were taken, were obtained from a frozen subject which was cut in coronal planes at ½ in. intervals, and mounted in jars; they were not removed but were photopaqued as they stood. The outline of the specimen on the negative was carefully cut out, and retained as a separate entity. Then the areas of bone and cartilage in the negative were blocked out with photopaque, and this prepared negative was printed on gaslight paper which gave a final print with a jet-black background—the bones and cartilage therefore appeared white. The subject was a man unlikely to have been under 60 years of age."

The sections are transverse and vertical, i.e. parallel to the coronal plane. The two sides are not exactly the same on account of the obliquity of cut; this is not intentional, but to maintain an absolute plane is difficult, and moreover not a disadvantage for it shows slight differences.

This communication is an introduction to a subject which needs considerable extension and may suggest a useful line of investigation.

Six of the photopaqued photographs are reproduced here (figs. 1 to 6).

FIG. 1.—Cut through the premaxilla at about the widest diameter of the central incisors. The narrow projection above is due to the incisor crest which is surprisingly high. As the teeth slope slightly upwards and inwards the plane passes through the septum of the nose up to the base of the nasal bones. The Λ-shaped arch, with a limb on either side, is through the nasal bones and the frontal processes of the maxillæ. The fragment of the mandible is cut through the chin.

FIG. 2.—On the left side of the subject the eyelids are present, on the right side the plane passes through the eyeball, being behind that of the left side. This obliquity is indicated by a variation in the position in which the bones of the nose are cut. The thin nature of these bones is obvious. Particularly noticeable is the thin inner wall of the orbit on the left side passing to the inferior turbinal which is also seen on the right side, where external to it, the inner wall of the antrum is distinct. The density of the maxillary and premaxillary bones is obvious and on the left side of the subject a thick plate passes up to the zygomatic bone, cut obliquely. On the right side the zygomatic bone is cut in its posterior aspect where it passes backwards to the zygomatic process. The frontal bone, with large frontal sinuses, is dense above and thin over the orbit below, also dense where it passes to the outer side of the orbit on the right. The character of the mandible is clearly shown.

FIG. 3.—Cut obliquely through the eye on the left side of the subject in front of the outer margin of the orbit accounting for the gap, and with the plane on the right side more towards the back of the orbit. The sections of the thin bones of the nose and inner walls of the orbit and of the antra are distinct. The arch of the frontal bone is dense and below on the outer side of the right orbit is continuous with that of the zygomatic bone. The tongue of bone below this is through the ramus of the mandible. The thicker part of the outer walls of the maxillary sinus is evident on the left side of the subject. Sections through the body of the mandible are seen below.

FIG. 4.—Is through the post-orbital region further forward on the subject's left than right. The back part of the nasal fossæ is well shown. The section cuts the posterior part of each maxilla, exposing the back part of the antrum. The ramus is continuous with the body of the mandible seen on the right; on the left side they are not connected. Inferior orbital fissure is cut across on the left side.

Figs. 5 and 6, *see* p. 514.

reparing this communication it has seemed best to me to report all cases of a and not to select a few subjected to one particular form of treatment. It is so to hear of the 75% or 80% of patients cured of cordal cancer; but these ent only a minority, and such a report gives no indication as to the fate of mainder. Accordingly I have made no selection, but give details of every t in this consecutive series.

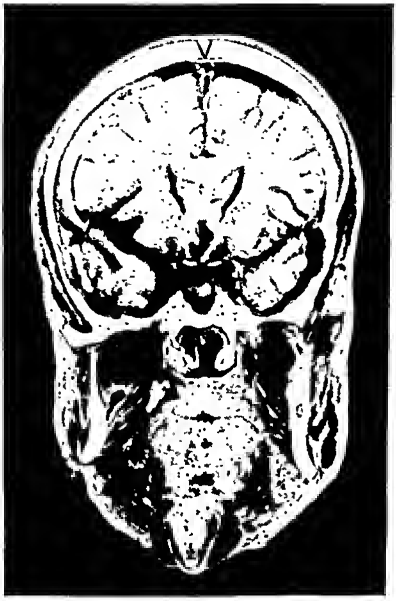

FIG. 5.—The mandible, the only facial bone present, is cut through the rami; that on the left side of the subject is in front of the right as it includes the sub-alveolar canal. The side which is deeper is partly through the coronoid process. The shorter fragment shows the thickening at the back part of the mandible. Eversion of the lower border of the mandible is seen on both. On the left side the attachment of the fibres of the masseter muscle and on the right those of the internal pterygoid are obvious. On the right of the subject, the base of the zygomatic process projects and the bone inside consists of the articular process continued through the wing to the body of the sphenoid.

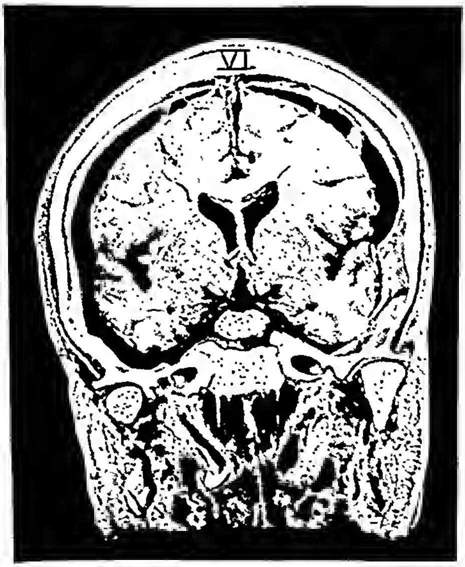

FIG. 6.—The section passes through the temporomandibular joint showing the head of the condyle with a portion of the neck on the left side. The outward projections are through the base of the respective zygomatic processes of the squamous part of the temporal bone. The upper part of the articular fossa is crescentic. The wall of the cranial cavity is seen above, it encloses the brain with the horns of the lateral ventricles centrally situated. On the inside of the joint the end of the petrous portion of the temporal bone and beyond this the basioccipital, are cut across.

The condyles of the mandible are the most posteriorly situated of any of the facial bones.

of disease after five years, and as *promising* if alive and free after a period less than five years, or if dying before the end of five years from other causes, but still free of laryngeal carcinoma.

TABLE IX.—UNILATERAL CORDAL CANCER (35 PATIENTS TREATED)

Results	Cases	Limited 14 C.	P.	F.	Extended 7 C.	P.	F.	Whole cord 14 C.	P.	F.
Laryngofissure	19	3	5	5	2	1	2	–	–	1

Deep X-rays	9	1	1	2	–	1	4
	32	3	1	3	4	6	15

Cured 7. Promising 7. Failed 18.

In comparing results, more than one factor must be taken into consideration. In my earlier cases there was less accurate discrimination as to the most suitable treatment, and in the war years of 1939 to 1946 there was much to do in connexion with battle and air-raid casualties, and the sick personnel of the forces; this, together with shortage of nursing staff, meant that operations were avoided as far as possible. Radiotherapy was therefore recommended for some cases who might, otherwise, have been subjected to surgery; the advantage was gained, however, of obtaining a somewhat balanced review of the possibilities available.

To compare the results according to the situation and distribution of the growth, the results in each primary group may be tabulated together, irrespective of the mode of treatment.

Relative merits of various methods.—It is not only the immediate danger to life that must be considered in giving advice, but also the discomforts to be expected during the after-treatment.

(1) *Laryngofissure with removal of one cord or part of both:* The patient does not suffer pain; he swallows a few hours after operation, is out of bed in three or four days and usually leaves after a total stay of two to three weeks. His voice is hoarse but serviceable for all conversational purposes; apart from this there is no disability.

If recurrence appears, further treatment is practicable.

(2) *Laryngectomy:* There is practically no pain after the operation, and if a suction pump be effectively employed, cough is not disturbing. The use of the Sorensen flap and of sulphonamide and penicillin powder in the wound or systemically should guarantee early healing in most cases, usually in less than two weeks. Normal swallowing is then resumed, but œsophageal speech must be learnt. For some patients, especially those of advanced years, this may be difficult or impossible; such patients are then cut off from conversation and may become severely depressed, even so far as to commit suicide. This has happened with two of my cases.

(3) *Interstitial radium:* An operation is required and sepsis may supervene. The needles must cover the subglottic region, and part of the cricoid should be removed. Perichondritis or stenosis are possible sequelæ. If successful, the method may restore the voice almost to normal. If recurrence occurs, laryngectomy is possible, and has been performed twice by me with no undue difficulty. The treatment is short and no tracheostomy is required.

(4) *Deep X-ray therapy:* The treatment is tedious, and must be prolonged over four or five weeks; it produces a feeling of ill-health, often with excessive secretion. Perichondritis may ensue, or may follow even after a lapse of years. The growth may be arrested but not cured, and slow spread may kill the patient after a prolonged period of suffering, greater in severity and duration than if no such attempt at cure had been made. In my opinion, the mere prolongation of life is no criterion of success.

If successful, the larynx may be restored to normal appearance, with a clear and resonant voice.

(5) *Radium beam:* The same disadvantages may arise, but usually in lesser degree; the local discomfort to the patient appears less than with deep X-ray therapy, but treatment is more tedious.

Perichondritis after irradiation: This danger is a real one, as these figures show:

TABLE VIII

	Cases treated	Perichondritis	Recovered	Died
Interstitial radium ..	9	2	1	1
Deep X-rays ..	24	4	2	2
Radium beam ..	10	2	0	2
	43	8	3	5

The affection of cartilages and of the soft tissues overlying may be of low grade and prolonged; treatment in the past appeared ineffective, but penicillin may prove effectual in some cases. In the insertion of radium excessive dosage may have been at fault in the patient who died.

Results of treatment according to situation of growth.—It is difficult to fix a criterion of success. A three-year period of freedom is useless, since I have seen late recurrences after laryngofissure, when operation had been performed according to the tenets of StClair Thomson, with wide removal of the endolarynx. Thus 2 patients, at first apparently free of disease, had recurrences after three years, and 1 other after four years; these are naturally not classed here as successes, thus detracting from the percentage of cures. I have classed patients as *cured* only if they were well and free

The treatments by irradiation were under the direction of experts, with efficient equipment. Irradiation seems to be ineffective in recurrent cases.

TABLE XVI.—COMPARISON OF METHODS OF TREATMENT

		Cases	Cured	Promising	Failed
Laryngofissure	primary	23	7	6	10
	secondary	1	–	–	(1)
Laryngectomy	primary	22	4	8	10
	secondary	4	1	(1)	(2)
Interstitial radium		9	3	1	5
Radium collar		1	–	–	1
Deep X-ray	primary	17	4	5	8
	secondary	7	–	–	(7)
Radium beam	primary	5	3	1	1
	secondary	5	–	1	(4)
		79+(15)	22	22+(1)	35+(14)

(The figures in brackets refer to patients already included)

It is impossible, in any analysis, to make an exact comparison of alternative methods, since that is adopted which appears most likely to benefit the various groups of patient. The situation, distribution and type of growth, the general condition of the patient, the skill of the surgeon or radiotherapist, and the environment of treatment are all factors which must be considered.

I believe that my present percentage of cures by laryngofissure would compare favourably with those published by others; I have had many disappointments from laryngectomy, but not, I venture to believe, from errors of technique.

Choice of treatment.—For me, the experience of these cases, spread over a period of twenty years, has allowed certain conclusions to be drawn.

(1) A growth limited to the membranous vocal cord is best treated by removal through the *laryngofissure* route. The figures given may not appear startling, but at the present day I should feel able, after selecting the case with all due care, to promise the patient a very good prospect of permanent cure, with little danger to life, with but slight suffering and with no subsequent disability except a somewhat husky voice.

(2) A unilateral cordal growth extending on to the arytenoid cartilage, or reaching the posterior commissure, and without fixation, would be treated by *external irradiation*. The alternative would be interstitial radium, but the former appears to offer a more even irradiation, although with more prolonged discomfort to the patient. Surgical treatment, if carried out, would entail removal of the whole larynx, with the loss of the natural voice and with no guarantee against recurrence.

(3) A diffuse growth arising in the larynx affected by chronic hypertrophic laryngitis, an extensive subglottic carcinoma or a growth widespread and with marked fixation of the cord, would be treated by *total laryngectomy*.

(4) Cases of recurrence after laryngofissure are best treated by *total laryngectomy* if otherwise suitable. External irradiation for recurrent cases has not given sufficient success to be justified.

CONCLUSIONS

Of patients presenting themselves with malignant disease of the larynx, of various types and at different stages of progress, 22 were permanently cured and 22 others were free of disease but had not passed the five-year standard; in 35 cases treatment failed, although the disease was in some instances arrested for some years. The intervention of the war years disturbed the keeping of records and in some cases adversely affected the treatment of patients.

I wish to acknowledge the help of my colleagues at King's College and Horton Emergency Hospitals, and also the radiotherapists who have treated patients referred by me; among them are Drs. Finzi, Langmuir Watt, Levitt, Allchin, Dr. Wood of the Radium Beam Therapy Research, and Professor Windeyer. From the latter,

TABLE XIII

	Cases	Cured	Promising	Failed
Unilateral cordal cancer..	35	10	11	14
Unilateral subglottic ..	5	1	1	3
Unilateral cordal and supraglottic	5	1	2	2
Bilateral cancer	32	7	7	18
	77	19	21	37

The results, both of those known to be free of disease after five years, and also those promising to be cured, are less good in the bilateral and subglottic groups, as might be expected. But the figures are not so divergent as might be looked for; the difference is better reflected by the severity of treatment required for more extensive growths.

Metastases and recurrences.—In only 4 of the series were palpable glands present before the commencement of treatment; the patients were not refused for this reason. In 8 cases enlarged cervical glands appeared after treatment; 5 were treated by block dissection and 3 by irradiation. One patient was noticeable as having a further recurrence after an apparently complete surgical removal; he responded to irradiation and it might therefore be presumed that this treatment would have been effective in the first place. General opinion favours the view however that for differentiated growths surgical removal of secondary glands is the correct procedure.

TABLE XIV

		Site of recurrence after temporary freedom from disease				
Primary treatment	No. of pts. with recurrence	Cervical glands	Larynx	Laryngectomy scar	Trachea	Mediastinum
Laryngofissure	7	–	5	–	2	–
Laryngectomy	8	5	–	2	5	1
Interstitial radium ..	1	–	1	–	–	–
Deep X-rays	3	3	–	–	–	–
Radium beam	1	–	1	–	–	–
	20	8	7	2	7	1

The possibility of recurrence indicates the necessity for careful selection of the right treatment, for wide endolaryngeal excision, for avoidance of narrow field laryngectomy and for removal of a sufficient length of the trachea in subglottic cases.

Treatment of recurrences.—Here a difficult problem is presented, since the results have generally been poor in my experience.

TABLE XV

Secondary method of treatment	Cases	Cured	Promising	Failed
Laryngofissure	1	–	–	1
Laryngectomy	4	1	1	2
Deep X-rays	7	–	–	7
Radium beam	5	–	–	5
	17	1	1	15

This presents a gloomy picture and gives the impression that if the primary treatment fails, the prognosis is extremely bad. The patient cured had been treated originally by teleradium; of the remainder, one had a previous laryngofissure on the opposite side and twelve of the others also had laryngofissure. Three were irradiated after laryngectomy, but without success.

As for the reasons for recurrence, I can offer no logical explanation. The operations were carried out with no restriction and a surrounding area of healthy tissue sufficient in extent appeared to be included in every case. Microscopical sections were examined to decide whether any growth had been left; in one doubtful case after laryngofissure, the larynx was reopened a week later and the posterior area coagulated by diathermy.

The subglottic cases had not been so satisfactory as the others; the unilateral supraglottic cases were more satisfactory, but not very good:

Treated by	Unilateral subglottic 5				Unilateral supraglottic 16			
	T.	C.	P.	F.	T.	C.	P.	F.
Limited surgery ..	–	–	–	–	1	–	–	1
External radiation ..	5	1	1	3	15	2	4	9
Total	5	1	1	3	16	2	4	10

Only a very small number of bilateral limited lesions had been treated:

Treated by	Bilateral Limited 6				Advanced 12 (Unilateral or bilateral)			
	T.	C.	P.	F.	T.	C.	P.	F.
External radiation ..	6	3	1	2	11	2	1	8
Interstitial radium ..	–	–	–	–	1	–	–	1
Total	6	3	1	2	12	2	1	9

The advanced group included cases of unilateral carcinoma in which the growth had invaded the thyroid, and here results and mortality figures were not so good.

The treatment of cases of hypertrophic laryngitis had not been successful except for one case which was treated by total laryngectomy.

HYPERTROPHIC LARYNGITIS	Primary		Secondary Treatment		
Treated by	Total	Failed	Total	Cured	Failed
External radiation ..	3	3	–	–	–
Interstitial radium ..	1	1	–	–	–
Total laryngectomy ..	–	–	3	1	2
Total	4	4	3	1	2

His next table showed the total cases in which radical treatment was attempted:

INTRINSIC CARCINOMA OF LARYNX	Radical treatment 1931-1941				Deep X-rays alone 1942-1943		
	T.	C.	P.	F.	T.	P.	F.
Limited surgery ..	5	2	1	2			
Total laryngectomy							
Primary	1	–	–	1			
Secondary	7	(2)	1	(4)			
External radiation							
Primary	53	17	7	29	20	12	8
Secondary	19	1	(1)	9+(8)			
Interstitial radium ..	2	–	–	2			
Total (Primary)	61	19	8	34	20	12	8

(The figures in brackets refer to patients already included.)

The final results in 81 cases showed 19 cured and 20 promising, making a total of 39, which was very similar to the figure given in the final table which Mr. Negus had shown. The interesting point was that 73 out of these 81 patients were treated by external irradiation whereas in Mr. Negus's series, out of a total of 79, there were 45 who were treated either by laryngofissure or total laryngectomy.

and from Mr. C. P. Wilson, I have derived much information, and many cases have been referred by me for treatment under their care.

Mr. Negus *showed five patients to illustrate the various methods of treatment of cancer of the larynx and the resulting voices.*

The first had a localized carcinoma of one cord, and was treated by excision through the laryngo-fissure route in 1936. He has remained in good health and is able to carry on his work without difficulty, including a good deal of talking to numbers of people.

The second had a carcinoma extending along the whole length of the cord, too extensive for local excision. Radium needles were inserted thirteen years ago and the patient has a good and powerful voice.

The third was seen early in 1942, with an extensive carcinoma involving the whole of one cord and also the subglottic region. He was treated under the care of Mr. C. P. Wilson and Professor Windeyer with deep X-ray therapy. His voice is now perfect and the larynx appears normal.

The fourth patient sought advice in 1938, and was found to have a carcinoma extending to the posterior commissure and also spreading anteriorly to the base of the epiglottis. There was some limitation of movement, but no obvious subglottic extension. He was treated by Professor Windeyer with teleradium and has a perfect voice and a larynx normal in appearance. He has given many lectures during the war.

The last patient was seen in 1938 with a longstanding history of hoarseness and with a note of removal of what appeared to be granulomata seven and two years previously. There was a diffuse carcinoma, with some limitation of movement, and subglottic extension causing dyspnœa. The carcinoma was of Broders' Group II. Laryngectomy was performed, and since this operation the patient has led a normal life and was able to make his voice audible to the large audience at the meeting.

Professor B. W. Windeyer said that he had some figures of his own to present from the Middlesex Hospital which were on a comparable basis to those of Mr. Negus.

His figures related to the total number of cases of intrinsic carcinoma of the larynx received in Middlesex Hospital from 1931 to 1943. Those years were chosen because the period from 1931 to 1941 included the five-year "cures", and the later two years, 1942-1943, brought in some extra cases in which cure had been maintained for at least three years. He had produced his own figures in the same way as Mr. Negus had done and according to the same criteria. Since 1932, when they obtained a 1-gram radium unit, he had, in close co-operation with Mr. C. P. Wilson, set out to record the results obtained by the use of external irradiation. A large bias towards external irradiation would be noticed in his figures, and only a small number of cases had been treated by laryngectomy.

He was grateful to Mr. Wilson for his co-operation in these cases because he knew what a great trial it was to him as a surgeon to see cases which he must have thought suitable for total laryngectomy being handed over for treatment by irradiation.

His first table showed the total number of cases during the years mentioned:

Intrinsic Carcinoma of Larynx

Total No. of Cases 106. Male 102. Female 4

	1931-1941	1942-1943
Radical treatment (primary)	62	24
Incomplete or palliative treatment ..	–	2
Treatment for recurrence	12	–
Untreated	4	2
Total	*78*	*28*

Unilateral Cordal Cancer (38 cases)

		Limited 11				Extended 15				Whole cord 12			
Treated by	Total	T.	C.	P.	F.	T.	C.	P.	F.	T.	C.	P.	F.

[*March* 7, 1947]

DISCUSSION ON LOCAL ANALGESIA

Dr. Norman R. James: *Premedication.*—One of the most important aspects of local analgesia is that of premedication. This does not consist merely in the haphazard administration of a hypnotic drug just prior to operation but in a carefully planned course of preoperative treatment designed to ensure that the patient has the maximum mental and physical comfort preceding and during the induction of the local analgesia and the subsequent operation.

The system of premedication which I have eventually found most satisfactory is as follows: Whenever possible the patient is visited the day before operation and the question of local analgesia frankly discussed and the reasons for its use fully explained. The ultimate choice should be left entirely to the patient. If he decides against it, there and then the anæsthetist should agree in an affable manner to administer a general anæsthetic despite his inclinations to the contrary. An exception to this rule is when the choice of local analgesia to the exclusion of general anæsthesia may mean a life-saving measure, such as in an advanced stage of intestinal obstruction.

Even here a tactful explanation during the administration of the local analgesia should be given, providing the patient is in a fit mental state to appreciate it.

The drug best suited to ensure the patient a tranquil night preceding operation without subsequent nausea is luminal (syn. phenobarbitone) which should be given in a dose of 1 to 3 grains by mouth according to the age, physique and condition of the patient. One and a half hours before operation the patient should be given a hypodermic injection of omnopon grain $\frac{1}{6}$ to $\frac{2}{3}$ using a fine sharp needle and not the usual blunted or barbed variety so commonly found in hospital wards, which tend right from the start to make the patient "needle shy" when local analgesia is to be used.

Presuming that the local analgesia is to be administered by the surgeon, then half an hour before operation the patient should be given, preferably in his bed (if the anæsthetist can spare the time), a *very* slow intravenous injection of 5% nembutal (pentobarbital sodium). After each c.c. has been injected there should be a pause and the patient questioned as to his feelings and asked to close his eyes and then open them quickly. The moment he shows signs of having developed a definite nystagmus together with a thick slurred speech of euphoric tendency similar to that of a person in a pleasant state of light alcoholic intoxication, then the injection is discontinued. If left alone the patient will often relapse in a few minutes into a deep sleep but can be quickly aroused and when awake is fully co-operative. The intravenous injection of nembutal should never be pushed beyond this pleasant stage because he will then tend to go into a state of basal narcosis and non-co-operation. After my five years of

It was difficult to say whether teleradium would produce better results than X-ray therapy. In the first series of cases teleradium was used as first preference. From the table it would be seen that 28 cases were treated, of whom 10 were classed as cured and 4 as promising, making 14 out of 28. During that time 22 cases, generally less favourable ones, were treated by X-rays and the results were not so good—6 cured and 3 promising.

EXTERNAL RADIATION	1931-1941				1942-1943		
	T.	C.	P.	F.	T.	P.	F.
Teleradium							
Primary	28	10	4	14	–	–	–
Secondary	7+(4)	–	–	7+(4)	–	–	–
Deep X-rays							
Primary	22	6	3	13	20	12	8
Secondary	3+(5)	1	(1)	2+(4)	–	–	–
Teleradium and Deep X-rays	3	1	–	2	–	–	–
Total (Primary)	53	17	7	29	20	12	8

In the 1942-43 period, when they were not using teleradium, and all cases were treated by X-rays, the results—none of them of less than three years and some of them approaching the five-year period, but still only classed in the promising group—showed that of 20 cases, 12 were in the promising group. The result with X-rays, adding the whole series together, was just about the same as had previously been obtained with teleradium.

Perichondritis was the bugbear of external irradiation in the treatment of carcinoma of the larynx. In some of the cases a very severe perichondritis had been experienced, and a number had lost their lives as a result of it. Others, as Mr. Negus had stated, had had a "niggling" irritation or pain which had been very distressing. They hoped to be able to control this sequel better by systemic penicillin which was being tried out.

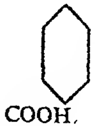
Mr. Negus had raised the question whether the histological classification was of very great importance. He believed that no very definite difference had been found between the undifferentiated and the more differentiated cases.

Finally as to treatment, he thought that their results would have been improved if more total laryngectomies had been done on cases, particularly the advanced ones, which were now thought to be suitable for that procedure and not suitable for irradiation. With regard to the early case which Mr. Negus had said should be treated by laryngofissure, he thought that the results of that treatment and of external irradiation showed no very great difference. The voice of the patient who was irradiated was a better voice than that of the patient on whom laryngofissure had been done, although that also might be quite good. There was no doubt that the patient undergoing external irradiation had a much longer treatment and an unpleasant treatment, partly because of the painful reactions which he experienced and partly because of the prolonged and wearying nature of the treatment itself. For the treatment of an early case his preference would be external irradiation.

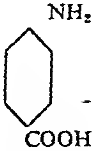
There was one other feature about teleradium and X-ray therapy, namely that the actual course of treatment with X-ray therapy meant shorter sessions for the patient. This was certainly so with the teleradium unit at their disposal—a 4-gram unit—with which each individual session lasted over an hour, whereas with X-ray therapy the individual treatment was not more than perhaps ten minutes.

These two papers, together with the subsequent Discussion, will appear in the *Journal of Laryngology and Otology*.

Dr. Frederick Prescott: *The chemistry and pharmacology of local analgesic drugs.*—With a few exceptions most local analgesic drugs are derivatives of benzoic or para-aminobenzoic acids



Benzoic acid



Aminobenzoic acid

Their activity depends upon the presence of the structure

in which R_1, R_2, R_3 and R_4 stand for different organic groups or radicals. This is only generally true; actually there are local analgesic drugs with no tertiary amine group in them, e.g. benzocaine, orthocaine and butesin (*see* Table II), while nupercaine is derived neither from benzoic acid nor from para-aminobenzoic acid.

The more common local analgesic drugs derived from benzoic acid are shown in Table I, in which B.A. stands for the benzoic acid grouping. The more common drugs derived from para-aminobenzoic acid are shown in Table II.

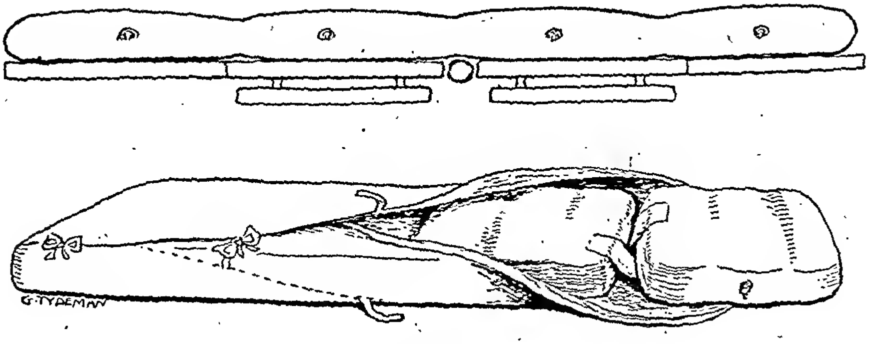
experience with intravenous nembutal preceding local analgesia for general surgery I have come to the conclusion that it is the only successful method when compared with the unreliable results obtained by giving it or similar barbiturates by mouth or *per rectum*. Recently Dr. R. P. W. Shackleton and I have applied it in the premedication of patients having local analgesia for plastic surgery. These patients, mostly ex-Service men, who have undergone many operations in various hospitals since their initial injury are all connoisseurs of anæsthesia and in most cases insist on the employment of intravenous pentothal. Many have unfortunately experienced the inefficient application of local analgesia at one time or another and are naturally biased against its subsequent employment for a suitable operation. Those willing to give intravenous nembutal premedication followed by local analgesia a trial are generally enthusiastic about it afterwards and are subsequently quite willing and in fact eager to undergo it again. Often there is partial or total amnesia for many hours following the operation and there is usually an uneventful recovery. The only sequelæ recorded have been slight nausea or "hangover" in two cases, one of these patients admitting later that he was a very heavy rum drinker. Needless to say nembutal should not be used when barbiturates are generally contra-indicated such as in hepatic or renal failure. Its use is also contra-indicated in intra-abdominal operations, such as gastrectomies. In these cases intravenous omnopon given in slow fractional doses according to the condition of the patient is the practical choice. Scopolamine is always contra-indicated in a conscious patient owing to the discomfort of a dry mouth with intense thirst which follows its use; and occasionally the patient may develop uncontrolled restlessness and even delirium. It is wrong to deprive the patient of meals prior to non-abdominal operations providing the meal is of a suitable light nature. Lack of nourishment often gives rise to a feeling of discomfort and faintness before and during operation.

In the past (with the exception of Robert Farr) little interest has been taken in the comfort of the operating table on which the patient might have to lie for two hours or more. The ordinary Sorbo covering is practically useless. A Dunlopillo cellular type of rubber mattress is an improvement. I have evolved after several experiments, with the aid of a grant from the M.R.C., a useful form of pneumatic mattress in sections (*see* figs. 1 and 2).



FIGS. 1 and 2.

The various sections for head, chest, lumbar region, &c., can be inflated to any desired tension in order to fit the particular patient's body contours. The inflation is performed by pressing on to the Schraeder nipples supplying each section, a B.E.N. type of automatic air chuck connected by a length of tubing to a small CO_2 cylinder via a reducing valve. The various sections are all bound together by flexible straps and enclosed in a washable canvas cover. Should a section be found to be overinflated and the patient not feel comfortable the pressure can be immediately reduced to comfortable proportions by pressing on the Schraeder valve just as when deflating an automobile tyre. Experience has shown that overinflation is the usual mistake in adjusting such mattresses to the comfort of the patient.

Where possible the patient should always be blindfolded when in the operating theatre by means of a folded piece of lint or similar opaque material and this does not tend to annoy the patient by tickling if it is damped with warm water before application. Conversation in the theatre should be minimal and nothing said or done to undermine the peace of mind and confidence of the patient. The surgeon should always warn the patient before starting to inject the local analgesic solution that he will feel a slight prick of the needle.

All these small points combined with the certain results obtained by the *intravenous* injection of nembutal, in contradistinction to its oral or rectal use, tend to give the maximum success when local analgesia is applied to suitable operations.

which are structurally related to it, replace it in the enzyme system, which, however, is blocked as it cannot utilize the substitute.

Mr. H. W. L. Molesworth: Even with the great advances in inhalation and intravenous anæsthesia, there are still some advantages to the surgeon and to the patient in regional analgesic methods.

One of these advantages is the relatively bloodless field, which has been termed a "physiological tourniquet". This advantage is most apparent in two regions, namely, the breast and the neck, where the technique lends itself to administration by the anæsthetist before the patient comes into the operating theatre.

The advantage of a bloodless field carries with it the obligation on the part of the surgeon to carry out most careful hæmostasis. But vessels which require ligature will bleed sufficiently to show, and I have not yet found that post-operative hæmatomas are more common, or, indeed, so common, as they are with general anæsthesia.

The technique which I use for the induction of analgesia for a major breast operation follows very closely one which was worked out by Mr. C. E. Corlette of Sydney, and I have had uniformly satisfactory results in 25 cases.

The patient must be adequately premedicated, and I have used the method of Mr. Corlette over the last two years in which morphine-sulphate and hyoscine are given in doses, arranged according to the patient's age and sex, at intervals of two hours before operation and one hour before operation, rather than the intravenous technique which Dr. Norman James has described (Table I).

TABLE I.—PREMEDICATION SCHEME, SHOWING DOSES FOR AGE-PERIODS
The dosage stated is founded on experience of pre-war Hyoscine

Age in yrs. (inclusive)	Sex	Time to be given before operation	Doses in grains		Doses in milligrammes	
			Morphine sulphate	Hyoscine-hydrobromide	Morphine sulphate	Hyoscine hydrobromide
14 and 15	Both sexes	two hours	1/4	1/150	16·0	0·4
16 to 19	F.	two hours	1/4	1/100	16·0	0·65
		one hour	1/8	—	8·0	—

75 to 84	Both sexes	two hours	1/4	1/200	16·0	0·3

(1) In this group a third intravenous injection of morphia may be needed.

The technique for an operation for carcinoma of the breast involves injections for the induction of analgesia and, in addition, injections whose object is to constrict the main blood-vessels supplying the area to be operated on. The whole procedure has taken, in my hands, from twenty-five to thirty minutes, and where this is done by the surgeon it obviously means that a breast operation will take longer than under inhalation anæsthesia. A certain amount of time is saved in dealing with bleeding points. Where, however, the analgesia is induced by the anæsthetist while the surgeon is scrubbing up or finishing the last case, quite a considerable amount of time is saved.

The patient is wheeled into the anæsthetic room and a brachial plexus block induced by the well-known Kulenkampf technique, using up to 30 c.c. of 2% ethocain in an isotonic solution containing adrenaline hydrochloride 1/250,000. It is of some importance that a 2% ethocain solution requires but 0·55% of sodium chloride to make it isotonic.

Procaine	H		$(CH_2)_2$	C_2H_5	C_2H_5

The local analgesic drugs are weakly basic or alkaline and their salts, which are the compounds employed clinically, are acid in reaction, with a pH of from 4 to 6. It is probable that the free base is liberated in the slightly alkaline tissues. With few exceptions, e.g. amethocaine, nupercaine, and metycaine, solutions of local anæsthetic drugs are destroyed on autoclaving. This is important from the point of view of their sterilization. In the preparation of weak solutions (i.e. 1% or less) distilled water should not be used as the resulting solution is hypotonic. Thus 1% procaine solution will hæmolyse red cells and rupture connective tissue and fat cells. Therefore normal saline should be used for making such solutions. Care should be taken over the glassware used for the storage of solutions as alkali glass causes decomposition. This is because alkali liberates the less stable base from the salts. Actually alkalis potentiate the action of local anæsthetic drugs if added immediately before use as they liberate the free base, which is the compound acting on the nerve endings. In practice it is not advisable to add alkali as the solution becomes turbid and cannot be sterilized by heating. It is stated that solutions of local anæsthetic agents in the strengths normally used are often bactericidal. This is true, but although they may kill pathogenic organisms, spores are not killed nor are some moulds.

The action of local anæsthetic drugs is potentiated not only by adrenaline, but by most of the sympathomimetic vasoconstrictors. This is because their duration of action is proportional to the time they are in contact with nerve tissue and vasoconstrictors prevent their spread. When they reach the general circulation they are carried to the liver, where they are detoxified by esterases, as shown by perfusion experiments. Some detoxification also occurs in the blood by the same esterase.

Those local analgesics derived from para-aminobenzoic acid, e.g. procaine, benzocaine, butyn, larocaine, orthocaine and monocaine, are incompatible with the sulphonamides. The sulphonamides are taken up by the bacterial enzyme system using para-aminobenzoic acid, which in small amounts can antagonize the sulphonamides as wound antiseptics. Those drugs derived from para-aminobenzoic acid exert a similar action and should therefore not be used in the case of patients receiving sulphonamide therapy. Apart from inactivating the sulphonamides they interfere with their estimation and should not be used in obtaining samples of cerebrospinal fluid or other fluids for sulphonamide estimations. Nupercaine, amylocaine (stovaine), and metycaine are not derivatives of para-aminobenzoic acid and are therefore free from these objections.

Little is known of the mode of action of local anæsthetics. Sensory nerves are affected before motor and the size of the nerve fibre determines the degree of sensitivity to local anæsthesia. There is also some evidence that local anæsthetics act partly at the myoneural junction, like curare. It appears probable that a reaction catalysed by an enzyme system occurs between acetylcholine and creatine phosphate, and that this reaction occurs when an impulse travels along a nerve. This reaction is inhibited by local anæsthetics such as procaine, and this inhibition seems to be due to a competition between acetylcholine and procaine for the same enzyme receptors (Rapp, C. G., *Arch. Biochem.*, 1947, **12**, 13).

Another possible mode of action is based on the interference with the carbohydrate metabolism of nerve cells, which utilize carbohydrate exclusively for respiration. For carbohydrate breakdown enzyme systems containing members of the vitamin-B complex, and possibly para-aminobenzoic acid, are essential. It is possible that the local analgesics, is changed for one of 0·5% ethocain in 0·86% solution with 1/250,000 adrenaline and the entire field of operation surrounded by a subcutaneous injection. The line of incision is also infiltrated with the same solution, and to constrict the blood-vessels, a point just anterior to the sternomastoid at the level of the superior thyroid pole, and one towards the lower end of the thyroid gland, are selected for deep injection beneath the pre-tracheal muscles of 10 c.c. of the weak solution. This constricts the vessels along the anterior border of the sternomastoid and of the superior pole of the thyroid, and we have found in the large number of cases both of thyroidectomy and for gland dissection that the operative field is far less bloody and that it permits of a one-stage removal of such a lesion as carcinoma of the tongue, combined with a block dissection of the glands of the neck, without serious shock or interference with healing. We usually prefer pentothal for the stage of diathermy excision of the tongue, though it is possible for this to be done under block anæsthesia as well.

Dr. F. W. Roberts: In my experience very good anæsthesia for abdominal operations can be obtained by a bilateral mid-axillary intercostal block of D6-D12. I use a mixture of equal parts of 1% procaine and 1/1,500 nupercaine, placing 10 c.c. in each intercostal space.

With a gentle surgeon splanchnic block is hardly ever necessary. I do not believe that there is any justification for the use of posterior splanchnic block. Its technique is difficult: Lundy in his book "Clinical Anæsthesia" reports 52% failure. The possible complications are by no means trivial, and it must be done before the operation—before it is known whether it is in fact necessary.

In the cases in which, after intercostal block only, traction of the bowel is necessary and seems to upset the patient, an anterior splanchnic block can be performed by the surgeon with more accuracy and safety.

Dr. S. G. Ransom: I would like to express appreciation of Dr. Norman James' careful consideration of the patient's comfort. These various apparently small points make disproportionate difference to his well-being.

To the "unnecessary withholding of food" I would like to add "unnecessary assault by the enema". There is apparently no reason for it whatever from the point of view of the anæsthetic, not for a general, still less for a local one, and it does considerably add to the patient's distress, making him windy after the operation and often unhappy before.

Mr. Harold Dodd: I wish to describe a method of local anæsthesia for abdominal operations which has been used with consistent success since May 1937 in thousands of cases. It is a combination of local infiltration in the area of the incision and of the operation, plus regional infiltration in the abdominal wall and splanchnic sympathetic nerves. Its advantages are its simplicity and also its consistent effectiveness. It is my practice to demonstrate it to my House Surgeon on the first day and after two or three occasions he does one side of the abdomen while I do the other.

It is not a complete method of anæsthesia in itself. It needs to be supplemented by a general anæsthetic during the general exploration and during that part of the operation where handling viscera may occur, as for example during a partial gastrectomy. Once this is dealt with, the general anæsthetic may be discontinued, i.e. before the abdomen is closed. I prefer to supplement it with open ether or trickle doses of pentothal. Gas and oxygen are not quite so satisfactory because of the heaving respiration which it causes and patients' inclination to vomit as they come round, often on the table.

I would emphasize that the supplementation is a sleep and not a full anæsthetic. It is discontinued for instance before the abdomen is closed.

The distribution is as follows, the surgeon does the incision, and one side of the abdomen, whilst his assistant does the opposite side. Time must be given for the anæsthetic to act; the anæsthetic medium is 1 : 1,000 amethocainewhich is sterilized by the autoclave and then 1 minim of 1 in 1,000 adrenaline is added to each ounce of anæsthetic immediately before use. The volume which may safely be used is 200 c.c. followed ten minutes later by a further 100 c.c. I have never seen any ill-effects from the use of this drug. It requires five minutes to produce anæsthesia. Before making the anterior splanchnic injection great care is taken to aspirate with the syringe. This ensures that the needle point is not in one of the large vessels in this area. Should blood be withdrawn the needle is taken away, pressure is applied with a firm swab for three minutes and the injection is remade.

Finally, a note on the size of the needle used. I find that a No. 15 hypodermic needle is best, and being short it makes the possibility of perforation of the peritoneum and puncture of the bowel slight. I always use a 5 or 10 c.c. syringe. This allows delicate work and does not fatigue the hand before the operation.

The following figures were shown and are to be seen in the *Post-Graduate Medical Journal*, 1946, 22, 389, "Local Anæsthesia for Abdominal Operations," by H. Dodd, Ch.M. (A Reprint will be supplied on request to Mr. Dodd, 42, Harley St., W.1.)

Having made the brachial plexus block, the patient is gently rolled over on to the sound side, or, as I personally prefer, on to the face, and an intercostal block, using 0·75% of ethocain in normal saline, which in this instance should be 0·75% in strength, given, containing 1/250,000 adrenaline. The block is carried out three fingerbreadths or about 4 cm. from the spinous processes, and must be carefully carried out in order to be sure of missing no intercostal nerve. 2, 3, 4, 5, 6 and 7 are injected, sometimes 8 as well, but it is an advantage to locate the first rib without injecting 4 cm. from the mid-line and opposite the seventh cervical spinous process (vertebra prominens). 10 c.c. per nerve is ample, and in order to avoid missing a nerve, two 8 cm. needles are used, one remaining in situ whilst the second needle leapfrogs from rib to rib until all six nerves have been injected. When this is completed the patient is again rolled gently on to her back and a solution of 0·5% ethocain in 0·86% saline with 1/250,000 adrenaline is used to surround the field of operation. A little over 1 c.c. of solution is used per cm. of the line extending along the whole length of the clavicle, down the middle line of the sternum along the costal margin, and along the eighth rib as far as the latissimus dorsi. In stout patients rather more solution is injected than in thin, the subcutaneous injection along the sternum should be especially generous since it is desirable to block the anterior perforating branches of the intercostal nerves on the healthy side to allow sufficient under-cutting. This concludes the measures necessary to secure analgesia.

The remaining solution must contain 1/250,000 adrenaline but need contain only 0·25% of ethocain. It consists of: First, injection into the anterior ends of the second, third and fourth intercostal spaces. This should be made with the needle point in contact with the deep surface of the costal cartilages and is designed to constrict the internal mammary artery with its principal perforating branches.

Second, an injection of 10 c.c. is made into the pectoralis major muscle at the level at which the surgeon will subsequently divide it.

Third, an injection is made deep to the pectoralis major and at the level of the upper border and of the lower border of the pectoralis minor muscle (10 c.c.). This is designed to constrict the pectoral and humeral branches of the acromio-thoracic artery, and also the long thoracic artery which runs along the lower border of the pectoralis minor muscle.

Fourth, injections are made on the chest wall of the axilla as high up as can be reached into the intercostal spaces in contact with the ribs. This is designed to constrict the lateral perforating branches of the intercostal vessels.

Lastly, an injection is made of 10 c.c. of the weak solution along the latissimus dorsi muscle, designed to constrict the trunk and branches of the long subscapular artery.

The patient will be ready for the operation to start as soon as these injections have been completed. No other injections are necessary, and in nearly all cases the patient slumbers peacefully during the operation. Blood loss is very greatly reduced, and we have found that shock, which is sometimes an alarming feature of a breast operation, has not been apparent.

The neck: In this region operations for removal of thyroid gland and for block dissection of glands of the neck are greatly facilitated by a relatively bloodless field, and by the absence from the vicinity of the operative field of an anæsthetist and his impedimenta.

I have used the lateral oblique route of Meeker and Hundling for cervical plexus block so often as to feel quite sure that the risks and occasionally reported fatalities from cervical plexus block are due to either intravenous or high intraspinal injection, and I have not only used this technique myself, but have had it done for me by three different anæsthetists and by house surgeons, and it has appeared to me as safe and eminently useful.

If the injections are made at a 45 degrees angle from above downwards, it is impossible to penetrate the spinal canal, and the usual precautions of using an unmounted needle and of aspirating before injecting will eliminate the risk of intravenous injection. The patient must be adequately premedicated, and in the case of toxic goitres a small dose of adrenaline should be given on the previous day to test for idiosyncrasy to this drug. In my experience real idiosyncrasy to adrenaline is uncommon.

The patient lies on her back with the face turned away from the side which is being injected. The tip of the mastoid process and the line of the cervical transverse processes are defined by palpation. Wheals are raised at the level of the tip of the mastoid 1·5 cm. below and 1·5 cm. below this again. The needle is inserted towards the line of the transverse processes and obliquely downwards towards the foot at an angle of 45 degrees. As soon as contact is made with bone, aspiration is carried out, and then 5 c.c. of 0·75% ethocain in 0·75% saline with 1/250,000 adrenaline are injected whilst the needle is moved to and fro through a distance of about one-half cm. When this is done, the remainder of the contents of the 10 c.c. syringe is injected as the needle is withdrawn towards the subcutaneous tissue. This first injection should reach the transverse process of the second cervical vertebra at the point where the downward sloping gutter between the anterior and the posterior tubercles gives attachment to the anterior and posterior inter-transverse muscles.

Having injected the second, third and fourth cervical nerves on the two sides, the solution

Section of Pædiatrics

President—DENIS BROWNE, F.R.C.S.

[*February* 28, 1947]

Lipodystrophy.—M. E. MACGREGOR, M.D. (for URSULA JAMES, M.R.C.P.).

A. W., 17.6.46: Brought to Victoria Hospital for Children, then aged 8 months, because of wasting of the limbs dating from birth.

Past history.—First child. Full term. Normal delivery. No asphyxia. Birth-weight 5½ lb. Breast-fed for six months. Circumcised at one week. No illnesses. Said to have lost 1½ lb. in first three days of life, but to have been ½ lb. above birth-weight by end of third week. Thereafter gained steadily. 14 lb. at time of first attendance. No *family history* of disease. From birth his limbs, especially legs, had been thin. Strength apparently normal and movements free.

On examination.—Limbs muscular. Little subcutaneous fat on legs, its lack being most pronounced distally. Some deficiency of fat in forearms also. Symmetrical distribution of fat loss. Hands and feet rather long. Face and trunk normal. Power of limbs and tendon reflexes normal. Mental and physical development otherwise normal for age.

Investigations.—X-ray of limb bones and electrical reactions of muscles of arms and legs were normal.

Diagnosis.—Lipodystrophy of unusual distribution. No treatment prescribed.

17.2.47: Weight 18½ lb.; age 16 months. Very healthy. Walks and has started to talk. Takes full mixed diet. Condition of limbs unchanged, but fat deficiency in legs and forearms is now more conspicuous.

Dr. Parkes Weber said that this case was unlike any previously shown to the Section or to the Society for the Study of Diseases in Children. It was obviously a congenital defect in the development of fat and thus probably different from the ordinary cases of lipodystrophy.

Congenital Defect of the Scalp.—SIMON YUDKIN, M.B., M.R.C.P. (for H. M. M. MACKAY, M.D., F.R.C.P.).

C. S., aged 4½ years.

History.—Birth-weight 4 lb. 4 oz., V.L.O.A. after a long but otherwise normal labour. At birth there were four areas on the vertex where the skin was absent. The areas were covered with granulation tissue and the edges appeared to be healing. The largest area was over the sagittal suture; there was a small area just in front of this, a third area over the posterior fontanelle and a small fourth area just behind this. The skull was deficient under the largest area as though the sagittal suture were very wide, and the posterior fontanelle was noted to be about twice the normal size.

Heart.—There was a soft systolic murmur at the apex.

Fig. 1.—Local anæsthesia of the upper abdomen as for a gall-bladder and stomach or an upper abdominal procedure.—It illustrates the local infiltration for a right paramedian incision. On the left side the numbers refer to the intercostal nerves. On the right side they refer to the volume of local anæsthetic injected; this may be increased to 10 c.c. at each point. The point of the seventh nerve is half-way between the ensiform cartilage and the intersection of the costal margin with the linea semi-lunaris.

Fig. 2 shows the method of subcuticular and deep injection for the local infiltration.—The needle is injecting subcuticularly 3 c.c. and is then almost withdrawn and reinserted vertically introducing a further 3 c.c. into the full thickness of the abdominal wall with pooling in posterior rectus sheath. The needle is kept as closely subcuticularly as possible to raise a wheal not as in this diagram.

Fig. 3 demonstrates the arrow-head injection.—The right side shows the correct method. The syringe is kept horizontally so that the needle may penetrate the full thickness of the flank. The left side shows how only part of the abdominal wall is infiltrated if the needle is introduced obliquely.

Fig. 4 outlines the local and regional injection for suprapubic cystostomy.—The former consists of the lower three-quarters of the mid-line between the umbilicus and the symphysis pubis. The latter is the arrow-head injection on both sides.

Fig. 5 indicates the local and regional injection for inguinal and femoral herniæ.—The local infiltration is superficially and deeply in the line joining the anterior superior iliac spine to the pubic spine. The regional insertion is the arrow-head injection on the side of the hernia, 10 c.c. in each direction.

NOTE.—The incision is from anterior superior iliac spine to pubic spine.

Fig. 6 gives the local and regional infiltration for appendix operations or colostomy (left side).—Incision for appendix operations (right side) or colostomy (left side) was indicated. The heavy line shows place of the incision which is infiltrated from the arrow-head injection to the pubic spine. All the structures of the abdominal wall may be divided in this line.

Fig. 7 illustrates anterior splanchnic anæsthesia.—The needle is introduced at the upper border of pancreas in the mid-line between the aorta on the left and the inferior vena cava on the right. The shadow of each is visible through the posterior parietal peritoneum. 40 c.c. of anæsthetic are pooled here. To expose the pancreas, the stomach is held down by the operator's left hand and swab as per the diagram. The liver is elevated by a Pannett's retractor.

Fig. 8 tells of local infiltration of the stomach.—On the right of the stomach note the insertion of 10 c.c. above and below the pylorus thus blocking the pyloric and right gastro-epiploic arteries. To the left a further 10 c.c. are injected at the lower pole of the spleen to insulate the nerves with the left gastro-epiploic artery. Just below the cardio-œsophageal junction exactly on the edge of the lesser curvature 10 c.c. of anæsthetic is pooled to neutralize the right and left vagus; the anæsthetic tracks round to the anterior and posterior surfaces of the stomach.

Fig. 9 points out the local infiltration for biliary tract operations.—The needle was introducing 10 to 15 c.c. into the gall-bladder bed. This allows stronger traction to be exerted on the gall-bladder thus revealing the common bile duct around which a further 10 c.c. of anæsthetic is introduced subperitoneally as indicated by the arrow.

Dr. Stanley Rowbotham (President): The problem of sedation with local anæsthesia has always baffled me. I have tried many of the barbiturates, but they have not, in my hands, proved wholly successful. I have used a product called "Pernocton" (not obtainable since the war) which kept the patient lightly asleep for a considerable time without excitement such as occurred during the elimination of many of the other barbiturates. On the whole I found that chloral hydrate by the mouth combined with small doses of omnopon subcutaneously gave the best results.

I have never undertaken to anæsthetize for radical breast operation by local alone, because I felt it would prove such an ordeal for the patient. Speaking of the cervical plexus block for thyroidectomy, I have personally anæsthetized a great many cases by this method, but I have not found it so successful as a properly performed infiltration. Mr. Molesworth, in fact, has said that he used local infiltration in addition to his cervical plexus block.

Referring to Mr. Harold Dodd's remarks, he (the President) could see no reason for using a solution of amethocaine stronger than 1 : 4,000. He found the posterior approach to the splanchnic area without difficulties, and equally effective as that performed after the abdomen had been opened.

13.1.47: X-ray. Further absorption of pneumothorax, with clearing of underlying lung. Physical signs: General condition very satisfactory; respirations quiet. Chest: No physical signs.

The interest of this case lies in the differential diagnosis and radiological progress of the cyst, there being three main possibilities, namely:

(1) A congenital cyst, (2) an encysted pneumothorax and (3) a pneumatocœle, in each case rupturing to form a generalized pneumothorax.

Congenital cyst is said to be a very rare anomaly, indeed its very existence is denied by some authorities who hold it to be invariably an acquired emphysematous condition, thus merging with the third diagnosis.

Encysted pneumothorax does not conform to the radiological findings which show the lung tissue curving round the periphery of the cystic area and the compression of the hilar structures typical of a cyst.

The most likely diagnosis is therefore that of a pneumatocœle. The pneumatocœle occurs during the course of a pneumonia, as in this case, the mechanics producing it being a check-valve bronchial obstruction caused by swollen mucosa leading to the formation of an obstructive emphysematous cavity. In this case there was certainly one such cyst, possibly two; the large definite one appearing in the area showing the signs of pneumonia. The cyst ruptured to form a pneumothorax, a phenomenon which as far as can be ascertained occurred in only two other cases of pneumatocœle, these being reported by Benjamin and Childe. The herniation of the pneumothorax across the mediastinum accompanied by the slight shift of the mediastinum confirmed the supposition that the air in the cyst was under tension. This is in keeping with the findings of Lister of America who demonstrated a positive pressure in these cysts by manometric measurements in the living subject. The uneventful recovery of the infant after the initial pneumonic attack was overcome is also in keeping with the case histories of other pneumatocœles.

In the discussion which followed, other similar cases of pneumatocœles occurring in older children were mentioned; these, however, had disappeared without any complications such as pneumothorax. Dr. Wyllie was surprised that the cyst had remained uninfected, attributing this to the early treatment with chemotherapy. Actually all the literature on the subject emphasizes the rarity with which these cysts are involved in complications, pointing out that they nearly always disappear spontaneously with no ill-effects either at the time or afterwards.

Traumatic Periostitis.—R. M. TODD, M.D., M.R.C.P., D.C.H.

P. J., female, aged 2 years 3 months.

History.—10.12.46 to 18.12.46: In hospital for septic area of skin overlying the right tibia. Treated with sulphathiazole by mouth and mag. sulph. locally.

22.12.46: Taken to hospital because of inability to walk on right leg. X-ray showed spiral fracture. Right tibia put in plaster. One week later plaster was removed because of painful swelling of right thigh.

6.1.47: Transferred to Queen Elizabeth Hospital for Children as case of osteomyelitis.

Past history.—No history of injury. Teething normal—no bleeding from gums. Never had cod-liver oil or orange juice at home, but has attended nursery. Has had fresh fruit when available.

On examination.—6.1.47: T. 99·6°, P. 120, R. 20. Flushed: Bruise on right side of face. Legs—Left: Slight pain on movement, no redness or swelling. Right: Lying in position of rest. Skin overlying lower end of femur, red, shiny and hot. Obvious swelling. Area of thickening over upper third right tibia. Nothing abnormal elsewhere.

Provisional diagnosis.—Osteomyelitis of right femur.

Course of penicillin commenced—30,000 units I.M. four-hourly for two weeks.

The ulcers healed well in about three weeks, and at the age of 4 months the anterior fontanelle was noted as being normal although the posterior fontanelle was still larger than normal.

Development was fairly normal although he has always been small for his age. X-ray examination at 1 year 8 months—skull, heart, long bones normal.

Family history.—Only child. Parents alive and well. No similar condition in any of the family.

On examination.—A healthy-looking boy, rather small for his age (weight 30 lb.). Scalp: Four areas of scar tissue with much keloid. Each area symmetrical in relation to skull mid-line.

There is still a systolic murmur at the apex.

Comment.—The symmetry of these lesions and their usual multiplicity, the fairly frequent presence of other congenital abnormalities, the occasional familial occurrence and the absence of any evidence of intra-uterine injury or amniotic adhesions suggest that they are developmental in origin. Ingalls has described several human embryos with a bullous area in the midline of the skull which appears to be the early stage of these defects.

The President said that a rather similar type of lesion could be caused by pressure due to prolonged labour and early loss of the amniotic fluid; these two types of lesions may be confused.

Dr. Parkes Weber thought that in this case the type of healing indicated an intra-uterine injury rather than a developmental defect.

Dr. Helen Mackay pointed out that these congenital defects of the skin were probably not rare, although usually small and so receiving little attention. A familial tendency was sometimes observed.

Pneumatocœle Occurring During Pneumonia and Rupturing to Form a Pneumothorax.—

JOSEPHINE HEBER, M.B. (for H. M. M. MACKAY, M.D., F.R.C.P.).

S. C., born 6.7.46. Normal pregnancy and delivery; birth-weight 7 lb. 12 oz.

Well until 7.12.46 when she was admitted to hospital, extremely ill, with very rapid and distressed respirations and marked cyanosis. T. 101°. Alæ nasi working. Chest: Signs of consolidation at right base.

Investigations.—10.12.46: R.B.C. 4,700,000, Hb 88%, W.B.C. 24,000, (P. 74%, L. 18%, M. 8%). 11.12.46: Throat swab. Moderate growth of *B. friedländer*.

Treatment.—Oxygen tent. Sedatives: Chloral 1 to 2 grains p.r.n. Chemotherapy: (*a*) Penicillin 10,000 units four-hourly, increased to 20,000 units four-hourly. (*b*) Sulphadiazine 0·5 gramme four-hourly, started at once.

Progress.—Remained extremely ill, with respirations of 90 to 100, for four days, after which slow improvement occurred. No abrupt changes. Temperature remained high, then slowly settled over fourteen days. Child too ill to X-ray initially. Physical signs slowly disappeared.

21.12.46: W.B.C. 12,000 (P. 22%, L. 56%, M. 14%). Sulphadiazine discontinued.

23.12.46: X-ray. Large unilocular air-containing cyst at right base. Remainder of lung appears compressed suggesting positive tension within the cyst. Mediastinum central. Physical signs: Dullness and diminished air-entry at right base.

28.12.46: X-ray. The air cyst at right base now ill-defined. Large mainly apical right pneumothorax present, with herniation of the upper anterior mediastinum across the mid-line and slight displacement of mediastinum to left. Partially collapsed lung shows irregular trabecular shadows. Left apical cyst has disappeared. Physical signs: No hyper-resonance. Dullness and diminished air-entry at right base.

30.12.46: X-ray. Right pneumothorax considerably less, with marked expansion of the underlying lung. Mediastinum central. No evidence of air-cyst.

9.1.47: X-ray. Small apical pneumothorax remains. Mediastinum now drawn to right. Penicillin discontinued.

(5) *Traumatic.*—Ossifying periostitis due to trauma in infants within the first three months of life is a well-known syndrome (Snedecor, Knapp, and Wilson, 1935) and is due to birth trauma and occurs particularly in breech deliveries. It can also occur in older children (Tietze's disease).

Conclusions.—Although there was no history of trauma in this case, the presence of spiral fractures of the tibiæ and a damaged right femoral epiphysis, and the subsequent clinical improvement with radiological signs of healing, confirm the diagnosis of traumatic periostitis.

Hyperelasticity of Skin.—E. M. KINGSLEY PILLERS, M.B. (for RICHARD DOBBS, M.R.C.P.).

V. R., aged 3½ years.

History.—Admitted for investigation of puffiness of hands and feet, and observation of mental capacity. *Family history.*—Nothing relevant known. Parents uninterested in the child who has recently been living with friends.

On examination.—Nervous and apprehensive. Intelligence probably normal. On admission there was marked puffiness of the hands which gave the appearance of a rubber glove filled with water. There was similar swelling on the dorsum of the feet. The finger-joints show hypermobility and this is present to a lesser extent in the toes which have deformed nails. The palate is high. At the sides of the apparently short neck are large folds of skin, which, when stretched, give a webbed appearance to the neck. Movements of head and neck normal. General physical examination revealed nothing abnormal.

Investigations.—Hb 84%, R.B.C. 5,000,000, W.B.C. 10,500. Blood cholesterol 175 mg.%.

X-ray long bones N.A.D. X-ray cervical spine: No Klippel-Feil deformity. Failure of formation of ossific centre for the upper anterior vertebral body margin of C5. Biopsy of skin: Normal histological structure.

The interest in this case lies, I think, in the diagnosis of which three possibilities must be considered: Klippel-Feil syndrome, Ehlers-Danlos syndrome and pterygium colli. Although bearing a superficial resemblance to a Klippel-Feil syndrome, the normal mobility of the neck and the X-ray of the cervical spine clearly eliminate this as a possible diagnosis. In Ehlers-Danlos syndrome three characteristics are usually found: hyperelasticity of the skin, hypermobility of the joints of the fingers and evidence of increased capillary fragility as shown by numerous bruises and cuts. This child shows the first two features of the syndrome but there is no evidence whatever of increased capillary fragility and the patient has had plenty of falls and minor injuries while playing with other children. In the previous cases of pterygium colli reported by De Briun and Kobylinski stress is laid that the folds at the sides of the neck are due to lack of skin in the cervical region. Normally the skin stretches perpendicularly downwards from the mastoid to the clavicle and then laterally from this point to the acromion. In these cases of congenital webbing, the skin is short and when the neck is rotated it is forced to bridge the distance from the mastoid to the acromion in a straight line. When, however, the neck is not rotated the folds are loose and feel soft. Other congenital abnormalities known to be associated with pterygium colli are also found in this case. I think the puffiness of the hands and feet may be due to congenital lymphangiectatic œdema, the palate is high, the toe-nails are deformed and as already noted there is hypermobility of the joints of the fingers and toes.

Investigation and progress.—7.1.47: T. 101·6°, W.B.C. 10,000 (metamyelocytes 3%, stabs 18%, polys. 36%, lymphos. 36%).

11.1.47: Temperature normal. Hb 80% (11·02 g.), R.B.C. 4,200,000, C.I. 0·9, W.B.C. 4,000 (stabs 9%, polys. 21%, lymphos. 61%), E.S.R. 3 mm. in one hour, platelets 156,000 per c.mm. Urine—No red cells: Ascorbic acid excretion 10 mg. in fourteen hours. Marked clinical improvement. Left leg normal. Right leg less swollen and tender. Temperature normal.

15.1.47: Bleeding time 50 seconds: Coagulation time one and a half minutes. Right thigh only slightly painful, not red, swelling still present.

21.1.47: Bony thickening of right femur, not tender. W.B.C. 10,000 (stabs 12%, polys. 45%, lymphos. 37%).

2.2.47: Walking round cot. No tenderness of legs. No pain on movement. W.B.C. 7,000 (polys. 42%, lymphos. 52%), E.S.R. 3 mm. in one hour.

12.2.47: W.B.C. 9,200 (stabs 3%, polys. 35%, lymphos. 54%).

X-ray appearances.—7.1.47: *R. femur*, diffuse subperiosteal new bone deposition over the lower two-thirds of the femoral shaft. There appear to be at least three separate layers of new bone and inferiorly the epiphyseal line is crossed. There is no evidence of fracture but slight posterior displacement of the lower epiphysis is not excluded.

R. tibia, there is an obvious spiral fracture involving the middle two quarters of the shaft of the bone. Position satisfactory. Moderately well-established callus is present.

L. tibia, 11.1.47: There is what appears to be a fracture line in the upper part of the L. tibia. 21.1.47: There is now a definite fracture of the upper part of the L. tibia and obvious periosteal reaction in the mid-shaft region.

X-ray conclusions.—The appearances are most easily explained by a traumatic ætiology producing spiral fractures of both tibiæ and damage to right femoral epiphysis with subperiosteal hæmorrhage spreading up the shaft of the femur.

Comment.—This case presented an interesting problem in diagnosis and the following possibilities have to be considered:—

(1) *Metabolic.*—The radiological appearance of subperiosteal hæmorrhage becoming calcified suggested the diagnosis of scurvy. Against it were (*a*) the absence of scorbutic changes in the gums and ribs, and the absence of red cells in the urine; (*b*) the presence of 10 mg. ascorbic acid in a fourteen-hour specimen of urine; (*c*) the absence of epiphyseal scorbutic changes.

(2) *Infective.*—(*a*) Syphilis—there were no clinical signs of spirochætal disease and Wassermann and Kahn reactions were negative; (*b*) osteomyelitis—multiple lesions are common in osteomyelitis of the newborn (Cass, 1940) and in these cases constitutional disturbance is minimal and prognosis is good. The age of this child was against the diagnosis, and white count and sedimentation were normal; (*c*) infection elsewhere in the body, e.g. intrathoracic lesions can give rise to extensive periosteal new bone formation which often has a laminated appearance as in this case. Against the diagnosis was the absence of clinical and radiological evidence of infection.

(3) *Neoplastic.*—In periosteal sarcoma the shaft of the bone is unaffected and there is rapid local and metastatic spread. Ewing's tumour can produce a similar radiological "onion-like" appearance. In this case the general condition of the child and the radiological picture were against a neoplasm.

(4) Recently a new syndrome occurring in children up to the age of two and a half years has been described by Smyth, Potter, and Silverman (1946) under the title "Periosteal Reaction, Irritability, and Fever in Young Infants", and by Caffey (1946) as "Infantile Cortical Hyperostoses", in which there is periosteal reaction in multiple bones. The facial bones are usually involved producing a characteristic facies. All the cases recover, but in the 17 recorded cases there was no evidence of fractures.

Biochemical examinations (Dr. W. W. Payne): Van den Bergh's reaction normal. Thymol turbidity ++ (19 units). Takata-Ara ++. Blood urea 18 mg. per 100 c.c. Blood cholesterol 245 mg. per 100 c.c. (The two brothers 160 and 181 mg. per 100 c.c.) Glucose tolerance and adrenaline curves normal. B.M.R. +4%. E.E.G. shows diffuse, fast and slow dysrhythmia and suggests idiopathic epilepsy.

The differential diagnosis was discussed and an idiopathic xanthomatosis suggested as most probable.

POSTSCRIPT.—Splenectomy and liver biopsy were performed by Mr. Charles Donald. Pathological report (Dr. M. Bodian):—The liver showed definite evidence of periportal cirrhosis. The liver cells were normal in appearance. The spleen showed moderate thickening of capsule and trabeculæ, and a rigid network of thickened reticulum in the pulp. The thickening of the reticulum was due to proliferation of reticulum cells and thickening of reticulin and collagen. These findings are indicative of Banti's syndrome.

Dr. Parkes Weber said that this might be familial Gaucher's disease and the abnormality of the phalanges might be due to minute collections of Gaucher cells. Another possibility was that the case might be one of the, as yet, imperfectly recognized lipoidoses.

DEMONSTRATION: DIAGNOSIS OF THREADWORMS

By J. M. WATSON, D.Sc., A.R.C.S., and R. C. MAC KEITH, D.M., M.R.C.P.

(*Wellcome Laboratories of Tropical Medicine & Institute of Child Health, University of London*)

INTRODUCTORY NOTE.—The accurate diagnosis of threadworm infestation depends on the recovery of the ova from the perianal skin. The clinical picture is unreliable for diagnosis and eggs are but rarely found in the fæces as the mature female worms emerge from the anus to oviposit on the neighbouring skin. Many devices have been used to recover the threadworm eggs from the perianal skin. Hall (1937) evaluated the comparative efficiency of those in use at that date and showed that swabs of cotton, chamois and rayon, and scrapers of celluloid, wood and metal were unreliable. He introduced the NIH cellophane swab which proved more convenient and more reliable than anything previously employed. Since that date several other methods of diagnosis have been introduced, some of which had certain advantages over the NIH swab. In a forthcoming paper it is proposed to record the results of controlled laboratory experiments and clinical trials designed to evaluate these diagnostic techniques. The demonstration was designed as a preliminary report making available some of our experience as to the relative practical usefulness of the methods. Only those which have proved to have definite individual advantages are described here.

(1) *NIH swab* (Hall, 1937).—A piece of transparent cellophane 3 × 1½ cm. is folded on the rounded end of a 4 mm. glass rod and held in position by a rubber band. The other end of the rod is inserted into a rubber stopper and the whole inserted into a 7/8 in. glass test tube for the protection of the swab in transport. The swab is applied to the perianal skin of the patient. The cellophane is removed and flattened on a drop of decinormal sodium hydroxide solution on a slide, two drops being placed on it and the preparation covered with a coverglass.

(2) *TP swab* (Watson and Mac Keith, 1946).—This device employs toilet paper in place of cellophane; the paper being applied with the finger or using a glass rod as with the NIH swab. The paper is rendered transparent by placing it, applied surface upwards, on a drop of clearing agent such as oil of wintergreen, another drop being added and the preparation covered with a coverglass. The eggs clear much more slowly than the paper and are readily visible against a translucent background.

(3) *Glass pestle* (Schuffner and Swellengrebel, 1943 and 1944).—For the pestle originally described we find a thick-walled test tube may conveniently be used, the lower end being roughened on a grinding wheel. For use the pestle tip is moistened with water and applied firmly with rotary motion to the perianal skin for about ten seconds. The ova, including those in the perianal folds, which may be missed by NIH or TP swabs, form with epithelial cells an emulsion which is transferred to a slide. It may either be covered with a coverslip and examined at once or else allowed to dry and examined at leisure after clearing with cedarwood oil or Monnig's medium.

(4) *Adhesive cellophane or Graham swab* (Graham, 1941).—3/4 or 1 in. cellophane adhesive tape is used. A 1½ in. length is applied to the perianal skin on the finger or on a glass rod as with the NIH swab. After application the tape is flattened on a glass slide to which it sticks. Examination may be direct but is facilitated by running a little decinormal sodium hydroxide solution under the

Dr. Parkes Weber said that Ehlers-Danlos syndrome consisted of cutis laxa, hyperextensibility of the joints and excessive friability of the cutis. The child in this case showed the first two features and was therefore an example of an incomplete form of this syndrome.

Cystic Disease of Bone.—N. F. ELLIOTT BURROWS, B. M. (for BERNARD SCHLESINGER, F.R.C.P.).

J. F., aged 6 years. Fourth child of normal parents. No relevant family history.

Quite well till October 1945 when he fell and fractured his right arm. Two days later fell again and refractured same area. X-ray revealed cysts of several bones, right humerus, radius, femur and tibia. Blood chemistry at this time: Calcium 10·4 mg., phosphorus 3·6 mg., alkaline phosphatase 27·5 units per 100 c.c. Fractures healed well.

Eight months later readmitted with fracture of right radius following a fall. Blood chemistry repeated showed practically identical figures to the previous estimations.

Dr. Herbert Levy suggested that the possibility of Rhesus incompatibility should be considered in these cases of polyostotic fibrous dysplasia (cf. H. Levy, *Brit. med. J.*, 1942 (ii), 738).

Dr. Parkes Weber said that this was obviously an example of osteitis fibrosa multiplex, i.e. it was of the same nature as the single fibrocystic lesions and was not due to parathyroid abnormality. Multiple instead of single cysts were present in the "multiplex" cases which might be termed "polyostotic focal fibrocystic dysplasia".

Hepatosplenomegaly.—J. P. M. TIZARD, B.M., M.R.C.P. (for DONALD PATERSON, F.R.C.P.).

V. T., female, aged 7 years.

History.—First-born child. Milestones delayed; always backward. No relevant illness until one year ago, when she had a single convulsion during a cold. Three further fits in January 1947 when she was otherwise in good health.

Family.—Two brothers aged 5 and 2 years, who are perfectly well and of normal intelligence. Both have livers palpable respectively two and three finger-breadths below the costal margin. Mother and father alive and well.

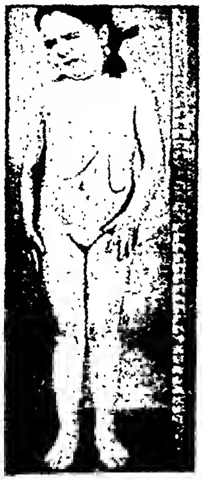

FIG. 1.

On examination (*see* fig. 1).—Height 46½ in. Wt. 58½ lb. Head circumference 20½ in. Dull expression, overhanging forehead; slow mentally and physically; spatulate hands, toes irregular in size, no lordosis, no limitation of joint movement. Coarse pale skin; slight icterus when first seen. Teeth widely spaced and carious. Protuberant abdomen; liver enlarged three finger-breadths, firm and smooth; spleen enlarged half-way to umbilicus; no ascites. Hypermetropia; no corneal opacities; fundi normal; deep reflexes sluggish.

Radiographs (Dr. F. L. Ingram).—Skull normal; long bones and spine normal; metacarpal bones and phalanges show irregularity of length and texture suggestive of enchondromatosis. (No abnormalities found in corresponding radiographs of the brothers.)

Investigations.—Blood examination (Dr. I. A. B. Cathie): 10.2.47: R.B.C. 3,670,000 per c.mm., Hb 80%, W.B.C. 6,300 (normal differential), reticulocytes 1·2%, red cell fragility normal, platelets 105,600 per c.mm.

28.2.47: R.B.C. 4,400,000 per c.mm.

Sternal marrow, leuco-erythroblastic ratio 3·5 : 1, otherwise normal.

Rhesus factor: Patient, Group A, Rh-positive; both brothers, Group A, Rh-negative; mother, Group A, Rh-negative, no antibody detected; indirect Coombs' test negative; a biological test cannot be carried out now as she is pregnant.

C.S.F. normal. Blood W.R. and Kahn negative.

With regard to the use of barbiturates as basal anæsthetics, allowing the patient to be brought to the theatre in an unconscious state, yet not sufficiently depressed for surgical procedures, I would like to stress the need to give sufficient of the barbiturate chosen. To do otherwise will bring disappointment, the child will often be in a wild, unmanageable state and induction of anæsthesia can be more difficult than if no drug had been given at all. It is probable that a dose of nembutal 0·7 grain per stone or seconal 0·75 grain per stone will be satisfactory. An injection of atropine should follow half an hour later.

The Induction and Maintenance of Anæsthesia in a Few Specific Surgical Procedures:

(1) *Tonsillectomy and adenoidectomy.*—This is still the commonest operation performed at any children's hospital. For this reason it is interesting to note that at Great Ormond Street neither the technique of the operation nor of the anæsthetic has changed very much since 1907. In that year Waugh, with the help of Sington, a past President of the Anæsthetic Section, began to dissect the tonsils and curette the adenoids under deep chloroform. Later a change was made to deep ether, using air or oxygen as its vehicle, for the anæsthetic agent. The vapour is delivered to the patient's mouth by a hooked metal tube, whose design has not changed since Waugh first described the operation. The airway is maintained by Waugh's gag whose jaws are made of small blocks of lead which fit snugly on the molar teeth, and the tongue is drawn firmly out of the mouth by a large pair of tongue forceps held by a nurse.

(2) *Abdominal surgery.*—In young babies the most frequent reason for a laparotomy is the condition of congenital pyloric stenosis. Some surgeons have excellent results with Ramstedt's operation, using local anæsthesia, others can point to a high degree of successful results using general anæsthesia. Ether and oxygen is the routine general anæsthetic used, and one is struck by the absence of post-operative complications when using ether. In addition, it is a personal opinion that the same good results are obtained by using ether on the other acute abdominal catastrophes of babies, for example, exomphalos, duodenal atresia and later intussusception. For these ill babies it has been my experience that the patient is brought more smoothly to a deep plane of anæsthesia if induction is performed with ether alone or with di-vinyl ether. Maintaining a perfect airway in these babies used to cause me anxiety, and I would therefore like to mention the very great help I have had from passing a No. 0 or 00 Magill tube through the mouth. All the advantages of the Magill tube in adult abdominal surgery are at once brought into play, and I do not think the delicate baby's larynx has suffered.

Etherington Wilson and others have described the use of spinal anæsthesia for babies undergoing major abdominal surgery. Bearing in mind the absence of post-operative complications in babies after general anæsthesia it has seemed safer to me to employ the latter method. This choice may be because I have not had sufficient experience in spinal injections on children. It will therefore be helpful to hear the views of others who have had more experience in this technique.

Hirschsprung's disease.—The neurological theory of autonomic imbalance as the causation of this condition is well known as is also the work of Telford (1939) who first used spinal analgesia in this condition here. This work has been continued since 1939 and described by Hawksley (1944). Cases treated by high spinal analgesia have also been described before this Society by Hawksley (1943), and by Court and Hasler (1942). Due to the war my own experience is small; it began in 1945 and is limited to 10 cases. I personally find paralysis of the whole sympathetic supply of the colon, which has been shown to reach as high as the 5th thoracic segment, to be more certain by using the Howard Jones method of dosage for nupercaine 1 in 1,500 solution. The youngest patient in my own series was 20 months.

The subject of autonomic nervous system imbalance does not end with Hirsch-tape and between it and a superimposed coverglass. The NaOH is unnecessary where the cellophane is applied with the finger, as in this case it is not dry and easily lies flat on the slide.

(5) *Direct slide* (Petersen and Fahey, 1945).—An ordinary 3 × 1 in. glass slide is pressed against the anal mucocutaneous junction so that one edge of the slide is towards the centre of the anus. The opposite edge of the slide is similarly applied to the opposite anal margin. The eggs adhere to the slide. The slide may be examined direct or after addition of a clearing agent or decinormal sodium hydroxide solution.

(6) *Brush* (Watson and Mac Keith, 1946).—This is an adaptation of the method of Nolan and Reardon (1939) for collecting household dust for examination for threadworm eggs. The small camel-hair brush is moistened with water and applied to the folds of the perianal skin with a stroking motion. For examination it is gently dipped into a few drops of decinormal sodium hydroxide solution in a deep well-slide. Any eggs present collect at the bottom of the well-slide, and are quickly found.

(7) *Vaselined cloth* (Hellsten, 1933).—This method is mentioned as it was omitted in Hall's (1937) review.

In replying to the discussion **Dr. Ronald Mac Keith** said that in deciding which is the best of these methods one had to consider the qualities of the devices: Reliability, simplicity of use (especially if parents are asked to do the necessary serial tests on the child or on themselves), ease of preparation and of cleaning for further use, and simplicity of examining the slide or preparation for ova. The NIH swab is sometimes inconvenient to read if the cellophane is stiff and dry. The TP swab is soft material which is readily obtained. The direct slide method is not always easy to examine but only a slide is required. The brush method is rather more complicated in preparation and cleaning but is simple to take and is the quickest and simplest for examination for ova. For routine use in survey work, he would recommend either the pestle-slide or the adhesive cellophane (Graham swab) methods, the latter being probably the most convenient for occasional diagnostic use.

DISCUSSION ON ANÆSTHESIA IN CHILDREN

Dr. R. W. Cope: In this Discussion we shall consider the principles rather than the details of technique underlying children's anæsthesia.

Apart from the difference in size of the actual apparatus and dosage of drugs used, how does this anæsthesia differ from that of adults? The reason for considering these differences lies in the fact that a bad anæsthetic will kill a child far quicker than it may kill an adult. A small degree of respiratory obstruction will rapidly change a normal, healthy baby to one who is grey, does not breathe at all, whose pupils are beginning to dilate and whose life is slipping quickly away.

The normal metabolic rate.—This is of importance throughout every moment of a child's anæsthesia. In the human subject the curve of oxygen demand and reflex irritability are parallel. The normal child therefore between the ages of 2 and 12 years will tolerate larger amounts of anæsthetic than might be expected for the size of the patient. A further point in this connexion is that the most frequent factor in producing a temporary rise in metabolism is apprehension and fear. Herein lies the great value to the anæsthetist—quite apart from the inestimable value to the parent and child—in the pre-operative administration of the barbiturates. By allaying fear and inducing normal sleep they are effective in lowering the increased metabolism. Since 1938 it has been the routine practice to use one of the barbiturates, either nembutal or seconal, before most operations at Great Ormond Street Hospital. To deprive a child unnecessarily of the benefit of this simple medication must help to put Medicine back many years.

the tube tends to slip upwards (i.e. anteriorly) into the glottis rather than downwards. Alternatively a stilette may be used in the tube and the tip tilted slightly upwards.

And here I should like to urge the abandonment of that prevalent practice among anæsthetists of using the right hand for introducing the laryngoscope, and having exposed the cords, changing over to the left, which is at best an awkward and inefficient piece of technique.

Having passed the tube and connected up to the apparatus, the first act of the surgeon after draping the child is to secure the endotracheal tube by stitching it to the tongue. This is done because the child is being carried at a very light stage of anæsthesia and is able to gag the tube out of the glottis. Furthermore, the surgeon may inadvertently withdraw the tube whilst changing a throat pack. I have seen both these accidents.

Now to consider the actual anæsthetic.

Premedication consists of atropine only.

Induction is with gas and oxygen and here great care must be exercised. The margin between consciousness and anæsthesia is a very narrow one and whereas at one moment you have a lustily crying baby, the next you may be faced with a deeply cyanosed, limp child who makes no effort at voluntary respiration and who is very near death. Having induced the child, ether is added until anæsthesia is deep enough to enable a tube to be introduced. I never use a throat spray which I consider superfluous. From now on the child is run on gas and oxygen. I find 20% oxygen sufficient and this proportion can be reduced with safety if necessary. The ordinary expiratory valve is used (fully open, of course), there being no necessity for an open outlet to the air. These children remain a good colour and respiration is as a general rule quiet and unhurried. With this rather high percentage of oxygen anæsthesia tends to lighten and usually drops to the second stage. Yet in spite of the light plane of anæsthesia, the absence of sedative premedication and the avoidance of a throat spray, these children tolerate the presence of a tracheal tube without coughing or straining. Nor does sickness occur either during or after the operation. When at the end of the operation the tube is finally removed, the child is fully awake and crying within a minute or so, apparently none the worse for its recent ordeal.

The operation for cleft palate is carried out in children at the age of about eighteen months. Nasal intubation is used in these cases and once again the tube is a problem. The Magill tube tends to kink just inside the nostril where it fits on to the metal connecting piece. The Woodfield-Davies tube has a collar and flange fitted to its proximal end and effectively overcomes this trouble by reason of the collar which reinforces the tube at its vulnerable point.

Regarding blind intubation, generally speaking the younger the child the less likely you are to succeed. Before abandoning this method it is worth while placing the fingers of the left hand under the neck and exerting a firm upward pressure at the moment of pushing the tube on. This manœuvre will often cause the tube to slip into the glottis. Incidentally it is frequently successful in the case of adults. If it is necessary to resort to the laryngoscope, a fine pair of crocodile forceps is preferable to Magill's laryngeal forceps which are somewhat bulky in this small space.

The anæsthetic for these cases is very similar to that for hare-lip.

In view, however, of the constant swabbing and sucking out of the pharynx excessive gagging often becomes troublesome to the surgeon and it is usually necessary to add at intervals small amounts of ether. But this is never sufficient to cause abolition of this reflex by the time the operation is over, since the surgeon is anxious at this point to test the child's ability to close the pharynx following his handiwork. When diathermy is used trilene is given instead of ether, but I find these children remain drowsy, sometimes for long periods, and do not recover so well as the others.

sprung's disease. The condition of congenital hydro-ureter has been investigated by spinal analgesia. What neurological imbalance is present here? And, if there is imbalance, what help can anæsthesia give? Scholefield and Chivers (1947) have recently published a report of the results of injecting the splanchnic ganglia with weak amethocaine solution in 5 cases of congenital megacolon. The results were encouraging, and it is hoped to repeat their work shortly.

Dr. D. Aserman: *Anæsthesia for hare-lip and cleft palate.*—The operation for hare-lip is performed on children of about three months. An infant of this age requires a No. 0 or No. 1 size endotracheal tube which is passed through the mouth. The ordinary Magill tubes in these sizes are too thin and flimsy to be safe, since, however carefully they are connected up, there is a considerable risk of kinking.

To overcome this difficulty Mr. Humby and I evolved at the beginning of the war the Humby Tube which I continued to use for some considerable time. But this tube was designed primarily for use with the Davis gag which held the tube snugly and firmly in position and assured a correct alignment of the rubber end-piece. In the absence of the Davis gag, however, the fitment tends to ride upward in the mouth, occasionally causing a slight bending of the rubber tube at its junction with the metal and thereby a certain measure of respiratory obstruction.

Mr. Denis Browne's solution of this problem consists of a reinforced tube—an ordinary Magill tube cemented within a tube of larger bore, the inner tube being prolonged beyond the outer to the extent of an inch and a half or so. This tube can be bent to almost any angle without kinking; it is simple and inexpensive and I now use it for all oral endotracheal work in children with complete satisfaction.

(I must point out that, although the first tube I saw was that of a rough model made by Mr. Denis Browne, yet apparently Dr. Magill had produced an identical tube a good many years previously.)

Two other tubes should be mentioned in this connexion. The Magill armoured tube is excellent, but it is expensive, delicate in structure and easily damaged. Portex tubes tend to soften as they warm up to body temperature and, at any rate in the sizes under discussion, they are not safe.

Turning now to the actual introduction of the tube, this little operation in the case of hare-lip can be extremely difficult. In the choice of laryngoscope my own preference is for the Magill and I invariably use the adult size blade, even in the case of the smallest infants. This gives that extra amount of room which can be so helpful. I am equally at ease with the right-angled or Guedl-angled patterns. In the case of hare-lip associated with cleft palate, on introducing the laryngoscope the edge of the blade is liable to slip into the cleft and one free end of the alveolus may drop into its lumen. When this occurs it is usually impossible to pass a tube through the restricted space and I know of no cases more difficult to intubate than these. Mr. Denis Browne has designed a special spatula to deal with this problem. This is somewhat similar to a Magill but is much broader at its proximal end and this extra width is intended to bridge the gap in the alveolus. I, personally, prefer manœuvring the ordinary spatula into position, usually by introducing it well over to one side.

It is in many cases impossible to expose the cords fully and only the posterior portion of the glottis can be seen. On attempting intubation in this situation the tube often refuses to enter the glottis and slides downwards off its posterior aspect. This can be overcome by recutting the end of the tube so as to bring the chamfer to its lower aspect, whereas it normally lies to the left. It will now be found that

Urine: Acid, alb. 1,600 mg.%. Deposit—a few W.B.C., R.B.C. and casts. Blood urea 38 mg.%. Serum protein 3·9%.

Put on to high protein salt-free diet. Total 82 grammes protein per day. Œdema rapidly subsided and clinical condition improved.

28.3.47: Plasma—Fibrin 0·48%, alb. 2·18%, glob. 1·83% (total 4·49%). Blood cholesterol 408 mg.%.

2.4.47: 2 grammes NaCl added to diet. Œdema immediately increased, marked rise in weight.

8.4.47: Diet salt-free again, weight remained stationary.

10.4.47: 2 grammes KCl added to diet followed by fall in weight.

Hypoplastic Anæmia.—I. A. B. CATHIE, M.D.

E. J. B., female. Normal birth (28.3.45). No neonatal jaundice.

Family history not significant.

History.—Pallor since birth; at 3 months Hb 24%, rose to 80% after transfusion but within a month had fallen to 49%. Further transfusions given. At 3 months passed bright blood in stool once. At 4 months purulent right ear discharge.

Admitted 29.9.45, aged 6 months. Well-nourished. Slight icteric tint to sclerotics. Liver enlarged 1 in. and spleen 1½ in. Right ear discharging.

Investigations.—Blood-count: R.B.C. 1,330,000, Hb 30% (4·2 grammes), C.I. 1·1. W.B.C. 17,700 (lymphos. 54%, poly. neutros. 44%, eosinos. 2%). Reticulocytes 0·2%, normoblasts 2 per 100 W.B.C. M.C.D., M.C.V. and M.C.H.C. within normal limits. Platelets 350,000. Red cell fragility normal. Cold agglutinin titre 1 : 4 at 8° C. W.R. and Kahn negative. Blood cholesterol 95 mg. per 100 c.c. Blood phosphatase 14 units. Takata-Ara reaction negative. Serum bilirubin 2·5 mg. per 100 c.c. Histamine test meal showed hypochlorhydria. Mantoux negative. X-ray chest and long bones—no abnormality. Bone-marrow (*see below*).

Progress: Since first admission, transfusions given about every six weeks, but Hb level falls steadily in intervening periods. Numerous forms of therapy have been tried, including iron, liver extract, proteolysed liver, vitamin B, ascorbic acid, thyroxin, penicillin, sulphonamides and bilateral mastoidectomy, without success.

Present condition: Aged 2 years, weight 28 lb. Does not walk. Readmitted 28.3.47 with bronchopneumonia and purulent discharges left eye and left ear. Liver 2½ fingerbreadths below costal margin. Spleen much enlarged.

Blood-count: R.B.C. 3,200,000, Hb 65% (9·1 grammes). W.B.C. 19,300 (polys. 73%, lymphos. 27%). 1.4.47: Transfusion of 1 pint. Hb next day was 100% (14·0 grammes). On 8.4.47 reticulocytes less than 0·1%. 10.4.47: Folic acid 15 mg. daily (intramuscularly).

Dr. I. W. Magill said that children do not stand suboxygenation well. He had abandoned nitrous oxide in favour of ether for dissection of tonsils and was convinced that results were better with this agent. In premedication, he was surprised that more use had not been made of opiates in suitable doses since such drugs were indicated where the metabolic rate was high, as it usually is in children.

Endotracheal tubes of rubber composition were made by different manufacturers and varied much in consistency. It was the duty of the anæsthetist to see that the tube was satisfactory before using it. For hare-lip and cleft palate operations in infants he had experimented with tubes of gum elastic, metal, and rubber composition, including tubes of different calibre cemented together. He had found an armoured tube satisfactory. The anæsthetic was delivered directly into the funnel-shaped outer end by a side inlet. There was no rebreathing. A useful protection for this tube was a small gutter made of malleable metal applied at the point where the tube rested on the alveolus.

[*April* 18, 1947]

MEETING HELD AT THE HOSPITAL FOR SICK CHILDREN, GREAT ORMOND STREET, LONDON, W.C.1

Diabetes Insipidus.—B. W. POWELL, M.B., M.R.C.P. (for BERNARD SCHLESINGER, F.R.C.P.).

G. L., boy aged 1 year; failed to thrive since 4 months. Thirst since birth.

Family History.—First pregnancy. Father's father and two brothers have diabetes mellitus.

History of present illness.—Since 4 months old has had bouts of vomiting lasting two to three days, coming on at intervals of several weeks. Has always been very thirsty and now gets three to four pints in a day. Has always been constipated.

On admission: Weight 14 lb. 10 oz., height 26·5 in. A wasted baby but with good hydration clinically. Liver edge palpable and tip of spleen just felt. Mantoux 1 : 1,000 negative. X-ray skull normal.

Blood-count: R.B.C. 4,400,000, W.B.C. 18,500.

Blood chemistry—28.3.47: Urea 53, chlorides 852, protein 7·4.

31.3.47: Urea 42, chlorides 637, protein 6·8, bicarb. 57 vols.%.

8.4.47: Urea clearance 81% of normal. Blood urea 40.

9.4.47: Total volume urine excreted 37 oz. S.G. 1002 (intake 50 oz.).

In view of normal kidney function and continued polyuria and thirst, is thought to be a case of diabetes insipidus.

Nephritis with Œdema.—B. W. POWELL, M.B., M.R.C.P. (for BERNARD SCHLESINGER, F.R.C.P.).

B. W., boy aged 3 years.

6.3.47: Loss of appetite, pale stools, dark urine (mild hepatitis).

9.3.47: Urine became scanty and œdema developed. No albuminuria at this time. Improved on high protein diet but after a few days œdema increased again and abdomen became swollen.

12.3.47: Seen as out-patient. Some œdema. No albuminuria. Blood urea 27 mg.% Plasma proteins: Fibrin 0·4%, albumin 1·36%, globulin 1·83% (total 3·59%), alb./glob. 0·75 : 1.

20.3.47: Admitted to hospital. Gross œdema. Tonsils large. Heart: Apex beat 5th space anterior axillary line. B.P. 115/70. Fundi normal. Abdomen: Some ascites.

erythroblastæmia were recorded as important features. Next, interest shifted to the pathology, studied and fully described by German investigators, between 1910 and 1920. Finally, the anæmia developing unexplainably in newborn infants was considered a new entity, shortly after 1920.

Our own interest in and experience with erythroblastosis fœtalis dates back twenty years, and in 1932 we collected and published records of 20 infants, suffering from œdema at birth, or jaundice and anæmia shortly after birth, splenomegaly and erythroblastæmia—all being manifestations of a single underlying morbid process.

The discovery of the Rhesus blood factor in humans in 1940 and in 1941, its important relation to erythroblastosis fœtalis, once more focused attention on this disease. In the succeeding five years, so much has been written on the Rh factor, and the disturbances which result from it, that it is worth while reviewing the subject and considering what is established fact and what is hypothesis.

The Rh blood factor is present in the red cells of 85% of the white population and absent in 15%. Since it is foreign to the system of the latter group, the Rh factor can act antigenically to start isoimmunization, when introduced into the body, either by transfusion or, in women—and even then only in a small percentage of them—by pregnancy. The antibodies produced by the Rh-negative individual, after sensitization, are agglutinins, capable of clumping and eventually destroying Rh-positive red cells. It usually requires one or more transfusions of Rh-positive blood into an Rh-negative patient, and an interval of two weeks or more, before a hæmolytic reaction is produced.

In women, subject to sensitization via pregnancy, even a first transfusion of Rh-positive blood may cause a serious untoward reaction. The factors which govern this are, first, the combination of an Rh-negative mother and an Rh-positive father, to whom are born Rh-positive children. These may serve to sensitize the woman when fœtal erythrocytes or tissues enter her circulation during gestation. Thereafter, the transfusion of this Rh-negative woman with Rh-positive blood will lead to a hæmolytic crisis.

Actually the danger of isoimmunization of the Rh-negative woman by pregnancies involving an Rh-positive fœtus is relatively small, since about 13% of all marriages are between an Rh-negative woman and an Rh-positive man, but only 1 in 150 deliveries produces an infant with erythroblastosis fœtalis, and even so the first Rh-positive infant almost always escapes. This means that less than one such woman in twenty need be concerned about becoming sensitized through pregnancy alone. However, a single transfusion of Rh-positive blood, followed by pregnancies, will increase the chances of trouble from 5% to over 50%.

Another hazard of isoimmunization following transfusion affects the fœtus. If an Rh-negative woman is given Rh-positive blood, the antibodies which develop may produce hæmolytic disease in any subsequent Rh-positive fœtus, even if it is a firstborn.

The modes of Rh sensitization of the Rh-negative woman then are, first, through transfusion of Rh-positive blood, second, through repeated pregnancies with Rh-positive babies, and third—a little appreciated menace—through the injection intramuscularly of even small amounts of Rh-positive blood, a mode of therapy fortunately now discarded for the treatment of hæmorrhagic diseases, pernicious vomiting of pregnancy and stubborn dermatitis. Although such intramuscular blood probably does little or no harm alone, if followed by Rh-positive pregnancies, even years later, it may be important in initiating isoimmunization.

The woman who, through any of the above mechanisms, has become sensitized against the Rh factor, may face several serious problems in subsequent child-bearing. If she is fortunate enough to marry an Rh-negative man—about one chance in seven—she need have no fears, since Rh-negative children will not be affected. If the sensi-

Sturge-Weber Syndrome.—N. F. ELLIOTT BURROWS, B.M. (for W. G. WYLLIE, M.D.).

A. McK., aged 1 year. Born with capillary angioma over entire left side of face and scalp. History of frequent twitchings, and turning of the eyes generally to the right. Pneumo-encephalography revealed a gross defect inside the skull on the side corresponding to the angioma.

Dr. F. Parkes Weber considered the diagnosis completely proved. The typical calcification would probably develop later. In regard to the relative parts played by Dr. W. Allen Sturge (1879), the pathologist, Dr. S. Kalischer (1901), and others, in the discovery of the syndrome, *see* F. P. Weber, *Rare Diseases and Some Debatable Subjects*, second edition, London, 1947, p. 9.

Dr. Parkes Weber continued: The condition is obviously a result of dysplastic development (partly definitely "hamartomatous") of the vascular elements of the affected portions of the skin and lepto-meninges (with underlying surface of the cerebral cortex). Sometimes there is congenital glaucoma (buphthalmus) on the same side as the cerebral lesion—evidently of analogous dysplastic origin. Apart from a possible inborn tendency in some families to dysplastic and hamartomatous development of various kinds, the condition seems not to be hereditary, but seems more likely due to some local accident of unknown causation, affecting the embryo during early intra-uterine life. Cases of the syndrome are by no means so rare as was formerly supposed.

Exophthalmic Goitre.—J. M. ALEXANDER, M.R.A.C.P. (for W. G. WYLLIE, M.D.).

J. L., aged 9 years, the second child of nervous parents, started having night terrors about 6 months before admission, when eyes became protuberant and pulse very fast. Also had profuse sweats.

On admission: Enlargement of thyroid gland, and fibrillary tremor of outstretched hands.

POSTSCRIPT (22.7.47).—Thyroidectomy has been performed. Symptoms have disappeared and eyes now appear normal.

Neurofibromatosis.—J. M. ALEXANDER, M.R.A.C.P. (for W. G. WYLLIE, M.D.).

M. B., aged 10 years, only child of healthy parents, born with two café-au-lait spots on buttocks and one on chest.

In 1941 had a fall; left shoulder became swollen two weeks later; glandular swelling in this region. Biopsy: Neurofibromatotic tissue. Given deep X-ray treatment, but three months later egg-shaped swelling underneath outer part of left clavicle reappeared. Café-au-lait spots increasing in number.

Pseudo-hypertrophic Muscular Dystrophy.—J. M. ALEXANDER, M.R.A.C.P. (for W. G. WYLLIE, M.D.).

G. Y., aged 5 years, has had difficulty in walking, particularly upstairs, for three years. "Climbs up himself".

Weakness of proximal muscles of legs and hypertrophy of calves.

[*May* 23, 1947]

Erythroblastosis Fœtalis or Hæmolytic Disease of the Newborn

(*Abstract of Illustrated Talk*)

By LOUIS K. DIAMOND, M.D.

(*The Children's and Infants' Hospitals, and Harvard Medical School, Boston, Mass.*)

RECENT and more widespread interest in erythroblastosis fœtalis or hæmolytic disease of the newborn has led to the erroneous impression that this is a new condition of recent origin. Actually it was well described, in the English literature, before 1900, being then recognized in the form of fœtal hydrops. Between 1900 and 1910, there were numerous articles, published in this country, dealing with familial icterus gravis, another manifestation of the same disease, and even the severe anæmia and

and fortunately did not recover. If they did improve, marked developmental retardation and muscle unbalance might result. Pathologically, kernicterus was usually found in such patients. This is a diffuse and symmetrical staining of nerve cells. It is unrelated to simple mechanisms such as intravascular thrombi or agglutination of red cells.

The tendency for the recurrence of infants with erythroblastosis fœtalis was always disturbing, especially since the disease became progressively more severe in succeeding siblings. Often, this resulted in the birth of hydropic stillborns, with severe anæmia, tremendous splenomegaly, hepatomegaly, and dilated hearts. Then again, a single child might escape serious damage and exhibit only moderate and easily repaired anæmia.

Not all of these clinical observations have been explained by the discovery of the Rh factor and the knowledge of the action of anti-Rh agglutinin on the Rh-positive infant's red cells. The serologists have tended to oversimplify the pathogenesis of the disease and draw too many analogies between what happens in the baby and what can be demonstrated in the test-tube.

With the disclosure of the role of maternal Rh antibodies in damaging the infant's Rh-positive red cells, it seemed logical to use only compatible Rh-negative blood for transfusion of the anæmic infant with erythroblastosis fœtalis. Such transfusions were given as frequently as needed, always into an easily accessible superficial vein, in amounts of about 10 c.c. per pound of body-weight, using a pressure system. More may be given, but if the infant has cardiac dilatation or a tendency to develop petechial hæmorrhage, sudden collapse may occur during large transfusions from cardiac decompensation or diffuse hæmorrhage.

During a period of about three years when our treatment consisted only of repeated small transfusions of Rh-negative blood, the gross mortality from erythroblastosis fœtalis seen in our clinic was about 30%. This improvement may have been due to earlier recognition and treatment of such infants as well as the use of Rh-negative blood transfusion.

By 1944, most of the obstetricians were well aware of the dangers of Rh antibodies in Rh-negative women, and were testing such patients more regularly. We had organized several prenatal clinics for the care of these problems and were following the titres in sensitized women throughout pregnancy. It was always distressing to detect a rising or a high titre, to wait for the delivery of the infant at term, and to have the infant succumb *in utero* only a few weeks from term, or even shortly after birth. In such cases, it seemed reasonable therefore to try to deliver the sensitized woman two or three weeks before term. During the years that this has been practised in conjunction with frequent transfusions of Rh-negative blood, as needed, the gross mortality has been lowered to 20%.

Finally, another improvement in therapy was attempted. We had shown for some time that the erythroblastotic infants who were most seriously ill or suddenly collapsed after being quite normal in appearance at birth, usually showed free maternal antibody in their cord blood. It seemed likely that this continued acting in the child's system and caused the sudden change for the worse in succeeding days. In addition, many of the babies' red cells were proved to be coated with maternal antibody. The removal of as much as possible of the affected infant's circulating blood, shortly after birth, in proper cases, seemed desirable.

The first attempts to do an early exsanguination-transfusion were complicated by mechanical difficulties. The longitudinal sinus is a dangerous vessel to puncture blindly, particularly in a newborn infant, whose head is moulded out of shape with normal anatomic relations distorted. Peripheral veins are small and fragile. Even arteries may be too small for ready cannulization and the exposure of a sick newborn infant for an hour or two while vessels are exposed and used may be a cooling and tized woman has an Rh-positive husband who is homozygous, i.e. carries two Rh-positive genes, every infant will be Rh-positive and will be affected, usually with increase in severity of the disease. If the husband is heterozygous, Rh-negative children are possible and only the Rh-positive infants may have erythroblastosis fœtalis.

It is important, therefore, not only to determine the Rh type of every recipient of blood and every woman during child-bearing, but if Rh sensitization is detected in the woman, to test the husband's blood for homozygosity or heterozygosity and so be able to prognosticate the chances of successful pregnancy. For such special tests, the ordinary simple Rh-typing serum must be supplemented with special specific anti-Rh serums which can only be found in certain diagnostic laboratories.

Prior to 1944, tests for sensitization of Rh-negative individuals were often quite unsatisfactory since, even in instances of proven hæmolytic transfusion reaction or definite erythroblastosis fœtalis, the serum of the affected individual often failed to disclose Rh agglutinins. In 1944, new tests were developed which detected antibodies coating Rh-positive red cells or blocking their further agglutination in saline suspension, or clumping them only in protein media. These new and more complex antibodies were named "incomplete antibodies", "blocking antibodies" or "hyperimmune antibodies". The latter name arose from the finding that if human experimental subjects were injected repeatedly with Rh-positive blood cells, their serum first contained ordinary agglutinins acting against Rh-positive red cells suspended in saline. These were named "early antibodies". With continued injections, such Rh-negative persons gradually lost their simple Rh agglutinins, but developed the "incomplete" or "blocking" form which no longer agglutinated Rh-positive cells in saline but did become attached to such cells and could clump them in plasma, serum, or albuminous suspension media, and, of course, did produce agglutination within the body. These were named "hyperimmune antibodies". They are more complex, much more stable and long-lasting and probably can produce more damage, especially to Rh-positive infants developing erythroblastosis fœtalis.

Just as in these experimental subjects stimulated by blood injections, Rh-negative women bearing Rh-positive infants, tend first to develop early saline-acting agglutinins but with succeeding pregnancies, form more of the hyperimmune antibodies and, later, only this form. However, the form of Rh antibody and its concentration or titre bear no direct relation to the severity or the type of erythroblastosis fœtalis which develops in the child of the sensitized woman.

Certainly only the roughest parallelism is to be found between the type of Rh antibody and its amount during and after pregnancy, and the form of the disease or its severity in any given infant. In general, the hyperimmune and high titred Rh antibodies are found in association with the more serious or more often fatal types of hæmolytic disease in the newborn. But a prognosis based on antibody tests and titres, in any given case, must be offered with reservations.

With regard to the clinical problems faced by the pædiatrician or practitioner, our own experience began about twenty years ago, when we first treated newborn infants with jaundice and anæmia, using compatible blood from the father (therefore Rh-positive) for transfusion. Many transfusions were often necessary since the red cells did not seem to survive long, but eventually a majority of such children recovered, especially if they had no complications such as severe jaundice, œdema, diffuse hæmorrhage or cardiac failure with secondary pneumonia. Over a period of fifteen years, including the infants who were born dead and diagnosed by the pathologist, we found a gross mortality of about 40%. Several features were intriguing then, just as they are now. Often, newborn infants displayed very little anæmia, but developed early and severe jaundice. Transfusion did not materially benefit these and sometimes they developed signs of brain damage, about the fourth or fifth day of life,

Section of Neurology

President—DOUGLAS MCALPINE, M.D., F.R.C.P.

[*February* 6, 1947]

CLINICAL MEETING HELD AT NATIONAL HOSPITAL, QUEEN SQUARE, LONDON

Dystonia Musculorum Deformans with Another Case in the Same Family.—DIANA BECK, F.R.C.S.

A. S., a schoolgirl, aged 8½ years, regarded as hysterical, but was referred to the Neurosurgical Unit from an orthopædic clinic for exclusion of organic disease.

The child of a normal, full-term first pregnancy terminated by a normal delivery without birth injury, the patient was perfectly well until a year ago when she began to kick up her left heel on walking. This was shortly followed by a similar uncontrollable disability on the right side; within six months she could only walk with support. Fine tremor of the hands had been observed throughout the illness.

The family history is of interest for the child's paternal uncle, L. S., now aged 39, began to have difficulty in walking at the age of 8 and with the years became progressively more unsteady. His disorder was diagnosed as chorea. He has never worked on account of his disability.

L. S. is an intelligent and otherwise healthy man. Spasmodic contractions of the masseters. Both sternomastoids contracted with periodic spasm; intermittent backward jerking of the head. Roving movements of the tongue. All limbs in continuous state of tremor and tension; rhythmic twitchings of biceps and triceps. Power in upper limbs good: impairment in lower limbs owing to severe spasm, especially marked in adductors and glutei. Great difficulty in walking: legs crossed; both feet in position of talipes equino-varus. No sensory or reflex disturbance.

The patient is a pale, auburn-haired little girl with a somewhat expressionless face. Very intelligent (I.Q. 148); emotionally mature and well balanced.

General examination normal. Cranial nerves normal. Roving movements of the tongue. Fine tremor of head and trunk, especially marked on standing up. Fine tremor of hands at rest; athetoid movements of outstretched arms; constant opening and closing movements of hands. There is diminished tone in the arms after initial difficulty in relaxation has been overcome; tone is increased in the lower limbs; both heels drawn up. No ataxia; no inco-ordination; no motor weakness. Fine movements somewhat clumsy. Stands and walks with hips and knees flexed; there is adduction and internal rotation at the hip-joints and the heels are drawn up whilst the feet are inverted. Gait very unsteady and only possible with support. Scoliosis with convexity to the right. Sensation normal. Tendon reflexes present and equal but difficult to elicit. Abdominal reflexes present and equal. Plantar reflexes flexor.

Investigations.—X-rays of skull and spine normal. Cerebrospinal fluid: clear, colourless: protein 25 mg.%; no cells; sugar 54 mg.%; chlorides 750 mg.%. Blood and cerebrospinal fluid: Wassermann negative. Liver function tests: Serum alkaline phosphatase 14 units; thymol turbidity 3 units; plasma proteins:—Total 5·9% = albumin 2·6%, globulin 3·02%, fibrinogen 0·28%, A/G ratio 1 : 1·2.

Electro-encephalogram.—Delta and theta discharge larger in postcentral regions and often focal on left side; almost completely inhibited on opening eyes. Frontal regions: strikingly little electrical activity. Electrical activity from central and postcentral structures closely resembles records from normal children of 1½ to 3 years. Tracings from precentral areas normal for child's age.

Electromyogram.—(*a*) Surface electrodes: motor unit discharge from both flexors and extensors. Relaxation slow. (*b*) Needle electrodes: some motor unit action potentials firing synchronously.

shock-producing procedure. Needles and tubing tend to clog as the blood thickens or the flow slows. The injection of heparin to prevent clotting is a decided risk in an infant who usually has hypoprothrombinæmia and a well-marked bleeding tendency.

Only through the development of special plastic catheters and their use in the umbilical vein were all these difficulties resolved and the techniques of exsanguination-transfusion made easier.

The indications for this operation have been fixed as follows until such time as sufficient data have been accumulated to evaluate the results. If the mother has been known, or is quickly demonstrated, to have Rh antibodies in her serum, and the infant shows definite clinical signs of erythroblastosis fœtalis, at or shortly after birth, treatment is begun at once. If the infant born to a sensitized mother exhibits no symptoms at birth, but is found, by immediate testing of the cord blood, to be Rh-positive and to have detectable Rh antibody still present in its serum, treatment is also indicated. If the infant not only looks well, but though Rh-positive has no free maternal antibody by suitable tests, no treatment is given at present. To date, about ten such infants have had no serious anæmia later, although a few of them have required single transfusion.

The results of exsanguination-transfusion have been quite satisfactory in many cases. Infants, very sick and anæmic at birth, have survived. Most of them have been ready for discharge with the mother in seven or eight days. Only a few have developed moderate anæmia by the third week and required another small transfusion.

Statistically, our mortality in about fifty sick infants has been near 10%. Several babies who succumbed had atelectasis, intracranial hæmorrhage and other signs of immaturity, rather than erythroblastosis fœtalis.

Much more study and data are needed before the problems of the management of blood incompatibility—antibody action between mother and child—and the best care of the newborn infant with hæmolytic disease are all solved. Notable advances have been made. But there is no justification for complacency or surety. Neither is there reason for undue anxiety when faced with the problems of Rh incompatibility.

[*June* 14, 1947]

MEETING HELD AT ROYAL VICTORIA INFIRMARY, NEWCASTLE-UPON-TYNE

The following papers were read:

Problems in the Organization of a Professorial Unit.—Professor J. C. SPENCE, M.C., M.D.

A Method of Recording Neonatal Infections in a Maternity Hospital.—MARY TAYLOR, M.D.

Prematurity in an Industrial Town.—F. J. W. MILLER, M.D.

Treatment and Prognosis of Bronchiectasis.—ALAN OGILVIE, M.D., F.R.C.P.

A Consideration of Acute Intussusception in relation to Medical Teaching.— DONALD COURT, M.R.C.P.

There were enlarged glands in the groins and right axilla; spleen palpable.

Dr. Macdonald Critchley showed radiographs indicating a condition of osteitis and periosteitis of the right femur. X-rays of the chest showed a soft swelling over the ribs on the right side which he imagined represented a gumma. The only other feature of interest was that the man was a eunuch. The most likely explanation of the syphilitic infection was that it was of extragenital origin, though it should be remembered that eunuchs, while not fertile, were not necessarily impotent.

Sir Charles Symonds asked what treatment this case had had. The prognosis in cases of complete spinal block was, on the whole, not a good one. He had had a case, however, of this type treated with penicillin, in which recovery was much more complete than usual.

Dr. Macdonald Critchley said that this patient had had 3·7 million units of penicillin since the onset of the paraplegia, but without effect.

POSTSCRIPT (6.3.47).—Despite another course of penicillin, the patient steadily went downhill and died. Autopsy revealed a condition of lymphosarcoma, with a large mass over the right side of the chest, infiltrating the spinal canal and compressing the cord. The right femur was invested by a diffuse tumour associated with the periosteum. From data subsequently obtained, it seems probable that the lues was of the inherited variety (M. C.).

Myoclonus.—E. A. CARMICHAEL, C.B.E., M.B.

A. L., male, aged 43. Perfectly well until February 1944 when he began to have infrequent generalized epileptiform attacks, sometimes with a focal sensory onset. In September 1944 he experienced progressive difficulty in walking because of involuntary shaking movements of the legs, so that by February 1945 he had to use a stick. By the following September he could only crawl on hands and knees, and by January 1946 he was only able to use his arms to drag himself along the floor.

Since then he has been bedridden. There are increasingly frequent involuntary movements of the limbs and trunk initiated by minimal stimuli, and interspersed by generalized epileptiform convulsions.

There is extreme weakness of the legs, slight weakness of left hand with marked inco-ordination of both arms. Progressive dysarthria and probably mental deterioration also. Nothing relevant in family history or history of past illness.

Dr. E. A. Carmichael said that this case had been the means of demonstrating some interesting central nervous phenomena, which Dr. Dawson had studied.

Dr. G. D. Dawson said that in the investigation of this case the most striking findings were that if any peripheral stimulus was applied it resulted in a very large change of electrical potential over the contralateral scalp. Control experiments showed that this was not an artefact, and that it did represent an electrical change in the brain. The response to stimulation of a leg appeared near the mid-line and to stimulation of an arm 5 to 8 cm. lateral to it. The time between a stimulus and the electrical change showed fairly clearly that the change picked up on the scalp was either associated with the arrival of the afferent volley at the cerebral cortex or occurred very shortly after this. The response occurred some 150 to 200 milliseconds before the myoclonic jerk which Dr. Carmichael had demonstrated. The distribution of the response in an antero-posterior direction was of interest because it was 3 to 5 cm. in front of the surface markings of the central sulcus. In five other cases of myoclonus of comparable severity examined previously, he (Dr. Dawson) had never managed to elicit any response of this sort. This response, then, was unusual and it showed that an afferent volley either had direct access to a much larger number of cortical cells than usual or on arriving at the cortex caused some spreading change there. The methods developed in examining this case had since shown that on peripheral stimulation a similar response could be just detected in the normal, about one-tenth of the size of that appearing in the patient under discussion, and it always appeared over the marking of the central area instead of, as in this patient, farther forward. So far as the secondary jerks were concerned, it seemed possible to suggest that these might be transcortical reflexes, because they were always preceded by the cortical discharges, to which they had a regular time relation. The first stimulus of a series was accompanied by a massive generalized jerking; later stimuli provoked only jerking in the segment stimulated. The cortical response changed in a corresponding manner. The first stimulus provoked a spreading discharge lasting up to a second ; the later stimuli were accompanied by a very much briefer localized discharge.

Dr. Purdon Martin asked whether this patient had pyramidal tract involvement or any indication of cortical atrophy.

Comment.—In the absence of birth trauma, other injury or illness this condition must be ascribed to congenital defect. The points of interest are the family history, the changes in the plasma proteins and the electro-encephalograms. The patient has a diminished plasma protein content and reversal of the albumin-globulin ratio. It might be argued that there is some degree of liver dysfunction in this child; this suggests a link with Wilson's disease. The electro-encephalographic findings are important in view of recent American work in which precentral cortical excisions are undertaken in cases of dystonia musculorum deformans.

Post-encephalitic Parkinsonism with Marked Palilalia.—MACDONALD CRITCHLEY, M.D.

H. S., male, aged 40, sustained an attack of acute epidemic encephalitis in 1924. He made a good recovery until about 1934 when he began to develop drowsiness, and slowness and clumsiness of movements. Another disturbing symptom was a tendency for the eyes to turn up involuntarily (oculogyric crises). On this account he gave up work in 1941. In 1945 his speech showed the repetitive features of palilalia which are now so conspicuous.

Physical examination reveals a Parkinsonian syndrome of moderate severity, more marked on the right side, and with a mild and inconstant degree of tremor.

Dr. Critchley added that there were a number of interesting neuro-psychiatric features in this case. One was his tendency to compulsive thinking, especially during the oculogyric crises, but at other times also. He would be compelled to repeat to himself a number of rhymes or verses of poetry. He was also apt to identify himself in the cinema with the characters on the screen and this feeling would persist for a while even after leaving the theatre. A third feature of his case, which is now a thing of the past, was the occurrence of bouts of rapid noisy breathing. The outstanding characteristic at present is his palilalia whereby he repeats the last few words of a sentence over and over again—perhaps as many as 15 times. But if requested to narrate a preformed speech pattern (days of week, &c.) or to recite something he knew by heart, no palilalia would occur.

A final interesting feature is his tendency to continue unduly any repetitive act, such as hammering a nail, combing his hair, or brushing his teeth. Whether this movement-perseveration represents a real palipraxia, or whether his involuntary tremor in such circumstances takes control of his volitional movement, is uncertain. His tremor, however, was 5·5 per second and his movement repetitions were much slower and were perhaps on that account to be regarded as a true psychomotor disorder, or a palipraxia.

In reply to Sir Charles Symonds, who asked whether the patient still got his oculogyric crises, which on the whole carried a better prognosis than any of the other symptoms, Dr. Critchley said that though much less frequent than formerly he did not think they had entirely disappeared. His experience too was that these oculogyric crises, unlike the Parkinsonian syndrome, were features that improved.

The President asked about the psychological background of the patient, to which Dr. Critchley replied that the man's personality prior to his illness was not of the obsessional type.

Paraplegic Eunuch with Lues.—MACDONALD CRITCHLEY, M.D.

D. F., male, aged 46, entered hospital at the end of November 1946 on account of pains in the right side of the chest and in the right leg. Whilst under observation he developed numbness over the abdomen, and later, a total flaccid paraplegia with incontinence and loss of sensation up to the level Th. 6. Lumbar puncture: yellow fluid; Queckenstedt positive; 18 cells, protein 180 mg.%. W.R. and Kahn positive in fluid, negative in blood.

The patient was 6 ft. 2 in. in height, with long slender extremities, smooth hairless skin, small penis and testes, no beard, pubic or axillary hair, high-pitched voice.

carotid ligature was considered inadvisable. He hoped that Dr. Meadows would publish the cases he was collecting since the correct treatment for this somewhat rare condition was still in doubt.

Dr. Purdon Martin had seen two cases in which there had been a thrombosis of the cavernous sinus after rupture had occurred. One of them came to post-mortem later and it was possible to confirm the diagnosis. The other patient lost all ocular movements and became blind; about a week later he recovered and was said to have left hospital quite well. Recovery was certainly possible.

Dr. Meadows, in reply to Dr. Purdon Martin, who asked whether any good was done to this patient by tying her carotid, said that before operation the proptosis was increasing considerably, and she was complaining bitterly of the bruit. Now she was very much better, the exophthalmos had almost disappeared, and the faint bruit did not trouble her.

Papillœdema associated with Chronic Bronchitis, Emphysema and Polycythæmia.—S. P. MEADOWS, M.D.

D. G. R., male, aged 42. Chief complaint is that of insomnia for past few years, due to bronchitis. Recurrent bronchitis with asthmatic attacks for over twenty years, worse during the winter. Dyspnœa on exertion past few years. Morning headaches when he sleeps badly.

On examination.—Obese, plethoric, cyanosed man. Moderate dyspnœa on exertion. No finger clubbing. Bilateral papillœdema with hæmorrhages scattered about the retinæ. V.A. 6/9. Visual fields full. No other abnormal signs in C.N.S. Lumbar puncture: C.S.F. pressure 240 mm. C.S.F. normal. Chest: Poor expansion, poor air entry with expiratory wheezings. Heart clinically normal. B.P. 140/80. No congestive failure. E.C.G.: Right ventricular preponderance. He had a short attack of auricular fibrillation while in hospital in December 1946.

Ventriculogram: Normal ventricular system. X-rays: Skull normal. Chest: Well-marked emphysema with very poor expansion of lungs and practically no diaphragmatic movements. Slight cardiac enlargement, both right and left ventricles. Main pulmonary artery and its branches are dense. The appearances may be due to pulmonary arteriosclerosis. Vital capacity: 1,562 c.c. (about 1/3 normal). Renal function tests normal.

Blood-count: Shows polycythæmia. R.B.C. 8·22 million and 6·82 million on different occasions, with 134% and 116% hæmoglobin.

Dr. Meadows suggested that the papillœdema in this case was secondary to the chronic increased venous pressure and polycythæmia, these in turn being due to the chronic chest condition (emphysema and chronic bronchitis). The possibility of pulmonary arteriosclerosis had been mentioned by the radiologist. Intracranial tumour and hypertensive retinopathy appeared to be ruled out.

He had seen a similar case with secondary optic atrophy before the war at the London Hospital, when the possibility of a cerebral abscess secondary to the chest condition had been mooted.

Cases of polycythæmia had been recorded in the literature with increased cerebrospinal fluid pressure and papillœdema, the latter indistinguishable from that which occurs in intracranial tumour. The matter was complicated by the fact that subdural hæmatoma might occur in polycythæmia.

Sir Charles Symonds said that he had seen a fundus exactly like this in primary polycythæmia, which he thought supported the view that that was the cause. He had observed very severe headaches as a symptom of obstruction of the superior vena cava but not papillœdema.

Poliomyelitis Limited to both Trigeminal Motor Nuclei.—DENIS WILLIAMS, M.D.

A boy aged 6½ years was brought to the National Hospital in January 1947 because he had been unable to chew since an acute febrile illness eighteen months previously.

In July 1945 he had an acute fever with meningism and semi-coma from which he recovered in a few days. His mother then noticed that he was not chewing normally. In September 1945 (six weeks after onset of weakness) he went to the Hospital for Sick Children where it was found that he had indistinct speech and complete inability to chew. The only abnormality found in the central nervous system was marked weakness of the pterygoid and masseter muscles on both sides. All tendon-jerks normal; no weakness of any other muscles. Complete R.D. in both masseters. He was observed each month until March 1946 but no change was found.

On examination in the National Hospital, his nervous system was normal throughout

Dr. Carmichael replied that, as to the first question, the reflexes were exceedingly brisk. As to cortical atrophy, his radiological colleagues told him that there was no sound evidence of this, though there might be some atrophy in the frontal region. Davison and Keschner (*Arch. Neurol.* 1940, 43, 524) had described a somewhat similar case in which they had found "inclusion" bodies in the nerve cells. There was no family history in this case of similar disturbance.

Dr. J. G. Greenfield stated that this question of inclusion bodies dated back for a long time before the paper in the *Archives of Neurology* to the observation of Lafora and Westphal, but he did not know whether the cases they described were clinically similar to the present case or not.

The President said that mental deterioration was rather characteristic of myoclonus, i.e. epilepsy, and asked whether this was considered a normal case in that respect.

Dr. Carmichael replied that this man was at one time euphoric, but was now depressed. When admitted, he was put on phenobarbitone and similar preparations; heavy doses were given without improvement. He was then taken off these drugs and given benzedrine, on which he showed some improvement. He was, however, now going downhill.

Spontaneous Carotid-cavernous Aneurysm.—S. P. MEADOWS, M.D.

Miss J. D., aged 56. October 1944: Sudden onset of throbbing noise in head, especially right ear, which persisted.

January 1945: Right upper lid became swollen, followed by increasing exophthalmos and redness of right eye.

April 1945: Pain right side of forehead and upper jaw, associated with a cold feeling over the same area. Epistaxis lasting an hour.

No diplopia or loss of vision. General health good.

Past illness.—1935: She was knocked down in the road, and was unconscious three hours and in hospital two weeks.

On examination (May 1945).—R. proptosis (6·5 mm.). No definite pulsation seen. Chemosis and engorgement of vessels of R. conjunctiva. Slight weakness of R. external rectus muscle. Retinal veins engorged in R. optic fundus.

Loud systolic bruit heard over right side of head and face, which almost ceases on compression of right common carotid artery. B.P. 220/125.

After about two weeks of daily digital compression of the right common carotid artery in the neck for periods up to thirty minutes, the right common carotid artery was ligated on June 3, 1945. This was followed by increase in the chemosis and exophthalmos, and the development of a third cranial nerve paresis (dilated, sluggishly reacting pupil, weakness of elevation and adduction of the right eye, and partial ptosis and sixth cranial nerve palsy). About ten days after the ligature, retinal hæmorrhages were noted scattered over the right retina, with papillœdema. The cephalic bruit persisted after ligature, but was fainter and more localized. The exophthalmos, chemosis, ocular palsy, and retinal hæmorrhages slowly subsided.

Present condition.—V.A.: R. 6/9 partly with glasses. Right optic fundus: No hæmorrhages. Disc slightly blurred. Ocular movements full. No ptosis. R. pupil slightly larger than L. and reacts well. Slight R. exophthalmos (about 3 mm.). Congested conjunctival veins. B.P. 235/115. Systolic bruit heard over R. eye, fainter than before ligature.

Dr. Meadows said that some of these cases healed spontaneously. One such case was an elderly woman in whom the bruit disappeared and the exophthalmos improved after repeated digital pressure on the common carotid artery. Another case was a dramatic one, that of a man who had bilateral exophthalmos and chemosis and one could not be sure on which side the aneurysm was, except by the lateralization of the bruit. On first inspection it resembled the exophthalmos of Graves's disease. An interesting point was why some of these cases had bilateral exophthalmos with a unilateral aneurysm. He thought it was due to the circular sinus which connected the two cavernous sinuses, and which varied in its patency in different individuals.

The President said that recently he had a similar case in a woman aged 75 who showed bilateral sixth nerve palsy. The bruit was heard well on both sides of the head. There was no exophthalmos and only a mild degree of chemosis on the right side. Presumably the bilateral signs were due to arterial blood reaching the opposite cavernous sinus via the circular sinus. On account of her age carotid ligature was considered inadvisable. He hoped that Dr. Meadows would publish the cases he was collecting since the correct treatment for this somewhat rare condition was still in douht.

Dr. Purdon Martin had seen two cases in which there had been a thrombosis of the cavernous sinus after rupture had occurred. One of them came to post-mortem later and it was possible to confirm the diagnosis. The other patient lost all ocular movements and became blind; about a week later he recovered and was said to have left hospital quite well. Recovery was certainly possible.

Dr. Meadows, in reply to Dr. Purdon Martin, who asked whether any good was done to this patient by tying her carotid, said that before operation the proptosis was increasing considerably, and she was complaining bitterly of the bruit. Now she was very much better, the exophthalmos had almost disappeared, and the faint bruit did not trouble her.

Papillœdema associated with Chronic Bronchitis, Emphysema and Polycythæmia.—S. P. Meadows, M.D.

D. G. R., male, aged 42. Chief complaint is that of insomnia for past few years, due to bronchitis. Recurrent bronchitis with asthmatic attacks for over twenty years, worse during the winter. Dyspnœa on exertion past few years. Morning headaches when he sleeps badly.

On examination.—Obese, plethoric, cyanosed man. Moderate dyspnœa on exertion. No finger clubbing. Bilateral papillœdema with hæmorrhages scattered about the retinæ. V.A. 6/9. Visual fields full. No other abnormal signs in C.N.S. Lumbar puncture: C.S.F. pressure 240 mm. C.S.F. normal. Chest: Poor expansion, poor air entry with expiratory wheezings. Heart clinically normal. B.P. 140/80. No congestive failure. E.C.G.: Right ventricular preponderance. He had a short attack of auricular fibrillation while in hospital in December 1946.

Ventriculogram: Normal ventricular system. X-rays: Skull normal. Chest: Well-marked emphysema with very poor expansion of lungs and practically no diaphragmatic movements. Slight cardiac enlargement, both right and left ventricles. Main pulmonary artery and its branches are dense. The appearances may be due to pulmonary arteriosclerosis. Vital capacity: 1,562 c.c. (about 1/3 normal). Renal function tests normal.

Blood-count: Shows polycythæmia. R.B.C. 8·22 million and 6·82 million on different occasions, with 134% and 116% hæmoglobin.

Dr. Meadows suggested that the papillœdema in this case was secondary to the chronic increased venous pressure and polycythæmia, these in turn being due to the chronic chest condition (emphysema and chronic bronchitis). The possibility of pulmonary arteriosclerosis had been mentioned by the radiologist. Intracranial tumour and hypertensive retinopathy appeared to be ruled out.

He had seen a similar case with secondary optic atrophy before the war at the London Hospital, when the possibility of a cerebral abscess secondary to the chest condition had been mooted.

Cases of polycythæmia had been recorded in the literature with increased cerebrospinal fluid pressure and papillœdema, the latter indistinguishable from that which occurs in intracranial tumour. The matter was complicated by the fact that subdural hæmatoma might occur in polycythæmia.

Sir Charles Symonds said that he had seen a fundus exactly like this in primary polycythæmia, which he thought supported the view that that was the cause. He had observed very severe headaches as a symptom of obstruction of the superior vena cava but not papillœdema.

Poliomyelitis Limited to both Trigeminal Motor Nuclei.—Denis Williams, M.D.

A boy aged 6½ years was brought to the National Hospital in January 1947 because he had been unable to chew since an acute febrile illness eighteen months previously.

In July 1945 he had an acute fever with meningism and semi-coma from which he recovered in a few days. His mother then noticed that he was not chewing normally. In September 1945 (six weeks after onset of weakness) he went to the Hospital for Sick Children where it was found that he had indistinct speech and complete inability to chew. The only abnormality found in the central nervous system was marked weakness of the pterygoid and masseter muscles on both sides. All tendon-jerks normal; no weakness of any other muscles. Complete R.D. in both masseters. He was observed each month until March 1946 but no change was found.

On examination in the National Hospital, his nervous system was normal throughout except that there was no demonstrable contraction of the temporal muscles, the masseters or the external pterygoids. There was jaw drop with no power in opposition of the jaws. The muscles supplied by the fifth nerve which are responsible for opening the jaw were in sharp distinction to those responsible for closing it in that power was fairly well preserved. There was a suggestion of slight weakness in the perioral muscles; all other muscles powerful; tendon-jerks brisk and equal.

The interest of the case is that the poliomyelitis virus had picked out almost exclusively that part of the motor nucleus of the fifth nerve on both sides which is responsible for closing the mouth.

The President said that this was a rare case. In his experience of acute poliomyelitis overseas during the war he had only come across four cases which showed this sequel. Three of the four cases had shown other brain-stem signs initially. In one case he had noted relative sparing of the pterygoids as in the present case. In this selective action of the virus he was reminded of a case of a Medical Officer who showed, as a sequel of the disease, bilateral paresis of the sternomastoids with sparing of the trapezii.

Dr. A. S. Hollins said that he saw a similar case in the Mediterranean in 1943 in a young medical officer from Sicily. He had had an acute febrile illness with intense headache, which was followed by weakness of the muscles of mastication. When seen in North Africa he had an almost complete palsy of the masseters, temporals and pterygoids on both sides. He had made almost a complete recovery when he was allowed to leave hospital for a convalescent wing.

Wilson's Disease.—Denis Brinton, D.M.

Joan S., aged 21. Single.

June 1940: Jaundice with fever, hæmolysis and reticulocytosis; discharged from hospital after three months with diagnosis of "Subacute hepatitis with recurrent bouts of pyrexia." Thereafter amenorrhœa till 1946.

1944: Won exhibition Cambridge. Shortly after, jaw kept dropping open and saliva dribbled.

1945: Walking difficult, handwriting deteriorating, involuntary movements arms and head, speech indistinct; chorea diagnosed.

1946: Steady deterioration, though intensity of each symptom widely variable; difficulty in mastication and deglutition; Kayser-Fleischer ring found.

1947: Speechless; painful spasms of arms; virtually bedridden.

Dr. Denis Brinton added that the case formed quite a good example of Wilson's disease. The patient's brother, who was about four years younger than she, had a very similar story of jaundice with recurrent fever; this happened about two years after the patient's first symptoms. Each of these siblings had had obvious jaundice of the skin and sclera, pale fæces, and a marked hæmolytic anæmia. The girl had had a blood-count in 1940 as low as 1,670,000 red cells and 35% hæmoglobin, with reticulocytes at 11%. In the brother's case the reticulocytes were 6%, and his anæmia was not so severe—3,000,000 red cells, with a 70% hæmoglobin.

He showed pictures of the Kayser-Fleischer ring in both the patient and her brother. The patient was now incapable of movement except on rare occasions. She had virtually lost her power of speech, and she was troubled by exceedingly painful spasms of the arms. If tension were placed on the flexed fingers a curious rhythmic contraction occurred. At an earlier stage the opinion had been entertained that the aphonia was of an hysterical kind, but that was obviously not the case. The tremor had a regular rhythm, suggesting extrapyramidal trouble.

A recent test at St. Mary's had suggested that her liver function was within normal limits. In the case of her brother both liver and spleen were palpable. This patient's liver was not palpable. The brother showed some slurring of speech and some facial immobility. Some investigations had been recently carried out on the blood copper, because Glazebrook (*Edin. med. J.*, 1945, 52, 83) had suggested that this might be important; in the girl's case, however, the blood copper was within normal limits. In reply to a question Dr. Brinton said that at the time of the jaundice no tests had been done for any form of antibody.

Dr. Purdon Martin said that this patient had a peculiar tremor which seemed to be due to clonic contraction of the flexors. He was interested also in the variability of her rigidity and her ability to speak first thing in the morning. There was evidently in the early morning a reduction in rigidity. Some patients with extrapyramidal rigidity were almost free from rigidity on waking in the morning and were able to dress themselves.

Section of Obstetrics and Gynæcology

President—JAMES WYATT, F.R.C.S., F.R.C.O.G.

[*March* 21, 1947]

DISCUSSION ON ANÆSTHESIA FOR CÆSAREAN SECTION

Mr. Rufus C. Thomas: The essential criteria for any anæsthetic for Cæsarean section must be, primarily, safety for the mother and child, and, subject to these, ease of operating for the surgeon.

I propose as my contribution to this discussion to give details of my experience of spinal anæsthesia induced with heavy nupercaine, under which almost all my Cæsarean sections have been done for the past nine years. At the same time, I do not wish to convey the impression that I think spinal anæsthesia is suitable for any and every woman. Briefly, the arguments against spinal anæsthesia in the case of pregnant women are these:—

(1) Pregnant women at or near term are supposed to be highly susceptible to the effects of the cocaine products. If this is so, the answer is that nupercaine is a quinoline compound, and is not related to the cocaine group.

(2) That collapse and sudden death are liable to occur from a sudden drop in blood-pressure due to paralysis of the vaso-constrictors and dilatation of the splanchnic pool. That might be so, if proper precautions are not taken, but this danger can be avoided, by giving ephedrine, ¾ grain before the spinal injection, by careful positioning of the patient to ensure that the solution does not rise above D.8 (this gives anæsthesia nearly up to the ensiform cartilage, which is ample for a Cæsarean section), by having the blood-pressure recorded at five-minute intervals throughout the operation, by the injection of methedrine, 15 mg. into the uterine muscle if the systolic pressure drops below 90 mm.Hg (methedrine acts very quickly by this route, and produces by peripheral vaso-constriction a sustained rise of blood-pressure up to or above the normal), and, finally, by the elementary precaution of not using spinal anæsthesia in unsuitable cases. For instance, cardiac disease with decompensation is, I need hardly say, an absolute contra-indication. It is dangerous to use spinal anæsthesia in cases of severe anæmia and low blood-pressure, unless and until the patient's condition can be restored by blood transfusion and other means. Severe anæmia and low blood-pressure may be met with in women who have had hæmorrhage from placenta prævia. But such cases can, by blood transfusion, be rendered fit for spinal anæsthesia, as I hope to show by my figures later.

(3) That a number of cases of meningitis, some of them fatal, have followed the use of spinal injections. One possible explanation was that the technique of manufacture might be faulty. I have watched the whole process in the laboratories. The precautions are so rigid that such a possibility is inconceivable. The theory of aseptic or chemical meningitis has never been proved, and Frankis Evans says that it must be treated with extreme caution. There remains the explanation of faulty technique in the preparation of the syringes, needles, hands of the anæsthetist, the ampoules, and the skin of the patient in giving the injection. The answer is that the procedure should be as rigidly aseptic as the Cæsarean section itself.

(4) The last objection is the incidence of post-operative headache. This does occur. In my view, it is due to leakage of cerebrospinal fluid through the puncture in the theca. If I am right, it can be reduced by using the finest needle, keeping the patient flat for twenty-four hours, and raising her very gradually to the semi-Fowler position.

The advantages of spinal anæsthesia under heavy nupercaine are:—

(1) If the precautions already outlined are taken, it is safe for the mother and is easy to administer. The only difficult cases are those with spinal deformities. The patient feels nothing after the initial prick of the needle when anæsthetizing the track. For this, 1 : 1,000 nupercaine with adrenaline, in 5 c.c. ampoules, is used.

(2) The amount of movement necessary is very small. She lies on her side when the injection is given, then turns on her back, or can be turned by the theatre staff without any effort of her own, an important point in cases of placenta prævia. The head and shoulders are raised, and the table tilted in the Trendelenburg to about 7 to 10 degrees. After five minutes the table is straightened and the operation can be proceeded with.

(3) The patient is, of course, conscious, hears her baby cry at birth, can be told its sex, and can even see it for herself. To many women, this is a great satisfaction. She can have drinks while being operated upon and after returning to the ward, and can see her husband immediately.

(4) The anæsthetic has no effect whatever on the baby. I have known many infants cry lustily before they were completely removed from the uterus. The advantage of this, especially in cases of fœtal distress, is obvious.

(5) The surgeon has the maximum of operative comfort. The muscles are completely relaxed, the abdomen is quiet, and abdominal packs can be placed in position with the greatest ease. Access to the lower segment is greatly facilitated. Uterine tone is excellent, there is very little bleeding, and, in fact, many operations are practically bloodless. The placenta often delivers itself. Closure of the uterine and abdominal incisions is easy.

(6) The post-operative period, apart from possible headache, is very comfortable. Vomiting and distension are rare, and chest complications practically non-existent.

I should like to give a few further details of the technique I employ.

Premedication.—Ephedrine, ¾ grain and atropine, 1/100 grain are given forty minutes before operation. Atropine is given in case the spinal has to be supplemented, but apart from an occasional nervous woman, this is rarely necessary. No sedative is given.

Sterilization of needles, syringes, and ampoules.—Needles and syringes are boiled in sterile distilled water, and stored ready for use in industrial spirit. The ampoules have, at present, paper labels. These are a source of danger. They are washed off with hot water and soap, the ampoules then rinsed in cold water, and stored in industrial spirit. This eliminates the danger of infection from the gum. I am informed that the etching of the description and dosage on the ampoules will be resumed shortly.

The skin of the patient's back is prepared in the ward by washing with ether soap, painting with spirit, followed by 1% flavine, and covered with a sterile towel. Before the spinal injection, it is again painted with spirit. The hands of the anæsthetist are, of course, prepared as for any surgical operation.

By a scrupulous adherence to this technique, there should be no risk of septic meningitis. We have now given well over 2,000 spinal anæsthetics for obstetric and gynæcological operations, and have not seen a case of meningitis.

In passing the spinal needle, I believe it is important, having carefully located the exact site, to push the needle steadily but slowly on in one continuous movement until the point is felt to pierce the theca. This moment can actually be felt if the operation is deliberate enough. Haphazard poking about must be avoided.

The amount of heavy nupercaine injected is 2 c.c. in most cases, though I have used 1·75 c.c. occasionally in very short women. The space for injection is between the third and fourth lumbar spines. If blood-stained cerebrospinal fluid is found, the next space up is used.

Up to date we have performed 346 Cæsarean sections under heavy nupercaine anæsthesia. Of these, 314 were lower segment operations, and 32 were classical. There has not been a maternal death either under or due to the anæsthetic.

The number of infants delivered, including four sets of twins, was 350. Of these, 2 were stillborn, and 10 died. The infant salvage rate is therefore 96·6%.

The chief indication for operation was disproportion, a large number of women having had a test of labour first. But we have used spinal anæsthesia now in practically all the recognized indications for Cæsarean section, including a number of cases complicated by ovarian cysts, for the removal of which the length of anæsthesia is ample. It is also worth noting that 58 sections have been done for cases of placenta prævia, showing that these patients can, by blood transfusion and other means, be rendered fit for spinal anæsthesia.

Finally, we have done Cæsarean sections under spinal analgesia twice for 41 patients, and three times for 5 patients. This suggests that the women themselves do not object to this form of anæsthesia.

Mr. J. H. Peel: My contribution is to report on a small series of cases in which the operation has been carried out under caudal anæsthesia. I do this not so much from the belief that caudal anæsthesia is necessarily the perfect and universally applicable anæsthetic, as from the conviction that this method is a very valuable addition to the anæsthetist's armamentarium in the preparation of patients for Cæsarean section. I think that this applies more particularly to the systematic and unhurried approach to the lower segment, than to the more rapid, less artistic and potentially more dangerous classical operation.

The dangers of ether, chloroform, pentothal and other anæsthetic agents in causing fœtal narcosis, and of nitrous oxide in producing fœtal anoxia are too well recognized to require emphasis. There seems to be a gradually growing conviction, both in America and in this country, against the use of general anæsthesia for Cæsarean section. Lull states (Control of Pain in Childbirth, London) "Our results at the Philadelphia Lying-in Hospital in the use of the anatomic approach in these cases over a period of several years, and totalling approximately 350 cases, have been so satisfactory that at the present time we resort to general inhalation anæsthetics only in a minority of cases, and we are of opinion that as the technique of giving fractional spinal and continuous caudal is developed and mastered by more men interested in this phase of medicine fewer women will be subjected to inhalation anæsthesia at the time of Cæsarian section." He goes on to state that he has spent three years in an endeavour to evaluate the difference between continuous caudal and fractional spinal in these operations and at present has not decided whether there is any real difference. I am not an anæsthetist and it is not for me to dwell on this point. I maintain an open mind and am quite prepared to admit the advantages of spinal. Both the American figures and those quoted by Mr. Thomas are excellent and very convincing. It is difficult, however, to dissociate one's mind from personal experience of disasters encountered where spinal anæsthesia has been used, and caudal anæsthesia completely obviates the risks of meningitis, nerve palsies and post-spinal headaches, as well as the occasional more disastrous sequel of immediate post-operative collapse and death.

I am indebted to Dr. A. H. Galley primarily for the opportunity of employing caudal anæsthesia for Cæsarean section. Briefly, the method consists of the injection of 50 to 100 c.c. of 1½% metycaine into the sacral canal via the sacral hiatus. A special malleable needle devised by Hingson and Edwards is used. Precautions against tapping the subarachnoid space placed abnormally low are taken, and if care is taken against too rapid injection of the fluid and the injection of quantities larger than are required to produce anæsthesia to the level of the umbilicus is avoided, completely satisfactory anæsthesia is induced without risk to the patients—mother or child. The technique sounds simple enough, but without question herein lies the one and chief difficulty of the method. Lull states that 10% of sacra show anatomical abnormalities which may preclude the successful employment of the method. In my experience there are probably another 10% to 15% in whom there is so much adipose covering to the sacrum that identification of the hiatus is difficult or impossible. Therefore, it can only be by persistent trial and experience that anyone will attain a degree of skill sufficient to employ this method with the certainty of achieving good results. Further I would say that even with complete familiarity with the technique it must take from twenty to forty minutes from the start of the injection to the moment when the patient is ready for the surgeon. But even admitting the difficulties in technique and practical drawbacks, the successful result, when obtained, is so perfect —from my point of view as the surgeon and from my patients'—that I am convinced the method merits a far more extensive trial than it has yet been given in this country.

I will give you a brief résumé of cases we have done at King's College Hospital. There are 51 cases in all. In addition there have been a number of cases in which failure has occurred, due in every instance to technical difficulties in the insertion of the needle. In the 51 cases the operation was performed successfully without any additional anæsthetic agent. Table I shows the indications for operation and illustrates a fairly wide applicability. The high incidence of diabetes in this list is due in part to our very dense population of diabetics at King's, but also it is because this method is particularly valuable for these difficult cases.

TABLE I.—INDICATION FOR OPERATION (51 CASES)

Diabetes	15	Breech with extended legs and contracted pelvis	2
Contracted pelvis	10	Chronic nephritis	1
Cardiac disease	7	Hyperemesis	1
Severe pre-eclamptic toxæmia	6	Prolapsed cord	1
Age with other factors	3	Pulmonary tuberculosis	1
Obstruction due to fibroids	2	Following repair of recto-vaginal fistula	1
Obstruction due to ovarian cysts	1		

There has been no maternal mortality, and no higher incidence of morbidity than is experienced in any series of Cæsarean sections. There were no stillbirths. Three neonatal deaths occurred, due to prematurity in one case (32 weeks), and to the diabetic condition of the mother in two. The majority of these operations were "set" Cæsareans, but in a few the patient was in labour at the time of the operation.

In conclusion I will indicate the more important and salient points about the method:—

(1) The operation can be performed without any hurry to extract the child for fear of narcosis or anoxia.

(2) Hæmorrhage from the uterine incision and from the placental site is minimal. It is perhaps the most striking feature of the operation performed with this method of anæsthesia.

(3) The baby cries immediately. There is no narcosis, no anoxia. This is particularly important in cases where the baby is premature. Atelectasis, pneumonia following inhalation of liquor, are reduced to a minimum.

(4) The Trendelenburg position can safely be used. This is often a great help in performing the lower segment operation. This is a small but important advantage over spinal using heavy nupercaine.

(5) A transverse incision through the abdominal skin and rectus sheath, which heals so well subsequently, can with greater safety be employed than when using general anæsthesia, because bleeding is less and time does not matter.

(6) With regard to premedication we have tried every conceivable premedication compatible with reasonable safety to the child. I have come to the conclusion that patients are far more co-operative and less worried if they have no premedication at all than if they have small doses of drugs which render them so often excitable. Larger doses are obviously more dangerous to the child.

(7) Success can only follow careful selection of cases, especially from the psychological angle.

(8) Apart from local abnormalities and difficulties in locating the sacral hiatus, the two most important contra-indications are recent hæmorrhage and low blood-pressure.

(9) Lull advocates giving ephedrine 25 to 50 mg. routinely. We have not done this and in only few patients have we experienced any appreciable fall in blood-pressure.

(10) Oxytocic drugs are unnecessary—in fact undesirable, as the uterus may contract so vigorously that the patient experiences severe uterine cramp after the analgesic effect of the caudal wears off.

(11) The patient should be given morphia ¼ grain, after the baby is born and in any case before she leaves the theatre.

(12) The immediate post-operative period is infinitely smoother than that following the use of general anæsthesia, and chest complications in particular are minimal.

(13) By far the most important drawback to the method is that it requires an expert, experienced in this particular technique, to administer the injection. The technique is difficult, but from the point of view of the surgeon who has to do the operation and look after the patient subsequently I would urge that this method be given a more extensive trial, especially by those who are of opinion that spinal anæsthesia is dangerous for women during pregnancy.

Mr. C. McIntosh Marshall (*Liverpool*): Some eight years ago when I wrote on this subject I had had a fairly extensive experience of the three main anæsthetic methods: inhalation, spinal and local. Though that experience has greatly increased there is nothing I should really like to retract while there is much I would heavily underline. But that chapter has also placed me in certain difficulties; it has brought me many personal communications and visitors. I have sometimes felt how much better it might have been had I been able to set down such confidential and "off the record" revelations, and when I think of the matter which is under discussion to-night I am quite unable to put out of my mind all those things I have heard out of court.

Of sacral anæsthesia I have had no experience. In one obstetric unit for which I am responsible I allow my anæsthetist to give *pentothal-curare-cyclopropane*. I am thus enabled to claim that I have a small but useful experience of the anæsthetic combination which some are already maintaining is the ideal one for this operation. These are three very powerful drugs and they are now available for all, and there I leave them, remembering what Beecher wrote in 1938: "Whenever an anæsthetic has enough good qualities to get it past an early trial period it seems to take about ten years to evaluate its bad effects."

To my mind there are several reasons why *inhalation anæsthesia* is unsatisfactory and even dangerous. I would place first those accidents during induction which seem so prone to occur in obstetrical anæsthesia. In the interests of the child pre-operative sedatives must be given with caution, the plane of anæsthesia is intentionally rather light than deep, the risk of vomiting and the aspiration of stomach contents into the bronchial tree is a very real one. I know of three deaths from this cause while I have seen a number of non-fatal cases of severe aspiration pneumonia, the most recent occurring after a forceps delivery only a few weeks ago. In the excellent papers by Mendelson (1946) and by Hartzell and Mininger (1946) this particular risk has at last received the publicity which I feel it surely merits. Further, most inhalation anæsthetics induce some degree of anoxia, of little importance as a rule. But if as a result of laryngeal spasm or vomiting the mother becomes temporarily cyanosed, the anoxic state is quickly reflected in the infant and a stillbirth or a neonatal death from atelectasis can result. Even in cases in which none of these mishaps arises many babies come under the influence of the anæsthetic and some resuscitation is required, and in the very occasional one this is not successful. There are, too, the effects of inhalation anæsthesia on uterine tone, none of them actually stimulating while some are certainly the very reverse. However, by timely and adequate administration of oxytocic drugs these disadvantages can usually be counteracted. Admittedly, in the perfectly sound woman operated on before the onset of labour, the dangers we have mentioned, while real, are not likely to occur often with the expert anæsthetist. It is, however, a strange and perverse fact that when a fœtal tragedy does occur it always seems to fall upon an elderly primigravida after some ten or fifteen years of infertility.

When, on the other hand, labour has been prolonged, when poor uterine action has been a prominent feature, when large amounts of sedatives have been used, when the membranes have been ruptured many hours and extreme moulding is present or there are frank signs of fœtal distress—then one or other of these dangers is much enhanced and general anæsthesia is, in my opinion, absolutely contra-indicated. It is among such patients that most of the immediate mortality of Cæsarean section falls. The prolonged emptying time of the stomach should be borne in mind ; blood loss is apt to be increased, temporary collapse and even death from shock are not uncommon. The fœtal risk requires no emphasis—it is always very great and is certainly not improved by inhalation anæsthetics. The only justifiable choice lies between spinal and local anæsthesia. Spinal is almost ideal for reasons which I need not recapitulate here. It *is* ideal if we can believe that with newer drugs and a perfected technique sudden collapse and death need never occur. Individual obstetricians can produce large series with none of these strange and almost unexplained fatalities. Only one has occurred in my own hospital. I still use the method and have not suffered a death but even with a minimal dose I occasionally meet a degree of collapse which is disturbing and deaths still appear in the literature—the latest to my knowledge being the one reported last October by A. E. Brown (1946). Unfortunately by no means all the deaths in this country due to spinal anæsthesia in Cæsarean section find their way into the literature. I use spinal in cases in which I can foresee special technical difficulties, in very large and obese women who support the method extremely well, and in the performance of an occasional extraperitoneal section. I have never seen spinal anæsthesia have the slightest adverse effect on the fœtus. Accidents can probably be avoided by the use of the minimal dose. It is for this reason, I believe, that its dangers do not manifest themselves when used for vaginal deliveries. With Anderson (1946) I fully agree that its use should be greatly extended among all those patients requiring difficult instrumental delivery.

I am, however, still unable to disbelieve the evidence of my eyes. *Local* is pre-eminently the anæsthetic of choice for the intraperitoneal lower segment operation. Few will deny its great value in patients who are poor surgical risks, in those who have a toxæmia, are suffering from pulmonary or cardiac disease or have a high grade anæmia. And yet—and here is a paradox I would rather not attempt to explain—a patient who is fit and sound in every way is by most of us denied the safest of all anæsthetics and must accept a procedure which will place her in some degree of jeopardy, however slight this may be. I could comprehend this attitude if from time to time there appeared accounts in the literature of tragedies due to the use of local infiltration methods in the operation. It is just the reverse; on such things the literature is absolutely silent. Among the hundreds of contributions to the subject of to-night's discussion one still remains unwritten: "The Dangers of Local Anæsthesia in Cæsarean Section." I do not believe that it will ever appear for those who use the method will have no cause and those who have not employed local will lack the courage to publish such an article. But I do not wish to give a false idea of my own practice. Over the years I quite frequently use an inhalation anæsthetic. "Video meliora, proboque; deteriora sequor." Were this discussion devoted to the reasons why local anæsthesia is not more widely used I would be only too glad to express myself more fully upon these lines by Ovid. It is unlikely that many obstetricians will ever extend this form of anæsthesia to the majority of their patients. Yet there is the clearest evidence that up and down the country interest in the method is increasing. I would make a serious plea that at least it should be considered in all patients mentioned above, in those with diabetes or other medical disorders and particularly when it is important to give the premature child every chance of survival. It is the anæsthetic which promises the normal and therefore the best oxygen supply in the mother's blood so long as the baby is dependent on the placental circulation.

For many years now, as a result of certain fœtal misfortunes, I have given no pre-operative sedative. Some received morphia ¼ grain at the beginning of infiltration, others receive nothing at all. On the other hand in order to ameliorate some of the rigours of local and to speed closure of uterus and abdominal incision I have someone give a little pentothal just before I incise the uterus. So far I have seen no harm result to mother or child and the patient is usually awake when the dressing is being applied. The specific advantages of local have been set out so well and so often by De Lee, Greenhill and others that I shall not repeat them here. There is only one word of warning and it concerns a technical point. When dealing with an uncorrected transverse presentation, never open the lower segment under local alone. The back, or the shoulder and an arm fall into the wound, and extraction may be almost impossible.

We are probably all agreed that in the present-day tendency to abolish all or most of the pain of childbirth there arise certain dangers for both mother and child. After all, and this is too often forgotten, the expectant mother is on the whole a most reasonable person. With simple and honest explanations her confidence can be won and she will no longer insist that safe delivery, whether vaginal or abdominal, should be entirely free from pain or discomfort.

Dr. Katherine Lloyd-Williams: I propose to refer to the records of 305 cases done over a period of several years in the Obstetrical Department of the Royal Free Hospital. They fall into a pre-war series of 224 between 1931–39, and a post-war series of 81. During the war most midwifery was transferred from London, the Obstetrical Unit of the Royal Free was scattered, and though I was able to give the anæsthetics for Cæsarean section on many occasions at some of the outlying hospitals, I have no such full and continuous records of cases done in the war period.

TABLE I.—1931-1939. ANÆSTHETICS USED IN 224 CASES OF CÆSAREAN SECTION

Spinals:		
Stovaine 10%	10	85
Nupercaine 1 : 2,000	75	
Chloroform→ether		22
Ethyl cloride→ether		71
Gas and oxygen + some other anæsthetic (ether, vinyl ether, trilene, chloroform, evipan)		43
Cyclopropane		3

There were no maternal deaths.

TABLE II.—1945-46. 81 CASES (50 CLASSICAL C.S., 31 LOWER SEGMENT)

Anæsthetics used:	
Intravenous pentothal, gas and oxygen + trilene or ether	78
Caudal block	1
Local anæsthetics	2

There were no maternal deaths.

Infant mortality:
1945: No stillbirths.
2 died within twenty-four hours (1 atelectasis, 1 due to cerebral congestion from tight cord round neck. C.S. for fœtal distress).
1946: 1 stillbirth. Mother diabetic. Child probably dead before operation.
3 died within twenty-four hours—all atelectasis (1 premature).

I will describe briefly the methods I used from 1928 onwards and what caused me to modify these methods.

In common with many of my generation I had no experience, when I qualified, of chloroform anæsthesia beyond the occasional few drops on a mask in the maternity wards for delivery. I was little better off after several months of being a resident anæsthetist and, like many others, I finally taught myself in fear and trembling, often, I see when I look back, on highly unsuitable cases. When first confronted with anæsthetics for Cæsarean section, I determinedly chose the anæsthetic which I felt I could give, i.e. ethyl chloride → open ether. No great depth of anæsthesia is required for the classical Cæsarean section which was the routine method in vogue, and on the whole this appeared to serve very well as far as the operation was concerned. I rapidly found, however, that the resuscitation of the baby frequently fell to my lot. It often took quite a long time to get respiration well established. I therefore began to use chloroform until the baby was delivered and then changed over to ether. Results were not always consistent, but I nevertheless convinced myself that the babies were not so slow in starting to breathe as when ether was used throughout.

Gas and oxygen came into common use and I pursued much the same course. If I could, I gave gas and oxygen until the baby was born but rather than push the anæsthetic (and even at this time to my mind nothing was more disastrous than "pushing" this anæsthetic, so cutting down the oxygen supply), I passed the gases over chloroform and after delivery deepened the anæsthesia by giving gas and oxygen and ether.

Gas and oxygen were often sufficient alone but in heavy plethoric cases it is obviously insufficient and the addition of ether was, more often than not, necessary for the closing of the peritoneum after the pelvis had been swabbed out.

I would at this point say that though in the large majority of cases both the operation and the anæsthetic for Cæsarean section are comparatively easy procedures, in my opinion there is no operation which is so dependent on complete confidence and co-operation between surgeon and anæsthetist. Almost all the obstetricians with whom I have worked prefer extremely light anæsthesia until delivery, and the minimum of abdominal investigation is done prior to this. If a surgeon requires deep anæsthesia throughout, the anæsthetist must adjust his technique accordingly.

I next tried spinal analgesia, first using 10% stovaine and later nupercaine. From the surgeon's point of view these results were very satisfactory. At this time I had not heard of rachi-sensitive subjects (as pregnant women are said to be) but nevertheless, being of a cautious nature, I obtained a 1 : 2,000 solution of nupercaine (instead of the usual 1 : 1,500) for the maternity wards, 11 to 13 c.c. being a usual dosage. Spinal anæsthesia for some time became the routine method for Cæsarean sections in the department preceded by a small dose of omnopon and scopolamine, unless the fœtal heart was not satisfactory or the baby was premature. This was followed post-operatively by paraldehyde 5 to 6 ℥ P.R. We thought there was less post-operative distension and discomfort by avoiding morphia and we also discouraged the intake of excess fluid and persuaded the patients to take solids as early as possible. This was easier where a spinal alone was used, as was frequently the case. If the patient was highly nervous she was given gas and oxygen, but the diaphragmatic breathing induced by this was not popular. Spinal anæsthesia has had a bad name for Cæsarean section since Dr. Fairfield's report in 1937 (*Proc. R. Soc. Med.*, 31, 237) in which she says that in a series of 781 Cæsarean sections there were 3, possibly 4, deaths due to spinal anæsthesia in the L.C.C. hospitals.

There is no record of the number of Cæsarean sections in which spinal anæsthetics were used but in this series of 781 cases no other form of anæsthesia caused death. I am glad to record that in our series of cases no deaths occurred, nor, once we had begun the use of nupercaine, had we cause for anxiety over patients. Complications such as backache or headache were common with stovaine, though I think as these were the early cases they were most probably due to faulty technique.

When the lower segment operation became common, spinals became less popular—or perhaps it was partly Dr. Fairfield's report. This is usually a more prolonged procedure and involves more manipulation which puts a considerable strain on the patient. We also thought the baby more difficult to extract because of the contraction of the uterus. We tended, therefore, at this time, to return to general inhalation methods with its disadvantages, and this accounts for the rather large number of ethyl chloride→ether in the table. Though we kept records throughout of the time taken to establish the baby's respiration I feel unable to make any definite statement from the records that one anæsthetic caused more delay than another.

The war years were a transition period and a time of experiment on the comparatively few cases we had. Cyclopropane was an obvious choice from the point of view of the baby, but surgeons thought it caused excessive bleeding. Gas and oxygen with trilene, chloroform, vinyl ether, ethyl ether were all in use at one time or another, most usually preceded by an intravenous barbiturate.

that up and down the country interest in the method is increasing. I would make a serious plea that at least it should be considered in all patients mentioned above, in those with diabetes or other medical disorders and particularly when it is important to give the premature child every chance of survival. It is the anæsthetic which promises the normal and therefore the best oxygen supply in the mother's blood so long as the baby is dependent on the placental circulation.

For many years now, as a result of certain fœtal misfortunes, I have given no pre-operative sedative. Some received morphia ¼ grain at the beginning of infiltration, others receive nothing at all. On the other hand in order to ameliorate some of the rigours of local and to speed closure of uterus and abdominal incision I have someone give a little pentothal just before I incise the uterus. So far I have seen no harm result to mother or child and the patient is usually awake when the dressing is being applied. The specific advantages of local have been set out so well and so often by De Lee, Greenhill and others that I shall not repeat them here. There is only one word of warning and it concerns a technical point. When dealing with an uncorrected transverse presentation, never open the lower segment under local alone. The back, or the shoulder and an arm fall into the wound, and extraction may be almost impossible.

We are probably all agreed that in the present-day tendency to abolish all or most of the pain of childbirth there arise certain dangers for both mother and child. After all, and this is too often forgotten, the expectant mother is on the whole a most reasonable person. With simple and honest explanations her confidence can be won and she will no longer insist that safe delivery, whether vaginal or abdominal, should be entirely free from pain or discomfort.

Dr. Katherine Lloyd-Williams; I propose to refer to the records of 305 cases done over a period of several years in the Obstetrical Department of the Royal Free Hospital. They fall into a pre-war series of 224 between 1931–39, and a post-war series of 81. During the war most midwifery was transferred from London, the Obstetrical Unit of the Royal Free was scattered, and though I was able to give the anæsthetics for Cæsarean section on many occasions at some of the outlying hospitals, I have no such full and continuous records of cases done in the war period.

TABLE I.—1931-1939. ANÆSTHETICS USED IN 224 CASES OF CÆSAREAN SECTION

Spinals:		
Stovaine 10%	10	85
Nupercaine 1 : 2,000	75

stand the operation without further anæsthetic, and of the remaining 63%, one-third had to have a general anæsthetic from the start and two-thirds received it as soon as the baby was born.

If those cases where a planned Cæsarean was done—cases of disproportion and of elderly primiparæ with complications—are extracted from the table, the neonatal death-rate is 4·2%. The neonatal mortality for normal labour is 2·45%. It seems extraordinary that a presumably healthy fœtus cannot be extracted from the mother without incurring mortality which is twice as great. This is of course an exaggeration as there are other factors to be taken into account but there is no doubt that the mortality is much greater than it should be.

It will be seen from Table III that the best results are obtained with epidural analgesia and I would like to describe this in some detail.

Premedication has been two doses of 100 mg. of pethedine, one one and a half hours before and the second three-quarters of an hour before operation, given intramuscularly. We have found pethedine of great value in all cases for allaying mental anxiety, and we have noticed no adverse effect on the infant, nor more than a tachycardia in the mother. However, if fœtal distress were present it would be wiser to forgo the pethedine.

We have always explained the procedure simply to the mother, making clear to her the difference between touch and pain.

Pre-operative use of pressor drugs has been omitted in patients with blood-pressure of 150 mm.Hg and over and has not been given routinely unless the blood-pressure has shown a tendency to fall.

Technique.—The patient lies on her side with her spine flexed. The skin is thoroughly cleansed with triple dye and an intradermal wheal of 1% novocain raised between L.2 and L.3, because the epidural space is widest at this level and the cord is not likely to be damaged. The Howard Jones spinal needle is inserted in the mid-line. Odom's glass indicator containing an air bubble is attached and then the needle is very slowly advanced through the ligamentum flavum until the air bubble is sucked in towards the patient by the negative pressure in the epidural space. If no negative pressure is observed another space may be tried.

We use 1 in 600 nupercaine in 0·45 normal saline, 45 c.c. in all, 10 c.c. of which is injected slowly, aspirating several times during its introduction, to make sure that C.S.F. is not being withdrawn. A wait of five minutes is now made in order to make sure again that the subarachnoid space has not been entered. If it has, C.S.F., which is warm, will drip out and a low spinal block will have occurred and voluntary movement of the toes will be impossible. Voluntary movements are not affected by epidural technique.

Following this safety pause, a further 35 c.c. of nupercaine are injected slowly (always aspirating several times and asking the patient to move her toes). This is well within the maximum dose and we have seen no toxic effects. The needle is then removed and the site of the puncture covered with elastoplast, and the patient lies on her back at a slight foot-down tilt while the analgesic solution is acting.

This usually takes twenty-five minutes and the surgeon must be discouraged from starting before this, otherwise the confidence of the patient is lost. With this dosage analgesia reaches approximately to D.8-D.10.

Those who definitely asked to go to sleep were given light supplementary gas and oxygen anæsthesia. Blood-pressure was taken continuously and several cases required no ephe-

The routine method is now:

Hyoscine 1/200 grain one hour pre-operatively. Pentothal combined with gas and oxygen, the intravenous injection not being given until the obstetrician is really ready to start. This is usually sufficient for the delivery of the baby. Omnopon 1/3 grain intravenously after delivery. This helps to reduce the respiratory excursion.

The operation is then completed with a further dose of pentothal if necessary or alternatively with the addition to the gas and oxygen of trilene, vinyl or ethyl ether in minimal amounts. With this method the baby more often than not cries immediately on delivery.

Post-operative anæsthetic complications seldom occur after Cæsarean section and there is indeed no reason why they should, for the amount of anæsthetic used is usually small, profound anæsthesia not being required. There were no complication in this series (Table II). In the 1931–39 series there was one case of lobar pneumonia occurring after the administration of chloroform–ether, and one disastrous case of an empyema and lung abscess which required rib resection. This occurred in an elderly woman (43) suffering from asthma and chronic bronchitis. A spinal puncture was attempted and failed and the anæsthetic given was gas and oxygen + chloroform and ether.

With the introduction of the intravenous barbiturates (and now curare and myanesin) there seems to me little reason for procedures which involve apprehension or mental strain for the patient. As I grow older, I ask myself before giving an anæsthetic: "Would I like it myself?" As far as spinals are concerned—or locals (which I admit for the special case are admirable)—my answer is "No".

Dr. C. J. Massey Dawkins: Every known method of anæsthesia has its advocates, but perhaps the fairest way of considering the matter is to look at it from the viewpoint of the consumers—which is the best anæsthetic for the mother and the fœtus? A search of the literature has revealed only one large series of cases where the results are tabulated according to the anæsthetic used, I refer to that published by Irving of Boston (Table I). In this table open ether carries off the honours, if the very small number of cases done under avertin are excluded. Table II, a series from the Obstetric Department of University College Hospital, shows that although the neonatal death-rate is about the same as the American series, the maternal mortality is considerably less. In Table III these figures are classified according to the anæsthetic used. For the last eighteen months we have ceased to operate on patients with diabetes, so that the neonatal mortality is now considerably less. Gas-oxygen-ether was used more often than any other anæsthetic but 46% of the babies required lobeline and carbon-dioxide and oxygen before they consented to breathe. This fact is a source of great strain to the surgeon and anæsthetist, the latter often has to leave his patient to resuscitate the baby and this form of anæsthesia should be condemned on this account. The maternal death was due to paralytic ileus which may of course occur with any operation. Local anæsthesia has not been entirely successful, only 37% of the patients being able to

from the fœtal point of view. It is unfortunate that all inhalation anæsthetics seem to be transplacental and to affect the fœtus to a greater or lesser extent. This is shown by the fact that the fœtus so frequently shows a disinclination to breathe properly or cry for some time after delivery. If one does give an inhalation anæsthetic I maintain that the least amount possible should be given for the shortest possible time before the fœtus is delivered. Some surgeons request a fairly deep anæsthetic from the start and then later proceed to harass the anæsthetist with inquiries as to why the infant is not crying.

Of the 13 inhalation anæsthetics, 4 children cried spontaneously within five seconds and the rest showed some difficulty for five to ten minutes. Of the 15 spinals, 14 cried as soon as the head was free; one was difficult for five minutes and this we felt was due to the fact that the mother was operated on as an emergency and had been dosed with morphia before coming into hospital.

Let us now look at the maternal point of view. Spinal anæsthesia is a recognized technique which, despite a considerable amount of controversy, has stood the test of time and is still recognized as a legitimate procedure in reasonably competent hands. I can see no reason why it should not be used for a Cæsarean section just as adequately as for the relief of any other abdominal tumour. I have found that when it is explained to patients that spinal anæsthesia would avoid a risk of poisoning the child they have been anxious to have it. Furthermore they seem to find much pleasure in hearing the infant cry as it is delivered, and those who have had previous children normally have usually been very pleased with the results of spinal anæsthesia.

Perhaps I may be allowed to trespass a little and discuss the effects of the spinal on the operation itself as seen from my end of the table. Anæsthetists must, of necessity, as a result of their peculiar position with regard to surgery, become very censorious critics of surgeons and surgical procedures. As I see it the surgeon must make one of two choices: if an inhalation anæsthetic is being given, he must either proceed in his normal way, tying off his bleeding points as he goes, regardless of the effects of the anæsthetic on the fœtus, or else he must proceed at a rate far in excess of his normal, which he is probably very reluctant to do; on the other hand, with a spinal, he can proceed at whatever pace he likes, safe in the knowledge that the fœtus is not being affected. Furthermore, he has a degree of muscular relaxation greater than which not even the most pernickety surgeon could require and which could only be got with a very considerable quantity of inhalation anæsthetic. The delivery of the fœtus is usually uneventful although I admit—and here I must make it clear that in general I am speaking of the lower segment operation—I have seen one case in which the contraction of the uterus made the delivery of a large head very difficult. There is usually a quick and spontaneous expulsion of the placenta and the uterus remains hard. So far, I have not seen any post-partum hæmorrhage following a spinal but I have seen considerable trouble with the uterus in three out of 13 patients who had inhalation anæsthetics, although in every case I endeavoured to keep the inhalation anæsthetic to a minimum commensurate with a reasonably satisfied surgeon.

To sum up: from my own experience I feel that when there is no contra-indication to its use, a spinal anæsthetic is one of those which gives the best chance of a live child and the minimum risk of post-partum hæmorrhage.

Mr. Linton Snaith: For the past four or five years I have been using local anæsthetic for practically all Cæsarean sections, supplemented frequently by pentothal or cyclopropane or gas and oxygen given usually after the uterus has been opened, but with negligible premedication. My experience covers between two and three hundred cases operated on personally and another hundred or so in which other members of the staff of my department were concerned. I am satisfied with the method, though I must admit that I fall short of the standard of local anæsthesia described by Mr. Marshall. In a number of cases, however, I have had the experience of delivering the baby and having it breathe and cry immediately, often before complete removal from the uterus, only to relapse into a condition of collapse not far short of white asphyxia. None of these babies have died, but they have given rise to anxiety and have required some artificial resuscitation, and I would like to know the reason. This has occurred in cases where there could not possibly be any depressing effects from general anæsthetic or from premedication, and I would emphasize that the child has in such cases shown activity and spontaneous respiratory effort before its relapse. It seems that not even local anæsthetic removes all risk of trouble with the baby and it may be that where similar trouble occurs under general or spinal anæsthesia the anæsthetic is unneccessarily blamed.

drine at all. All the babies breathed spontaneously at birth. There were no headaches, chest complications, or urinary troubles. Vomiting was almost negligible. Relaxation of the abdominal muscles was good. Retraction of the uterus was satisfactory and there were no cases of post-partum hæmorrhage.

Many have been deterred from using this method owing to technical difficulty and occasional failures but I think the results justify the trouble involved.

I quote the opinion of one of the ward sisters at U.C.H. [2] who has nursed a great number of Cæsarean sections: "The patients return to the ward conscious and are most co-operative. They are calm, and quiet, compared with the restlessness following general anæsthesia, and do not complain of thirst and are free from pain. As a rule their general condition is better than with other anæsthetics, and they do not vomit. Very soon after operation they are able to take light but solid food and hence are much less likely to get discomfort from flatulence. The amount of post-operative drugs required is much less than with general anæsthesia. The impression of the nursing staff is in favour of epidural analgesia for Cæsarean sections."

Epidural block has many advantages over spinal analgesia. There is no risk of meningitis or nerve palsies, the fall in blood-pressure is much less, and there is no headache. I inquired from a ward sister of a provincial hospital where spinal analgesia is given as a routine, as to the condition of the patients after operation, and the reply was to the effect that the majority suffered from severe headaches owing to the haste with which they were elevated to Fowler's position. I have yet to meet an anæsthetist who would choose to have a spinal himself.

In conclusion I should like to say that an anæsthetist who cannot produce a baby which cries immediately on delivery has failed in his duty towards his patient.

Dr. J. N. Cave: I have perhaps been biased in favour of spinal anæsthetics in consequence of my early contact with Dr. Clement Norman of Broadstone, who is one of their great exponents. Subsequent experience has, however, left me convinced that they are among the best anæsthetics for Cæsarean section.

As all anæsthetists here will probably agree, although one may have considerable convictions about the suitability of a method of anæsthesia we are often hampered by the quite strong prejudices of surgeons. I venture to say that anæsthetists, perhaps because they have more than one card to play, are usually the more adaptable and so one cannot always pursue a line of inquiry as far as one would like, especially as it is obviously undesirable to have a surgeon operate in a disgruntled state of mind.

Since demobilization last year I have given anæsthetics for 28 Cæsarean sections. Of these 15 have been spinals, 12 inhalation and 1 a local going on to an inhalation. Of the 12 inhalations 7 were given for a variety of surgeons who expressed either a strong prejudice against spinals or expressed a strong wish for an inhalation anæsthetic.

The remaining 21 anæsthetics were all given for the same surgeon—of these 15 were spinals, 5 were inhalations, 1 was the mixture of local and inhalation. Of these 6 inhalation anæsthetics, 2 were given because the situation was obscure and examination under an anæsthetic was necessary before deciding on surgical interference. As in such cases the odds are slightly against the Cæsarean being required it did not seem justifiable to give a spinal. Two were given because the patients insisted on being put to sleep—and one because a patient became hysterical when the lumbar puncture was being made. The mixture of local and general was for a patient who was sent in as an emergency and was in poor shape when she reached the theatre—obviously a bad subject for a spinal. Local was used until the uterus was reached, gas and oxygen and a small amount of ether for the delivery of the child and final sewing up.

In the majority of cases the object of a Cæsarean section is to produce a live child; if the life of the mother were the only consideration the child could, by one means or another, be removed by what one might call the usual channels. So let us examine the results first of all

Section of Ophthalmology

President—HAROLD LEVY, F.R.C.S.

[*February* 13, 1947]

The following cases were shown:—

Familial Dystrophy of Cornea.—P. G. DOYNE, F.R.C.S.

Arteritis of the Temporal Vessels Associated with Loss of Vision.—SIMON BEHRMAN, M.R.C.P.

Persistent Pupillary Membrane Showing a Network Pattern.—HOWARD REED, D.O.M.S., for Professor ARNOLD SORSBY, F.R.C.S.

Mooren's Ulcer.—M. LEDERMAN, M.B., and A. RUGG-GUNN, F.R.C.S.

Melanotic Sarcoma.—P. GARDINER, M.B., for T. KEITH LYLE, F.R.C.S.

Denig's Operation for Trachoma (Two Cases).—NOAH PINES, M.B.

Mooren's Ulcer.—Professor B. W. WINDEYER, F.R.C.S.Ed.

Devicz's Disease.—A. S. PHILPS, F.R.C.S.

Retinal Glioma (Three Cases).—Professor B. W. WINDEYER, F.R.C.S.Ed.

Bilateral Embolus of Central Retinal Artery.—C. L. GIMBLETT, F.R.C.S.

Megalocornea (H.B., *see* Table)—H. E. HOBBS, F.R.C.S.

Mr. H. J. Malkin gave a preliminary report on 767 consecutive cases of Cæsarean section performed by his colleagues and himself during the last eight years at the City and Women's Hospitals, Nottingham. Of these, 736 were done under spinal anæsthesia, for which light duracaine was used almost entirely. This series covered all types of cases, including set and emergency operations for contracted pelvis, cardiac disease, toxæmia, placenta prævia, diabetes, &c.

There were eight fatalities, the causes of death being as follows:—

Pulmonary embolism ..	19th day	1
Peritonitis	6th day	1
Diabetic coma	12 hours	1
Hypertension, cerebral hæmorrhage	2 hours	1
Hæmorrhage from extra-uterine implantation of placenta ..	2 hours	1
Lobar pneumonia	9th day	1
Intestinal obstruction, previous Cæsarean section and multiple adhesions	2nd day	1
Staphylococcal septicæmia following breast abscess ..	12th day	1

It appeared that no fatality could be attributed to the spinal anæsthetic *per se*.

Among the earlier cases there were some which gave anxiety during the operation, but modification of technique had reduced these to a minimum. The modifications were: (1) reduction of the dose, (2) reduction of the time during which the patient is turned over on to her abdomen, and (3) the giving of a vasopressor substance. The turning of a pregnant patient on to her abdomen was a drawback to the method, but could be met by adequate support to the chest, and if necessary the pelvis, by pillows; this drawback did not apply to heavy nupercaine.

Mr. Malkin thought that absence of premedication had an unfavourable effect on some cases, and he had found that preliminary pethedine and hyoscine, as mentioned by Haultain, or chloral, was of great assistance. He expressed his thanks to his colleagues, Miss Glen Bott and Miss Bates, for allowing him to include their cases in the series, and to Dr. Cochrane and Mrs. Marrow for their considerable help in the collection of the records.

Dr. J. B. Cochrane (City Hospital, Nottingham), who had performed a considerable number of Cæsarean sections in the series referred to above, gave details of the technique of administration of the anæsthetic. The method employed consisted in giving 1·4 c.c. of light duracaine, turning the patient over for one minute only, and the intramuscular administration of 30 mg. of methedrine when the spinal anæsthetic was inserted. He felt that with this technique, light spinal duracaine gave no cause for anxiety in Cæsarean section.

Hence one is naturally loth to apply any form of caustic to the ulcer which might conceivably give rise to a nebula, and although each individual attack clears up in a variable time with simple treatment—the milder ones even doing so spontaneously—recurrences are very difficult to check.

In some cases the attacks may continue in a milder form after a course of treatment, and a further course after a suitable interval may be required.

In superficial punctate keratitis, an obstinate condition, about half my cases have benefited from radiotherapy; this is a condition which, as I think most will agree, does not respond readily to other methods of treatment.

I am sure that my results warrant my saying that the treatment is well worth a trial in any given case.

The ætiology of superficial punctate keratitis is admittedly obscure, different cases show varying clinical characteristics, and it may well be that they are not all of the same nature. Some of my successful cases had a history of long duration, and in those especially the cures were most gratifying.

Phlyctenular keratitis bears some resemblance clinically to acne-rosacea keratitis, in that the corneal lesions occur initially as infiltrates. But the exacerbations of this disease respond as a rule readily to other methods of treatment, and I have not found it necessary to resort to radiotherapy except in a few obstinate cases, which responded well.

My views on the effect of mild radiotherapy in cases of spring catarrh are as follows:

Severe cases with gross vegetations covering the palpebral conjunctiva, in whom the disease is present throughout the year and merely exacerbates during the spring and summer, show no encouraging results with mild radiotherapy. But in the mild cases whose eyelids are normal during the winter months, and who show fresh manifestations in the early part of each year, the treatment is well worth a trial.

If applied immediately when any signs of recurrence become evident, it may check further developments. I may emphasize here that I am dealing only with a mild dosage.

In the treatment of other types of corneal ulcer, including Mooren's ulcer and dendritic ulcer, I have not had any success with this method. Nor have I found it of value for any form of deep keratitis.

I must admit, however, that owing to my unpromising initial results—so different from those obtained in the rosacea cases—I was not encouraged to proceed further with the treatment of such conditions.

Professor B. W. Windeyer: A cardinal principle in the radiotherapy of malignant disease of the eye is to avoid or shield the eye itself whenever possible, owing to the danger of permanent damage resulting from even moderate dosage.

The most common sequelæ are those associated with the lids and lacrimal apparatus, the conjunctiva and the lens. Scarring of the lids may cause entropion or ectropion and closure of the punctum by scar tissue may result in persistent epiphora. Heavy irradiation of the conjunctiva may be followed by chronic conjunctivitis with some loss of sensitivity and chronic irritability. In such cases vascular changes are usually apparent; microscopically there is degeneration of the arterial vascular endothelium, followed by regenerative hyperplasia with narrowing of the lumen of the vessels and, clinically, dilatation of superficial capillaries and permanent telangiectasis occur.

The changes which occur in the lens after irradiation have been studied by various workers. As a rule no immediate change is seen in the function or appearance of the lens even after exposure to heavy dosage and in the great majority of cases the lens remains apparently perfectly healthy. At a later date, however, there may be degeneration of the lens with the formation of cataract and this is probably the most common late sequela of irradiation of the eye. The radiosensitivity of the lens as determined by liability to cataract formation varies greatly in different individuals. In some cases after exposure of the eye to very heavy dosage, for example in the treatment of malignant tumours, there has been no demonstrable effect, even many years later. In others with more moderate dosage, usually after the lapse of several years, progressive cataract formation has been observed. It is probable that radiation cataract is more likely to occur in those who are debilitated and undernourished, in young children and in elderly people with a tendency to spontaneous cataract formation, but it has also been found in healthy young adults. The quality of the radiation, whether hard or soft, does not seem to be a determining factor, and there would appear to be some danger of cataract formation with any dosage level which causes a definite conjunctival reaction.

DISCUSSION ON RADIOTHERAPY IN THE TREATMENT OF NON-MALIGNANT SUPERFICIAL EYE LESIONS

Mr. R. Affleck Greeves: I propose to deal solely with the treatment of superficial corneal lesions by means of mild sub-erythematous radiotherapeutic doses, with an additional brief reference to spring catarrh treated by the same method.

The possibility of treating corneal lesions by this method first occurred to me eighteen years ago in connexion with cases of acne-rosacea keratitis.

In the course of my routine out-patient hospital work, a number of these distressing cases appeared from time to time; the condition is, as a rule, extremely resistant to ordinary methods of treatment.

While, in my experience, it is not uncommon for the corneal complications to develop late in the disease, at a stage when improvement may have already taken place in the skin condition, one also meets with cases in which both types of lesion are present. I was in the habit of sending such cases to my colleague, Dr. MacCormac, for dermatological treatment, and, struck by the great improvement in the skin lesions resulting from radiotherapy, it occurred to me that it might be possible to apply the same measures to the cornea.

In conjunction with my colleague, Dr. Douglas Webster, I therefore explored the literature dealing with the results of experimental application of X-rays and radium to the eyes of animals with a view to determine if possible a dosage which would undoubtedly be free from any harmful effects. By this means we arrived at the decision that what was known in those days as a third of a pastille dose would be perfectly safe. The dose actually given was smaller than this.

Many chronic cases which had been coming to Out-patients week by week, with mournful regularity, improved rapidly with this treatment and ceased to attend.

The eyes whitened, infiltrates were replaced by healing scars and pain and photophobia vanished. On the whole the results were excellent and the majority of my cases reacted most favourably. But in line with one's common experience of therapeutic measures in general, there is always a tiresome minority of obstinate cases, which do not respond so well or so quickly, and this method is no exception to the rule.

I do not claim that radiotherapy for acne keratitis cures the condition. Its underlying constitutional cause is obscure and it is therefore obvious that until further knowledge has been gained, so that suitable general treatment directed towards removing the cause of the disease can be instituted, local manifestations are almost bound to recur.

I am convinced, however, that the periodic exacerbations can be checked in most cases by means of radiotherapy, expecially if this is given at an early stage.

The exacerbations are especially prone to occur in spring or early summer, a fact which suggests that sunlight may have a provocative effect. They take the form of an infiltrate, in the superficial layers of the cornea associated with pain, photophobia, and lacrimation; this infiltrate breaks down and becomes an obstinate and chronic corneal ulcer, and is ultimately replaced by scar tissue which forms a fairly dense nebula.

Before I instituted the treatment, these cases dragged on for weeks or even months in misery, but when treated their improvement was rapid, and after two or three weeks, disappeared, only to turn up again in the following spring with a fresh attack. But these fresh attacks yielded rapidly to the treatment, and the patient again disappeared until the following year, or in some cases after a much longer interval, when they again demanded that the treatment should be repeated.

Encouraged by my results in acne-rosacea keratitis, I tried the treatment in other corneal diseases.

It has proved to be markedly beneficial in recurrent abrasion and superficial punctate keratitis. In cases of recurrent abrasion it is, I think, especially useful. Here the ulceration is usually limited to the corneal epithelial layer and therefore heals without leaving any scar.

lasting for one or two days, but in the majority there has been no appreciable reaction and a rapid subjective and objective improvement has occurred.

The cases have been confined almost entirely to acne-rosacea keratitis, recurrent abrasions and erosions, and superficial punctate keratitis of the multiple erosion type. With this group of cases it is not possible to give a statement of results based on a definite statistical analysis as they have not been followed routinely with this end in view. Even without routine follow up it has been possible however to be sure of certain conclusions.

The cases of acne-rosacea keratitis appear to give the most gratifying results, as practically all of them get marked subjective improvement and rapid healing of individual exacerbations of the disease. They do recur at varying intervals, but the patients recognize that they have derived such benefit that they usually come for treatment again early in an attack which can be cut short in the majority of cases and may not need a full treatment.

Recurrent erosions and abrasions also respond with rapidity and although recurrence may occur after X-ray therapy it is not so frequent nor of such severity when the patient comes again for treatment. Many have remained healed with no recurrence after a single cross-fire treatment.

Cases of superficial punctate keratitis of the multiple erosion type have been the largest single group in our series and at least half the cases have shown a satisfactory response. Some have shown the same tendency to recurrence as the cases of acne-rosacea keratitis and have received up to six treatments over periods up to four years, showing improvement after each treatment similar to the acne-rosacea cases. Others have had one or two treatments spread over one to three months with relief of symptoms. The outstanding impression gained from a study of these groups of cases, acne-rosacea keratitis, recurrent erosions and superficial punctate keratitis was that X-ray treatment had often succeeded after other methods of treatment had failed or had only produced some temporary alleviation and that, while many cases did recur after X-ray therapy and needed a further course of treatment, they tended to be free of symptoms in the intervening period and did not have to make frequent attendances for local applications, as many of them had done previously.

My experience of other superficial non-malignant conditions of the eye has been much more limited. In Mooren's ulcer this technique has not been found to be effective and for the last three or four cases which have been treated the dose has been increased using the same cross-fire arrangement of fields. The patient shown to-day, a young woman, was first treated by the actual cautery in June 1945. In July and August 1945 she was given 1,200 r to both medial and lateral fields over a period of twenty-eight days. At the end of treatment there was definite improvement and the ulcer was healed either on account of or in spite of this treatment within six weeks. I have had no experience of the treatment of these lesions with radium applicators with either β or γ radiation.

In spring catarrh the results on the whole have been disappointing. We have not thought that it was justifiable to give heavy dosage which might cause permanent scarring and chronic conjunctivitis for a condition which is ultimately self-limiting. We have employed milder dosage, either by everting the lids and applying a lightly screened β ray radon applicator or by irradiating with X-rays, through the closed lid after cocainization of the conjunctiva and the insertion of a lead screen to protect the eye. Doses of the order of 150 r have been given in this way with X-rays generated at 95 kv. with 1 mm. aluminium filter and have been repeated at intervals of two to three weeks up to four treatments. There has been only slight response when treatment is given during an exacerbation in the spring or summer, but there seems to be definite benefit to be derived from giving such a course of treatment towards the end of the winter before the eyelids begin to be inflamed again. In some mild cases the seasonal attacks are almost aborted and in others their severity is reduced.

Dr. M. Lederman: Although radiotherapy is now accepted as a therapeutic agent of value in many specialities, in ophthalmology it has not yet received the recognition it merits.

The reasons for this are twofold: (1) Current misconceptions concerning the susceptibility of the eye to radiation damage; (2) the eye diseases for which radiotherapy is suitable are not common, hence its field of usefulness is rather restricted.

The view that the eye is readily damaged by radiation cannot now be supported, as it is largely based upon early, unscientific experimental work, and the ocular disasters encountered by pioneer radiotherapists. With modern apparatus and technique, damage to the eye is avoidable when treating non-malignant lesions; risk of ocular damage has to be accepted only when treating malignant neoplasms which affect the eye or its neighbouring structures.

Philippa Martin, who has made a study of injury to the eye by therapeutic radiation, gives two years or even longer as the period likely to elapse between the time of the treatment and the onset of cataract. She has, however, observed the early occurrence of cataract; in one case it appeared three days afer the irradiation of the eye and was mature after the lapse of seven weeks, while in another case of which the lens showed vacuolation ten days after treatment, the vacuoles had disappeared after fourteen weeks. Colwell and Russ state that the earliest recorded time for cataract to appear is four months after irradiation.

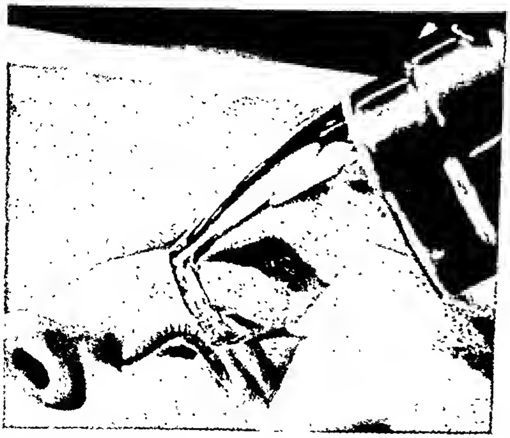
The typical irradiation cataract is posterior cortical with radiating rows of vacuoles and these may be arrested in the vacuolar stage or may go on to maturity, vacuolar opacities gradually becoming scattered through the entire lens cortex, which eventually becomes completely opaque. A mature irradiation cataract shows no special clinical features and responds as well to operative treatment as do other forms of cataract.

While cataract formation is not an uncommon sequel of irradiation it must not be forgotten that cataracts do form in elderly people without previous irradiation, and that every case of cataract in people who have been irradiated is not necessarily due to this cause.

Many other rarer sequelæ of irradiation of the eye have been described but these recapitulated here are the commonest and might occur perhaps without excessive dosage.

The technique which has been used at the Middlesex Hospital for the treatment of superficial non-malignant conditions of the eye has been designed to avoid these dangers both by the direction of the beam to avoid the lens and by limiting the dose delivered to one which has been shown to be well tolerated and insufficient to cause any damage.

In 1937, Dr. Douglas Webster described the technique which he had worked out with Mr. Affleck Greeves for the treatment of superficial corneal lesions by cross-firing the cornea with X-ray beams. This technique, with very minor modifications, has been used continuously from 1926 up to the present time. The technical factors are as follows: X-rays generated at 95 kilovolts; 1 mm. aluminium filter; 2·5 milliamperes current; 18 cm. focal skin distance.



The cornea is irradiated from the lateral (*see* fig.)—and the medial sides, using a beam which is sharply defined by means of a lead glass applicator with a 2·5 cm. diameter aperture. The tube is arranged for each field so that the lower margin of the beam only is directed across the cornea and irradiation of the lens is avoided. but the whole of the surface of the cornea is irradiated.

The patient is treated with the eye open and is instructed to look fixedly at a white mark which is placed in a suitable position on the X-ray tube housing. This produces sufficient fixation of the eye with slight internal rotation for the lateral field and external rotation for the medial field. The setting of the tube for each treatment, which is invariably carried out by one of the radiotherapists and never by a technician, has to be undertaken with great care, especially the medial field where the applicator comes in contact with the patient's nose.

A dose of 100 r measured at the aperture of the applicator is delivered to each field. Taking into consideration the distance from the end of applicator to the centre of the cornea, which is calculated as 1·8 cm. and the fact that the extreme edge of the beam is used, it is estimated that the cornea receives a dose of 60 to 65 r from each field or a total of 120 to 130 r per treatment. With the factors stated the treatment of each field takes less than two minutes. This dose is repeated if necessary at fortnightly intervals, up to a maximum of four treatments in a single course. Some patients have had the course of treatment repeated several times at intervals of nine months to a year or more.

Webster reported the treatment of 146 patients with superficial corneal lesions treated between 1926 and 1936 and since that time a further 108 patients have been treated, a total of 254. The numbers were smaller during the war years. There has not been any evidence of late damage in these cases. In some cases there has been an exacerbation of symptoms

The dosage required is important since: (1) Improper dosage may aggravate the condition: (2) repeated treatments for recurrent attacks may become necessary, and without proper care can be dangerous.

My first cases of superficial punctate keratitis and rosacea keratitis were treated by superficial X-ray therapy, the technical factors being: 90 kV., 4 ma., 1 mm. Al filter, F.S.D. 23 cm. A field just large enough to fit between the margins of the bony orbit was used and treatment given directly through the closed lids. No special measures to protect the lids or lashes are necessary. Doses of the order of 70 to 100 r were given once a week for four to five weeks.

With these doses there may be an exacerbation of symptoms. In order to eliminate this possibility and also with a view to the probable need for repeated courses of treatment, in recent years I have been giving a minute initial dose, i.e. 10 to 15 r. I have noticed no difference in results by starting with this small dose and gradually increasing it to a final dose of 40 to 50 r, treatment being given twice a week. The initial "flare-up" is eliminated and the total dose required, about 200 to 250 r, is almost half that given by the earlier technique. Total doses of this order spread over four to five weeks can be safely repeated on a number of subsequent occasions if necessary. It is important to emphasize that a rigid standard technique is to be avoided and individualization of treatment is essential.

Miscellaneous conditions (Table III).—I have treated a few opacities with no striking results, although every now and then there does seem to be some improvement. I have also treated a few corneal dystrophies without much success. Although I have not had the opportunity of treating pterygium, the American literature contains quite definite claims for radiotherapy in the treatment of this condition.

Two of the remaining conditions, namely corneal ulceration and recurrent erosion, are most definitely favourably influenced by radiotherapy. A single dose of X-rays (75 r) will often act like magic on an erosion. Symptoms are relieved very quickly and only exceptionally is a second or third dose necessary.

In corneal ulceration, excluding Mooren's ulcer, X-ray therapy not only relieves symptoms but sometimes results in healing. The technique of treatment is approximately the same as that employed for superficial punctate keratitis and rosacea keratitis.

TABLE III.—MISCELLANEOUS CONDITIONS

Corneal ulcer, including Mooren's ulcer	*Degenerations and dystrophies*	Pterygium Cornea
Corneal opacities, following infection or trauma	*Traumatic lesions*	Recurrent erosion

Mooren's ulcer presents a special problem. Radiotherapy has frequently been advocated but its value has never been established. I have seen 6 cases, including 2 with bilateral lesions. Good results have been obtained in only two lesions, one has remained healed for two years four months, and the other for two years five months. In both cases treatment was given with a special beta-ray applicator (fig. 1). The remaining lesions treated by X-ray therapy were all failures.

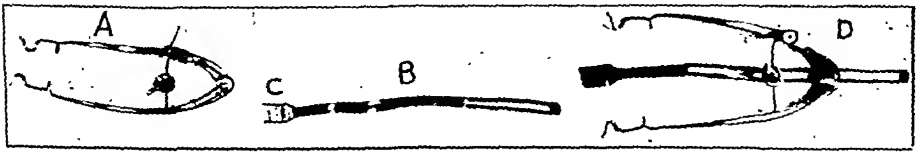


FIG. 1.—BETA-RAY APPLICATOR

A = Speculum with universal screw.

B = Radium spatula consisting of a malleable, slotted brass holder and C = A hinged radium applicator. The radium spatula can be used separately for lesions of the palpebral conjunctiva or lids.

D = Apparatus assembled for treatment of lesions of the cornea or bulbar conjunctiva.

Acknowledgments.—I am indebted to the members of the staff of the Royal London Ophthalmic Hospital and the Western Ophthalmic Hospital for referring cases for treatment and for permission to use the material thus obtained. I am particularly indebted to Mr. C. Dee Shapland, Ophthalmologist to the Royal Cancer Hospital, for helpful advice and criticism.

The beta-ray apparatus was made by Messrs. Down Brothers, and the radium applicator by Messrs. Johnson, Matthey & Co.

Three types of radiation can be used in the treatment of non-malignant lesions of the eye; the beta and gamma rays of radium and X-radiation. X-rays have largely replaced radium in ophthalmology because of technical simplicity, the ease with which the tissues not requiring treatment can be protected, and the short treatment times needed.

Nevertheless, radium still has its indications. Thus, beta radiation, using special applicators, offers advantages in the treatment of certain lesions of the cornea, limbus and conjunctiva. Similarly gamma radiation possesses certain advantages over X-radiation, in the treatment of hæmangiomata and keloids.

The non-malignant lesions for which radiotherapy can be used fall into three groups: (1) Benign tumours; (2) inflammatory lesions; (3) miscellaneous group.

The purpose and technique of treatment vary from group to group but the underlying principle of treatment is to give the smallest possible dose which will achieve the desired result.

Benign tumours.—Table I shows some of the commoner benign tumours encountered by the radiotherapist. Not all of them respond to radiotherapeutic treatment and it is of vital importance that cases be properly selected. When this is done the results of treatment are usually extremely gratifying, whereas indiscriminate treatment may be both harmful and dangerous.

The hæmangioma and the keloid are essentially the province of the radiotherapist whereas the pigmented tumours are best left alone or dealt with surgically. Solitary papillomata and hyperkeratoses can be treated quite adequately by radiotherapy, but where there is any doubt about their benign nature, excisional biopsy should be performed.

TABLE I.—BENIGN TUMOURS

Hæmangioma	Eyelids	*Hyperkeratosis*	
	Conjunctiva		
	Orbit	*Benign Melanoma* (Pigmented nævus)	Lids
Keloid			Conjunctiva
Papilloma	Lids		
	Conjunctiva		

With regard to *inflammatory lesions* one is on less certain ground. At some time or another radiotherapy has been tried in the treatment of most ocular inflammations. Whilst many of the claims made in the literature should be accepted with reserve, the fact does emerge that radiotherapy can be of use, particularly in the treatment of some of the more refractory inflammatory disorders.

Any indiscriminate or immediate resort to radiotherapy in the treatment of ocular inflammations is to be deprecated. Radiation is, after all, a noxious agent, its precise mode of action on inflammatory processes is still a matter for conjecture, its effects are by no means prompt, and in acute cases valuable time may be lost. When chemotherapeutic, surgical or other procedures are known to give satisfactory results, these should always be given priority.

Table II lists a number of conditions in the treatment of which I believe radiotherapy has a part to play.

Superficial punctate keratitis and rosacea keratitis are the two conditions of which I have had most experience and they can be considered together, as it is in their treatment that radiotherapy is neglected.

TABLE II.—INFLAMMATORY PROCESSES

Pyogenic	Blepharitis	*Virus*	Trachoma
			Herpes ophthalmicus
Granulomatous	Tuberculosis		Superficial punctate keratitis
	Sarcoidosis	*Unknown ætiology*	Rosacea keratitis
Allergic	Spring catarrh		
	Phlyctenular kerato-conjunctivitis		

Radiotherapy cannot cure all cases, but for the stubborn case much can be done by way of symptomatic relief and improvement of physical signs, and on occasion clinical cure can be achieved. There can, of course, be no guarantee against recurrence.

There is a very high percentage of bilateral lesions in this series—higher than is usually quoted in the literature.

Dr. N. S. Finzi said that he would like to discuss the cases just presented. Mr. Durden Smith had said that he gave 6,000 r of the beta radiation. It was necessary to point out that gamma radiation would not fall off in anything like the same degree per mm. of tissue as the beta radiation. How much of the results was due to the gamma radiation he would be able to tell in the future, because after a time he would be able to use radioactive isotopes, and Dr. Finzi thought that radioactive phosphorus would give beta rays only, so that it would be possible to see whether he could get the results with beta rays alone without the addition of gamma rays.

With regard to the other cases he agreed with what Professor Windeyer had said and with most of what Dr. Lederman had said. He did not agree that capillary angioma did not respond at all. He had occasionally got very good results in that condition. Professor Windeyer had made the actual measurements with his cases so that Mooren's ulcer did require more dosage, but when one was using the edge of the applicator it was very easy, especially with a lead-glass applicator, to get a little bit out and not to give quite the dose one thought one was giving. Therefore he might possibly have given rather smaller doses than he supposed, but Professor Windeyer was a very careful observer and it must be accepted that the doses he mentioned were actually given in these particular cases. With inflammatory conditions in general very small doses were required.

Mr. Eugene Wolff said that he had seen half a dozen cases of stenosis of the punctum and canaliculus after radiation. These cases were difficult to treat, and he wondered whether one ought not to slit the canaliculus in every case, before radiation.

Dr. B. Thorne-Thorne referred to a young girl, aged 6, who had dermolipoma of both eyes. In one eye there was now infiltration down over the cornea which seriously affected the vision. He wondered whether any form of radium or X-ray application was likely to bring about relief.

Professor Windeyer said, in reply to Dr. Finzi, that it was very difficult to be absolutely sure of the measurement, as a very small alteration in the accuracy of setting up might make a difference of as much as 50% to the dose received on the cornea, and it was likely that inaccuracies would decrease rather than increase the dose. Nevertheless, he felt reasonably confident that the dosage which he had described had been given.

On the question of scarring of the punctum (Mr. Wolff), this was a very serious thing in the treatment of certain malignant neoplasms, particularly basal-cell carcinoma around the lid, and it was a very distressing condition. He did not think that splitting of the canaliculus would get over the trouble, because in these cases, i.e. heavy doses for malignant disease, there was very marked scarring. He had not observed this to have occurred in the treatment of these non-malignant conditions in which they had given such small dosage. He did not think it a danger to worry about.

A dermolipoma (Dr. Thorne-Thorne) he thought unlikely to be radiosensitive.

Dr. M. Lederman, also in reply, referred to the dosage used with Mooren's ulcer. He himself had not used one consistent dose but had attempted to gain the maximum information. One unilateral case he had treated with small doses was an utter failure, and cases he had treated with doses almost approaching those used in malignant disease were equally a failure. In his two successful cases a single dose of 1,500 r was given using a special beta-ray applicator—the treatment time being about eleven minutes.

With regard to dermolipoma he would say on general principles that radiation was unlikely to help.

He reiterated what Professor Windeyer had said concerning the canaliculus.

Mr. A. J. Durden Smith: *Mooren's ulcer.*—Among non-malignant conditions affecting the eye Mooren's ulcer is outstanding for several reasons. It is a rare disease—the series I propose to examine amounts to only 42 cases and these have been treated at the Radium Institute over a period of fifteen to sixteen years. It is among the most distressing of eye conditions in that the symptoms—pain, epiphora and photophobia—are usually so marked as to reduce patients to a pitiable condition of mind. It is a form of corneal ulceration which is very difficult to cure and even when healing is achieved the results in terms of loss of vision are often deplorable, and depend in any case on the extent of the ulceration at the time of its first treatment.

Treatment.—Treatment has been uniform over a number of years, and Roy Ward of the Radium Institute in London did much of the early work on the subject. Contact radiation with unscreened radium applicators has been the method used, the applications being given as a rule three times at intervals of six weeks, whether the primary result is satisfactory or not.

Technique.—After cocainization the patient lies on a couch in the dorsal position with the head immobilized by sandbags. A speculum is inserted into the affected eye, and the radium applicator, covered by para-rubber and lubricated with liquid paraffin, is held in contact with the cornea. A piece of adhesive tape, previously applied to the applicator, is used to fix the latter to the cheek and eyebrow, and other pieces of tape are used, if necessary, to position the applicator accurately on the cornea. The room is then darkened and a dull red neon lamp on a stand and capable of movement in all directions is so adjusted that when the patient gazes at it with the sound eye the area of ulceration is beneath the applicator. This is done by the light of a stick lamp. The patient is warned that he must continue to gaze steadily at the lamp and he is inspected at frequent intervals to see that he is doing so, and that the applicator remains in position. Treatment time is usually in the region of an hour. A good deal of concentration on the part of the patient is required for this, and one gets the impression that the best results are obtained in cases where the patient is intelligent and co-operative.

Dosage.—The radium applicators used are all of full strength, i.e. 5 mg. per sq. cm. and are substantially unscreened—the contact surface consisting of 0·1 mm. monel metal. The most usual sizes are 1·0 and 1·25 cm. in diameter.

A typical applicator gives 6,000 r per hour on the surface and the intensity is uniform over the whole area of the applicator. The intensity falls off very rapidly in the surface layers of the cornea being about 50% at 1 mm. and 25% at 2 mm. This means that there is no considerable dosage to the lens, or indeed to the deeper layers of the cornea. This form of beta radiation is analogous biologically to hard gamma rays differing a good deal from soft X-rays in their effect. Treatment time is short and there is no caustic action, radiation reaction being slight or absent. The dosage, although it appears to be unusually high, is comparable with dosage by other forms of radiation allowing for the rapid fall-off in depth dose and for the fact that the biological efficiency is less.

Results.—42 cases of Mooren's ulcer have been seen at the Radium Institute since 1932. Two of these were not treated—in one case the first treatment was incomplete and the patient refused further treatment. In the other case the ulcer was exceedingly deep and conjunctivitis marked. This ulcer perforated a few days later and the eye was excised.

Of the 40 cases treated—21 occurred in men and 19 in women. The average age was 55. As a result of treatment 18 of these were healed and free from recurrence for periods of two years or more.

Thus: 1 for nine years, 1 for seven years, 1 for six years, 2 for five years, 10 for four years, 1 for three years, and 2 for two years.

11 other ulcers were known to be healed when last seen, but were lost sight of for varying periods of from four months to two years after treatment.

This would suggest that nearly half these cases did well, for periods long enough to hope that they would remain healed permanently and that over 25% of the rest did well primarily.

The picture is not quite so bright as this, for a high percentage of cases was bilateral on arrival—17 in all. A further 6 cases had primarily had ulceration in the other eye but this had been cured—in two cases by excision of the eye.

Of the 17 cases who had bilateral ulceration on arrival, 7 cases healed on both sides as a result of treatment, 4 cases healed on one side but not on the other, and the remaining 6 failed to heal on either side. Of the 6 cases in which one side had healed as a result of previous treatment, the more recently ulcerated cornea was healed in 3 cases.

brought me six different makes of lipstick that she used. Patch tests showed that two makes caused severe blistering, three others caused various degrees of redness and swelling and only one was free from reaction. Within a week of changing her lipstick to the innocuous variety her eye symptoms disappeared for ever.

The plants commonly causing trouble are primulas, chrysanthemums, dahlias, poison ivy and some virginia creepers. Usually there is some local irritation on the hands, but this may be so slight as to be scarcely noticed. Lids and conjunctiva are usually severely affected. Patch tests are necessary for the diagnosis of this type of sensitivity.

(2) The air-borne allergens are an important group and sensitivity to these allergens may be very difficult to deduce from the history. The common offenders are pollens, house dust (i.e. dust from disintegration of textiles, such as carpets, bedding, &c.), feathers, animal hairs and dandruff, orris root and moulds. Patting an animal and then rubbing the eyelids may cause a severe conjunctivitis in a sensitive person.

Since contact with house dust and feathers in bedding is very close and continuous it is difficult to obtain a direct history of irritation due to such contacts and routine testing by the intradermal method is required. Occasionally a clear-cut history is obtained, as for example a woman who had her first severe attack after spring cleaning and rubbing down wall paper and thereafter exacerbations whenever she used a brush and pan for cleaning the stair carpets. She did well on desensitization and changing to the use of a Hoover for cleaning purposes. In cases due to these allergens it is essential that the condition be explained to the patient and co-operation in avoidance of the irritating contacts obtained.

Where the actual irritating substance can be found and eliminated, results are excellent. Where it is found but cannot be wholly eliminated—partial elimination and desensitization give good results, the length of benefit being often proportional to the co-operation of the patient with regard to avoidance.

(3) Finally, a few cases of allergic eye reactions have been found due to ingestion of allergic food-stuffs. Children are most likely to be affected in this way. Wheat, milk and eggs are the most common allergens and I have seen cases due to all three. In my experience other allergic signs will be found somewhere in the body in all such cases.

ENDOGENOUS ALLERGY

Here we are on less sure ground and the results are equally uncertain. Focal eye reactions such as iritis may be due to bacterial allergy from sites of infections in teeth, tonsils, sinuses or even gall bladder. Here we can only treat by searching for and eliminating the focus, helping things in some cases by a bacterial vaccine. There is evidence of specificity of the vaccine in some cases, as the injections may cause a recrudescence of the iritis if an overdose is given. Cure following such treatment is not uncommon when the local focus can be easily dealt with. In bacterial allergy, skin tests are useless as almost all persons show skin reactions to the common bacteria. They have been abandoned by most allergists.

I have spoken almost entirely of the type of case where the pathologist can help. In other types of endogenous allergy particularly, little specific treatment is available. Benadryl and other anti-histamine drugs have a place, although a small one, in palliative treatment of certain cases.

Dr. J. T. Ingram: The term allergy covers those expressions of the individual which reflect his personal and peculiar sensitiveness to certain experiences and stimuli from within or without. I cannot see any great distinction between expressions which arise from vague, general or indifferent causes and those which arise from definite and recognized stimuli. We must not, because of the magic word allergy, feel that a dermatitis of the lids provoked by eye-shadow is to be placed in a different field from a dermatitis produced by rubbing and scratching and consequent upon a psychogenic pruritus.

In the former case we have recognized one material factor to which the tissues are sensitive and the exhibition of that material will always revive the tendency to reaction—it has become a habit, like a conditioned reflex. In the latter case—the neurodermatitis—the stimulus is not a specific or a recognized material one though, no doubt, some material metabolite produced by nervous, endocrine or other activity is as definitely responsible as the exogenic agent in the cosmetic. In this latter case too the factor of habit-formation is by no means absent. We must remember that not only individuals but their several and particular tissues are as habit forming as the famous horse of Evesham.

I would, therefore, start from the individual, giving consideration to all those influences, endogenic and environmental, which bear upon his physiological tone and pathological reactions.

Allergic reaction.—It would seem probable that the allergic reaction is merely incidental and not related to immunity, that it serves no very useful purpose and is only harmful

[*March* 13, 1947]

DISCUSSION ON ALLERGY IN OPHTHALMOLOGY

Mr. Gayer Morgan in his opening remarks gave a short description of what was meant by allergy and the allergic reaction. He stressed its great importance in clinical medicine and pointed out that almost every disease of the eye had been reported as allergic in origin in some particular case. It was necessary to find some underlying feature which would suggest allergy, and so he discussed the type of person who is naturally allergic by inheritance, and those people who develop the tendency during the normal periodic stresses and strains of life, or the abnormal worries and frustrations which are such frequent accompaniments of modern existence. These produce a mental and physical exhaustion and so predispose to hypersensitivity. In this state there are biochemical changes, endocrine disturbances and liver dysfunction, and a person becomes sensitive to many different antigens, the one to which he falls depending on his environment.

Characteristics of the allergic reaction were discussed. The patient's complaints are far in excess of the actual condition found—waxing and waning of the symptoms is a prominent feature. Tissue fluid mobilization is very characteristic, and on these lines many different pathological conditions were considered affecting the lids, conjunctiva, cornea, iris and ciliary body, lens, choroid and retina.

The question of migraine and epilepsy as possibly allergic phenomena was discussed.

Dr. C. J. C. Britton: *Allergy in ophthalmology from the point of view of a clinical pathologist.*—Before an allergic investigation is undertaken it is essential that a local bacterial infection in the eye shall be excluded. It is surprising in how many chronic, mild or moderately severe cases the cause of the chronicity is a bacterial infection, even although the fundamental basis may be a true allergic sensitization to an exogenous allergen such as house dust, &c. Of course some cases are wholly bacterial and I have seen a number of cases in which *Staph. aureus, H. influenzæ* and even β hæmolytic streptococci have been the cause of a longstanding but relatively, in fact surprisingly, mild conjunctivitis.

Once infection has been excluded a presumptive indication of an allergic ætiology in a conjunctivitis may be determined by examining a smear of the discharge from the eye for eosinophils. In actual fact this examination is often omitted, as although the presence of numerous eosinophils is of importance in a positive way, occasionally eosinophils may be absent in some cases in which there is no doubt as to the allergic basis. Thus, I have sometimes failed to find eosinophils even in cases of true pollen conjunctivitis.

The next stage is to take the full history as to asthma, hay fever, skin troubles, urticaria, stuffy noses, sneezing attacks or severe chronic catarrh, migraine and bilious attacks. A positive family history is suggestive.

Next comes the history of the onset, the periodicity and the time of day when worst, and the use of drugs.

Based on these replies skin tests are carried out—intradermal, scratch or patch tests.

Allergic eye conditions may be due to three main causes: drugs used locally; endogenous allergens; exogenous allergens.

Drugs used locally.—Some of the less rare offenders in this group are atropine, yellow oxide of mercury, zinc sulphate, cocaine and allied anæsthetics, penicillin and sulphonamides.

The endogenous allergens include the cases due to bacterial or bacterial toxin allergy and cases due possibly to metabolic or endocrine disturbances. These cases are most difficult to diagnose, in fact the diagnosis is largely by exclusion.

EXOGENOUS ALLERGY

The exogenous allergens form an extremely wide group and may be subdivided into:—

(1) Contact irritants other than drugs; (2) airborne irritants; (3) ingestants.

Contact irritants other than local drugs.—The common offenders in this group are cosmetics, certain plants, and occupational dusts and contactants. Common cosmetics causing trouble are hair dyes (aniline or vegetable), shampoos, face powders, wave-setting lotion, lipstick and nail polish or polish remover. I have seen cases with lesions entirely or almost entirely confined to the eyes due to all of these. It is curious how little irritating effect say nail polish or shampoo may have on the fingers or scalp and yet the conjunctivitis may be severe and swelling of lids marked. In one case, that of a lady who had had severe irritation of the conjunctiva and swelling of the lids for many months despite all types of local treatment, the irritation at night was so severe as to make her almost suicidal. Testing for sensitivity to all the usual allergens proved negative until the patient stated in general conversation that her lips tended to get rather dry. Clinically there was no obvious lesion on the lips. She brought me six different makes of lipstick that she used. Patch tests showed that two makes caused severe blistering, three others caused various degrees of redness and swelling and only one was free from reaction. Within a week of changing her lipstick to the innocuous variety her eye symptoms disappeared for ever.

The plants commonly causing trouble are primulas, chrysanthemums, dahlias, poison ivy and some virginia creepers. Usually there is some local irritation on the hands, but this may be so slight as to be scarcely noticed. Lids and conjunctiva are usually severely affected. Patch tests are necessary for the diagnosis of this type of sensitivity.

(2) The air-borne allergens are an important group and sensitivity to these allergens may be very difficult to deduce from the history. The common offenders are pollens, house dust (i.e. dust from disintegration of textiles, such as carpets, bedding, &c.), feathers, animal hairs and dandruff, orris root and moulds. Patting an animal and then rubbing the eyelids may cause a severe conjunctivitis in a sensitive person.

Since contact with house dust and feathers in bedding is very close and continuous it is difficult to obtain a direct history of irritation due to such contacts and routine testing by the intradermal method is required. Occasionally a clear-cut history is obtained, as for example a woman who had her first severe attack after spring cleaning and rubbing down wall paper and thereafter exacerbations whenever she used a brush and pan for cleaning the stair carpets. She did well on desensitization and changing to the use of a Hoover for cleaning purposes. In cases due to these allergens it is essential that the condition be explained to the patient and co-operation in avoidance of the irritating contacts obtained.

Where the actual irritating substance can be found and eliminated, results are excellent. Where it is found but cannot be wholly eliminated—partial elimination and desensitization give good results, the length of benefit being often proportional to the co-operation of the patient with regard to avoidance.

(3) Finally, a few cases of allergic eye reactions have been found due to ingestion of allergic food-stuffs. Children are most likely to be affected in this way. Wheat, milk and eggs are the most common allergens and I have seen cases due to all three. In my experience other allergic signs will be found somewhere in the body in all such cases.

ENDOGENOUS ALLERGY

Here we are on less sure ground and the results are equally uncertain. Focal eye reactions such as iritis may be due to bacterial allergy from sites of infections in teeth, tonsils, sinuses or even gall bladder. Here we can only treat by searching for and eliminating the focus, helping things in some cases by a bacterial vaccine. There is evidence of specificity of the vaccine in some cases, as the injections may cause a recrudescence of the iritis if an overdose is given. Cure following such treatment is not uncommon when the local focus can be easily dealt with. In bacterial allergy, skin tests are useless as almost all persons show skin reactions to the common bacteria. They have been abandoned by most allergists.

I have spoken almost entirely of the type of case where the pathologist can help. In other types of endogenous allergy particularly, little specific treatment is available. Benadryl and other anti-histamine drugs have a place, although a small one, in palliative treatment of certain cases.

Dr. J. T. Ingram: The term allergy covers those expressions of the individual which reflect his personal and peculiar sensitiveness to certain experiences and stimuli from within or without. Thus, I have sometimes failed to find eosinophils even in cases of true pollen conjunctivitis.

The next stage is to take the full history as to asthma, hay fever, skin troubles, urticaria, stuffy noses, sneezing attacks or severe chronic catarrh, migraine and bilious attacks. A positive family history is suggestive.

Next comes the history of the onset, the periodicity and the time of day when worst, and the use of drugs.

Based on these replies skin tests are carried out—intradermal, scratch or patch tests.

Allergic eye conditions may be due to three main causes: drugs used locally; endogenous allergens; exogenous allergens.

Drugs used locally.—Some of the less rare offenders in this group are atropine, yellow oxide of mercury, zinc sulphate, cocaine and allied anæsthetics, penicillin and sulphonamides.

The endogenous allergens include the cases due to bacterial or bacterial toxin allergy and cases due possibly to metabolic or endocrine disturbances. These cases are most difficult to diagnose, in fact the diagnosis is largely by exclusion.

EXOGENOUS ALLERGY

The exogenous allergens form an extremely wide group and may be subdivided into:—

(1) Contact irritants other than drugs; (2) airborne irritants; (3) ingestants.

Contact irritants other than local drugs.—The common offenders in this group are cosmetics, certain plants, and occupational dusts and contactants. Common cosmetics causing trouble are hair dyes (aniline or vegetable), shampoos, face powders, wave-setting lotion, lipstick and nail polish or polish remover. I have seen cases with lesions entirely or almost entirely confined to the eyes due to all of these. It is curious how little irritating effect say nail polish or shampoo may have on the fingers or scalp and yet the conjunctivitis may be severe and swelling of lids marked. In one case, that of a lady who had had severe irritation of the conjunctiva and swelling of the lids for many months despite all types of local treatment, the irritation at night was so severe as to make her almost suicidal. Testing for sensitivity to all the usual allergens proved negative until the patient stated in general conversation that her lips tended to get rather dry. Clinically there was no obvious lesion on the lips. She enlightening, but I will first consider certain granulomata provoked by drugs, toxins and infective organisms. The conjunctiva, as well as the skin, may participate in such reactions.

Granulomatous reactions occur on the lids from sensitiveness to drugs like bromides and iodides, the former being more common in infants.

But in this group we naturally turn to those reactions associated with infective organisms as the treponema of syphilis and the tubercle bacillus.

In tuberculosis, I have seen erythema nodosum—the earliest of the sensitization reactions—on the face and presume it may attack the lids. The Mantoux reaction is strongly positive. I believe that phlyctenular conjunctivitis may be of this character but in my department at Leeds which deals with about 6,000 new cases a year and several hundred cases of tuberculous skin disease, phlyctenular conjunctivitis is hardly ever seen.

The papulo-necrotic tuberculide—the superficial gummatous tuberculide—is the reaction more commonly seen and is related to a later stage of the disease. So far as the skin itself is concerned the affection is not a serious one and is rarely associated with any severe degree of infection of viscera or glands, but in the eye it can, presumably, cause much disorganization. There is a strong positive reaction to the Mantoux test. Though dependent for its character upon the age of the infection, it would seem that only certain types of individual are susceptible. We know little of the type except that there would seem to be some disturbance of endocrine balance exercising an effect on neurovascular tone and these subjects are peculiarly susceptible to climatic influences.

In the absence of any major tuberculous disease demanding attention, the best treatment is to seek a suitable climate, though empirical remedies such as arsenic, gold and tuberculin injections are of some value.

Lupus vulgaris is another peculiar and personal type of reaction to the tubercle bacillus, and may occur on lids and conjunctiva.

Sarcoidosis may be tuberculous, shows a negative or minimal reaction to the Mantoux test, is uncommon on the lids but may occur. Uveoparotitis I believe to be tuberculous but do not include in sarcoidosis.

There is a group of eruptions we call tuberculides and which particularly affect the face, including the lids—acnitis, acne agminata, follicular lupus of Tilbury Fox and the rosaceous tuberculide of Lewandowsky. On rare occasions these may be sensitization reactions to tuberculous disease, but in the majority of cases there is no evidence to support the suggestion.

Rosacea.—The lids are commonly involved and lesions occurring on the conjunctiva may give rise to serious ulceration and scarring. Rosacea is an affection of rather acute character producing a chronic pattern of allergic reaction. It is not dependent upon any single stimulus—infective or otherwise—but is intimately bound up with the individual pattern of patient, has great psychological significance, is influenced to a marked degree by endocrine function and vasomotor tone and is variably linked with a number of nutritional and other factors. At the same time response to local treatment is often dramatic.

Finally, any conception of allergy is unfortunate that confines our views upon a subject which in fact covers the greater part of the field of medicine and pathology. Conceptions and practices based upon ideas of skin tests or a few particular biochemical reactions and methods of desensitization must limit our vision. Treatment is still in large part empirical. Work on the anti-histamine preparations may give us another useful weapon.

Mr. Eugene Wolff mentioned a lady aged about 50 who had a painful eye, with tension, every time she got an attack of urticaria. The condition was promptly cured when 0·5 c.c. of adrenaline was injected subcutaneously.

Dr. Eric Lipman Cohen said that Dr. Britton had overrated the value of the intradermal test. A negative intradermal test meant nothing, and a positive intradermal test did not mean that the cause of the patient's symptoms had been found. It had been shown repeatedly that nearly all infants would give a positive intradermal test to certain substances, notably eggs, but these children would not necessarily get symptoms from ingesting eggs. Again, to recommend intradermal testing to those who were not doing it all day long was a dangerous thing, because patients had been known to collapse during these tests. Although scratch tests were less satisfactory technically, they were much safer.

With regard to benadryl causing drowsiness in the daytime, that could be arrested by giving in the morning a small dose of amphetamine sulphate.

Dr. E. Felix said that the whole science of allergy was nothing else but the science of symptoms. Nothing indicative of irreversible allergic tissue changes are found post mortem, when it involves a vital organ or tissue. The practical value and significance of skin tests—scratch and intradermal—are limited and they have added not a little to our confusion.

In the biochemical field little has yet been achieved but research is obviously necessary and important. The problem is complicated by the secondary biochemical disturbances set up by the production of histamine in the allergic reactions themselves. The researches of Lewis have shown much of the nature of the acute physiological reactions consequent upon the action of histamine-like substances upon blood-vessels.

The pathological reactions, transient and persistent, are various and show a focal œdema and degeneration of connective tissue which may proceed by histiocytic proliferation to granulomata of the rheumatic or tuberculoid patterns or to eosinophilic infiltrations. These are being clearly defined and correlated.

Clinical features—acute.—On the clinical side we have to distinguish between reactions which are primarily epidermal and those which are dermal. Reactions sometimes relate to particular tissues, as to lens tissues in cataract or to vessel walls in polyarteritis nodosa.

We must differentiate between acute reactions, almost physiological in character, and those of a more chronic and pathological character as from some drugs, toxins and organisms.

Epidermal and some dermal reactions are acute and tend to be of a catarrhal type like eczema or dermatitis, or urticaria. The eyes and eyelids figure conspicuously in the emotional life of the human animal. The eyelids are a favourite site for itching and neurodermatitis of emotional origin. Œdema is readily evoked by rubbing and may be confused with urticaria or with the swelling of a contact dermatitis.

Contact dermatitis—dependent upon specific sensitiveness to some material making contact with the skin—arises from cosmetics, including face creams and powders and those used on the eyebrows, lids, lashes and in the eyes. Nail varnish, without causing dermatitis on the fingers, may provoke a dermatitis of the lids or face by contact. Swelling of the scalp from dermatitis due to hair-dyes may present itself as œdema of the lids. The eyelids are sometimes involved in dermatitis due to spectacle frames, but the ears are the site of election. Actinic rays, vapours, dusts, pollens and plant emanations may be an exciting cause, but in this age of therapeutic danger we must remember local applications to the lids or conjunctiva. Penicillin and sulphonamides head the list at the moment, but atropine, mercurial applications and boracic acid are always with us, giving rise to what the dermatologists called "spectacle dermatitis" before they were confronted with the hazards of the plastic spectacle frames.

These cases in which the conjunctiva as well as the skin may be affected are in the nature of detective problems, and the diagnosis can be confirmed in the majority by the application of a patch-test of the agent under suspicion to the upper arm. Sensitization of this specific character, when once established, generally persists for many years or for life, though in some instances it is related to a temporary disturbance of health or tone and may clear when that is corrected. Attempts at desensitization are not, I think, often successful or justifiable if the agent can be avoided.

Treatment of the reaction is by simple alkaline lotions locally and alkalies internally.

The group of seborrhœic ills must be considered in relation to differential diagnosis, as must erysipelas and infection of underlying tissues.

Urticaria may be localized to the lids and conjunctiva as in angioneurotic œdema and may, like dermatitis, be due to non-specific influences, emotional causes or may arise from specific sensitization to penetrating contacts or to blood-borne stimuli as foodstuffs, drugs, metabolic or infective toxins. The problem calls for the most careful physical overhaul and an assessment of the patient as an individual and his relationship to his environment, in its widest sense.

Among causative drugs the aspirin group is worthy of special mention.

Bullous eruptions and purpura are of somewhat related significance and call for similar considerations.

These epidermal and urticarial reactions are of a transient, evanescent character—they may be regarded as the acute sensitization reaction in which the stimulus, whether it be emotional or material, acts upon the physiological balance of the individual for a short period. The characteristics of the lesion are determined by an upheaval in vascular function related to blushing. The reaction is an expression of disapproval and will pass when equanimity is restored.

Clinical features—chronic.—The more chronic ills relate less to function than to structure; they are essentially pathological in character. The individual rather than the stimulus is still the central feature of the problem but he is now diseased and not merely disturbed. The characters of the lesion turn upon the behaviour of the fixed tissue cells and not upon vascular tone. There are a number of intermediate states, as rosacea, which are very

Disorders of Skill: An Experimental Approach to Some Problems of Neurosis. [*Abstract*]

By D. RUSSELL DAVIS, M.D., M.R.C.P., D.P.M.

Medical Research Council, Applied Psychology Research Unit, Cambridge

SKILL connotes adaptation to the environment, and the hypotheses which are developed to explain disorders of skill may also explain the disorders of adaptation which constitute neurosis. There are precedents in research on experimental neurosis for the explanation of clinical problems by hypotheses derived from the laboratory study of disordered behaviour. The study of disorders of skill, however, has certain advantages over that of experimental neurosis, namely: human subjects are employed, and observations of variations in behaviour are amplified by reports of associated variations in feeling; slight variations of stimulus conditions may cause disturbances of activity, which, because they do not amount to complete breakdown, can readily be recorded and scored with the same devices as the normal behaviour; hence the nature of the disturbances can be defined clearly. It was possible, in the case of the disorders studied by the author, to show that the type and degree of the disorder in different individuals were dependent upon the kind and degree of neurotic predisposition (Davis, 1946*a*).

Following the lead of Pavlov, many experimenters have tried to relate experimental disorders to processes in the central nervous system, and their theories deal with the mechanism of disorder. To show how stimuli become connected with responses and with each other, the laws of association have been invoked, such as the Law of Exercise. A more interesting problem, however, is the nature of the external situation in which a given disorder arises. Not only actions have then to be considered, but the effects of actions, and reference has to be made to the Law of Effect. Whenever a principle stating how effects determine behaviour has been applied to the explanation of neurosis, however, the difficulty has inevitably been encountered that in neurosis behaviour persists, whose effects appear to be more punishing than rewarding; whereas, if the second half of the Law of Effect is valid, the tendency to a mode of behaviour, accompanied, or closely followed by punishment, should be weakened. Freud resolved the difficulty by supposing that, although apparently punishing, neurotic activity is adaptive from the standpoint of the inner needs of the individual. Other attempts at resolution have involved reversion to laws of association (e.g. Freud's principle of repetition—compulsion). Mowrer and Ullman (1945) have recently put forward an attractive theory. An alternative theory was suggested by the author's researches.

Explanation was sought of the excessive activity observed in experiments with the Cambridge Cockpit (Davis, 1946). Although it was accompanied by a progressive increase in anxiety, this activity persisted in apparent contradiction to the second half of the Law of Effect. First it was supposed that the subjects of the experiments were motivated by *anticipatory tension*, relating to the danger of failure to attain a satisfying standard of performance. Anticipatory tension is a secondary drive which has been postulated to account for the results of the experiments called "instrumental avoidance training" by Hilgard and Marquis (1940). Tension might be reduced, if a subject gained effective control of the machine, but, since the conditions of the tests nothing conclusive that allergy is the only causative factor even in periarteritis nodosa. He thought they should tackle the allergy problem without looking upon allergy as a disease. Advance might be made if they took into account the feature of faulty intracellular metabolism, especially the breakdown of proteins and carbohydrates, which in the first instance permits an individual to become allergic.

Dr. Vera Walker said that in 1941 it was decided to hold an Allergy Clinic at the Oxford Eye Hospital once a week, although it was doubtful whether a sufficient number of allergic cases would present themselves to justify such a clinic. An endeavour was to be made to find out whether there could be any allergic cause underlying the many chronic cases which attend this and other Eye Hospitals year after year, and which have in the past appeared to derive no benefit from any routine treatment. About 17,000 cases pass through the general Out-patient Department of the Oxford Eye Hospital each year, and taking the average from 1941 until the present time 2% (340 cases) of all these patients had been satisfactorily proved to be allergic, not only by skin tests, but also by removing the offending allergens and then trying to reproduce the symptoms by further contact. Among these 340 cases, 55% suffered from conjunctivitis, 2·9% from keratitis, 3% from iritis and iridocyclitis, 0·1% from cataract and 36% from migraine.

Out of 47 cases of iritis investigated during the year ended September 1946, six were allergic and belonged to allergic families, eight were rheumatic and three of psychological origin. The remaining thirty cases were still awaiting diagnosis. Of the six allergic cases, three had iritis associated with asthma at some stage in their lives; two had iritis in the summer only, and were found to be allergic to a specific pollen. The sixth case was that of a farmer's wife, aged 57, who had had recurrent iritis and iridocyclitis during twenty years. Between 1942 and 1945 she was in hospital seven times for treatment. There was a family history of asthma and of osteoarthritis. Allergy tests showed a high sensitiveness to house dusts, to orris and to cats, and it was discovered that for twenty years, when she was not in hospital, she had slept with a cat on her pillow. Since desensitization she has remained well for eighteen months.

Dr. D. Harley said that none of the speakers had thought fit to say what they meant by allergy. It was not possible to speak of "allergy" in a definitive way any more than of "indigestion". Allergy was not one specific disease or condition but a group of conditions. He suggested that some of the apparent confusion and conflict of opinions during the meeting was due to some of the speakers not understanding clearly what the other man meant by "allergy". Some attempt must be made to define what was meant by allergy and to give some description of the various groups of allergic phenomena.

Mr. Gayer Morgan, in reply, said that the question of allergy needed the full co-operation of the physician, biochemist and pathologist, and until they could tell us exactly what were the true characteristics of the allergic reaction and the correct place it took in clinical medicine, and why an individual could acquire the tendency to pervert what was, after all, part of the protective mechanism of the body so that it became a disease, we must remain very much in the dark as regards diagnosis and treatment.

Dr. C. J. C. Britton said that, in the use of vaccines, the difference between the immunization dose and the dose in desensitization was difficult to decide. It was a personal question in every case. Usually the dose of a vaccine for desensitization was at least one-tenth of the strength used for immunization. For desensitization a minute dose was used and built up, and no more than a mild reaction must ever be obtained. If such a reaction did occur a lower dose must be given and gradually increased.

With regard to clinical diagnosis of allergic ophthalmic disease he could not determine on appearance alone which cases were true allergies. The intradermal or scratch test might be extremely useful, but the patient as a whole must be dealt with.

Dr. J. T. Ingram, also in reply, said that allergy was not a matter of symptoms only; the point he had tried to bring out was that there were physiological and pathological patterns in allergy. He did not think he could have given a simple definition of allergy.

The following case was shown:

Penicillin and Sulphonamides as a means of Arresting Cavernous Sinus Thrombosis in a Case of Pneumonia complicated with Ophthalmic Symptoms.—R. LINDSAY-REA, F.R.C.S.

[*April* 8, 1947]

DISCUSSION ON THE SOCIAL ASPECTS OF HOMOSEXUALITY

[*Summary*]

Dr. E. A. Bennet: The purpose of this paper is to discuss the social distinctness of the adult homosexual and some of the reasons for it; and to point out our ignorance of certain aspects of male and female homosexuality and the advantages which might be expected to follow increased knowledge. The interests and aspirations of our society in family life promote a solidarity in which the homosexual has little or no part. The feeling of difference, the social stigma, the legal penalties—all these close off the domain of inversion. Although an indictment cannot be preferred against a woman for a homosexual act, lesbianism receives no official or articulate social sanction.

I.—The disapproval extended to inverts is in part explained by the abhorrence felt for the discreditable acts, happily rare, which are publicized in the newspapers when legal action is taken against a homosexual. Such accounts provide for many their only information about homosexuality and they conclude that all homosexuals are reprehensible. Amongst homosexuals, as amongst normal people, every variety of character is found. The attitude of homosexuals themselves towards inversion varies and some bitterly regret their exclusion from family life. The doctor and the lawyer tend to see unstable homosexuals; and it is therefore unwise for them to generalize. But I doubt if social instability is commoner among homosexuals as a whole than amongst heterosexuals.

Nevertheless, the social status of homosexuality in this country implies that the invert is a danger to society. The seducer of boys and girls be he homosexual or heterosexual is clearly a social menace. The number of persons found guilty of such crimes forms a small percentage of the homosexual population, and homosexuality among adult males has been condemned for other reasons. The average man may feel justified in condemning it as abnormal, unnatural and unproductive; and also he considers that if he did not condemn it, or scoff at it, it might be thought that he approved of it. Silverberg [1], a psychoanalyst, claims that passive male homosexuality is condemned because its ultimate strategic aim is to extinguish the race. The opinion of the man-in-the-street to-day in this country on homosexuality is emotionally tinged, subjective and largely determined by hostile prejudice.

A danger with which a homosexual is faced is blackmail. This is perhaps one of the chief reasons why the homosexual is silent. It will hardly be disputed that our knowledge of homosexuality as a social phenomenon is fragmentary and that we are in no position to adopt an attitude of complacency or of wholesale condemnation.

II.—Psychiatry to-day is overnourished with theory and undernourished by facts—facts acquired and tested by observation. We are liable to project unwittingly and to propound theories of homosexuality without substantial knowledge of the social phenomenon itself. We do not know the number of homosexuals in this country. Havelock Ellis [2] gave it as his opinion: "That we may probably conclude that the proportion of inverts is slightly over 2%. That would give the homosexual population of Great Britain as somewhere over a million." Myerson and Neustadt [3], declare that statistics vary from "as high as more than 50% of an unselected population to as low as 2%". Davis [4], writing of homosexuality among unmarried college women, states that 26% of a group of 1,200 women college graduates have had intense emotional relationships accompanied by overt physical practices with other women. Conditions in Great Britain are different from those in America and it would be rash to draw conclusions from these figures about the incidence of homosexuality in this country where no systematic sociological inquiry has been made.

did not favour success, tension tended to increase. Secondly it was supposed that an increase in anticipatory tension is reflected in an increase in the amount and vigour of activity. This increase in activity would generally be of biological value in emergency, as Cannon (1929) argued in the similar case of emotion, but it occurs even though its effects are disastrous, and it is not lessened by punishment. Increase in the amount and vigour of activity impaired performance in the experiments, because of the constraints of the situation, and especially because of the design of the apparatus. Attainment declining, and the danger of failure becoming more imminent, anticipatory tension increased more, and the consequent increase in activity caused a further decline in attainment. Thus a vicious circle was set up, which was stopped only by the development of a new form of disorder which was called the "withdrawal reaction".

The competence of this theory to explain the overactive form of disorder in the cockpit experiments was proved by devising a new situation, the "Skilled Response" test, in which according to the theory similar effects would be expected to occur, and by demonstrating that these effects did, in fact, occur. Thus under conditions (ambiguous stimuli) in which it could be assumed that anticipatory tension was increased, skilled responses were more extensive, more precipitate, more disturbed by restless movements and less accurate than under conditions (simple stimuli) in which anticipatory tension was normal. No success has yet been achieved in devising a similar proof of a hypothesis explaining the "withdrawal" form of disorder. The features of this disorder (retarded responses of small range) were also shown in the performance on the "Skilled Response" test of those of a miscellaneous group of neurotic patients who were diagnosed as hysterical.

Application of the theory to neurosis leads to the following conclusions. Neurosis is quite distinct from health, and it is wrong to say that all individuals are more or less neurotic, or that clinical disorders are at the extreme of a distribution which includes the healthy. Neurosis begins at a point at which in a given situation an increase in anticipatory tension impairs adaptation, and at which the vicious circle of increasing tension—decreasing attainment is instituted. Anticipatory tension (or anxiety, to which it is equivalent) may increase without the development of neurosis, if it does not impair powers of adaptation. The more restrained are the responses which a situation requires, the more readily does an increase in anticipatory tension lead to impairment of powers of adaptation. It is not necessary to suppose that the disasters which befall the anxious are motivated by masochistic or any other gratification, since, if it leads to impairment of performance, tension may make inevitable the very disaster of which it is anticipatory, or, by leading to an impulsive action, create a situation to which adaptation is impossible. If anticipatory tension increases to a point at which powers of adaptation are impaired, the consequences cannot be prevented by an effort on the part of the sufferer.

In the cockpit experiments, various types of interference by the experimenter were shown to cut short the overactive form of disorder, but the "withdrawal" form was not readily influenced. The problem of the persistence of activity in these experiments is analogous to that of the origin of neurosis. Further research is necessary to explain the "withdrawal" form of disorder and, hence, to elucidate the psychopathology of fully developed neurosis.

women admit overt homosexual activities—and the same is probably true of men—the severity of public disapprobation comes to be understood as arising, to some degree, from a sense of guilt on the part of the heterosexual majority and not entirely from the supposed depraved quality of inversion. In the study of sexual deviation our chief need to-day is for facts on which to base our medical, educational, legal and ethical conceptions of the social aspects of homosexuality.

Dr. H. Mannheim: Criminology—in its widest sense as including Penology—has four main functions:

(1) To define the conception of crime (the purely legal definition is tautological and therefore useless for our purposes) and to fix the boundaries of the criminal law, i.e. to determine the types of human behaviour which should be punished.

(2) To collect and analyse the facts about crime and the criminal; to study the causes and the whole structure of crime in individual countries and localities; and, finally, to integrate and, as far as possible, to reconcile the different views and methods of the psychologist and psychiatrist, the anthropologist and biologist, the sociologist and the lawyer, by providing a centre, a neutral territory where they all can meet on equal terms.

(3) To study the penal systems, past and present, and the effect of the various methods of dealing with lawbreakers and of crime prevention as applied in different countries.

(4) To prepare the ground for legislative and administrative reform, especially through teaching and educating public opinion.

If the problem of homosexuality is approached on such lines, the following points will have to be made:

(*a*) Should homosexual activities be punished as crimes? It is one of the fundamental lessons which Criminology has to teach that only such forms of human behaviour should be punishable which are distinctly anti-social, i.e. harmful to the community at large; which arouse a strong communal feeling of indignation so as to make sure the support of the public in enforcing the law; which can be defined in legal terms and are of such a character as to make the production of evidence in a criminal court not an impossible task.

In England, homosexuality remained a purely ecclesiastical crime until 1533. This ecclesiastical origin of the penal law on the subject should make us particularly cautious as it may explain much of the moral indignation and of the resulting social stigma. It would also seem to justify the demand for an unbiased scientific investigation into the nature, strength, and origin of that feeling of moral indignation, to find out, e.g., how far it is related to homosexual activity itself and how far it may be only the result of the harsh treatment meted out to behaviour of this kind by the law. Degrading penalties have attached a social stigma to human behaviour that would otherwise not have been regarded as infamous. Granted that homosexual love between women differs in many ways from that between men, it would be an interesting

We need, and need badly, a fact-finding investigation. The social problem of homosexuality is of such importance that a representative committee, with wide terms of reference, should be formed to accumulate information. Facts are needed regarding the number of homosexuals, the significance of constitutional and hereditary factors, the effects of environmental influence in schools and elsewhere, the results of psychiatric treatment, and the consequences of punitive measures upon homosexual and bisexual persons of both sexes. An alteration of the Law as it affects those found guilty of homosexual offences would be more likely to succeed if backed up by an array of facts.

The members of the proposed fact-finding committee would have to decide what questions needed answers. Take Education for example. We are uncomfortably aware of our ignorance regarding the effect of homosexual proclivities or acts amongst adolescents. Are these modified or increased by co-education and the public school system? Fenichel [5] considers that: "Occasional homosexual experiences between adolescents should not be looked upon as pathological so long as they appear as temporary phenomena of adaptation and do not result in definite fixations." The results of such experiences, or experiences with older youths or adults (both of which I regard as morbid), upon normally constituted adolescents are certainly not uniformly disastrous. But when the adolescent is of imperfect constitution, the results may be severe.

Doctors who are free to look at the problem of homosexuality objectively would welcome a fact-finding inquiry into the results of psychiatric treatment—a matter on which there is conflict of opinion. Allen [6] has reported on two patients both of whom recovered completely; and he points out that many cures are recorded in the literature. Ernest Jones [7] claims that psychoanalysts are able to obtain a large proportion of cures amongst inverts. I have personal knowledge of men whose sexual instincts are now normally directed who for long regarded themselves as homosexual. Curran [8], on the other hand, doubts the efficacy of psychotherapy with inverts.

There is no accepted criterion of homosexuality of which there are many forms and degrees; and the term itself is used in varying senses. The common association of homosexual and psychoneurotic characteristics adds to the complexity. *Cure* is not a precise entity which can be set out by measure. And is homosexuality constitutional or acquired? Here again we have no settled body of knowledge. Havelock Ellis [9] regards "this fundamental abnormality usually called sexual inversion" as probably inborn. Freud [10] considers the question to be "fruitless and inappropriate". Feelings run high when the claims of the constitutional and fixation theories are discussed, particularly if the emotions are involved consciously or unwittingly. Stoller [11] adopts a wiser attitude: "Those who regard homosexuals as purely constitutional, as well as those who consider homosexuality as purely of psychogenic origin, are over-simplifying an extraordinarily complex subject."

III.—Homosexuality is probably as common amongst women as amongst men, but it is less prominent and it has been given less attention. In the world of affairs masculine standards largely prevail. Women can compete in public life on equal terms with men, but they are expected to keep their femininity in the background.

The homosexual is forced to seek the society of homosexuals or to live emotionally alone. The heterosexual may choose his sexual isolation—the homosexual may not. For homosexuals whose standard of life is high this isolation brings inevitably a sense of remoteness, sadness and indignation, particularly when they see that society is willing enough to accept what they contribute to the cultural values in life. The utter loneliness of the homosexual is a real thing. Our greatest service to him (or her) and to ourselves is to increase knowledge which will bring a change in educated opinion. If more than 25% in a group of educated separate classes is of fundamental importance in understanding the problem of homosexuality. Clinically, the more important although rarer type of sexual inversion is the congenital or endocrinic. Of the male congenital invert it has often been said, following Ulrichs (1864), that he possesses "a female soul in a male body". Havelock Ellis restricted the use of the term homosexual to this class alone, and in his later years (1933) he came to regard homosexuality as an anomaly, or variation of the normal sexual pattern, rather than as a perversion or a vicious moral disease. "Congenital sexual inversion is an anomaly, an inborn variation of which we are beginning to understand the causes; it is, even when extreme, only pathological in the same sense as colour-blindness or albinism or transposition of the viscera is pathological."

Among Continental workers in the same field, there has been a progressive shift of opinion away from views such as those of Charcot and Magnan (1882) that inversion is "an episode in a more fundamental process of hereditary degeneration, comparable with morbid obsessions such as dipsomania and kleptomania", and of Krafft-Ebing who, in his earlier writing (1879), considered inversion to be "a functional sign of degeneration, a partial manifestation of a neuropathic and psychopathic state which is in most cases hereditary". The latter author, in the last edition of his work (1900), was inclined to regard inversion as being "not so much a degeneration as a variation, a simple anomaly", an opinion which approximated closely to that which had long been held by inverts themselves, while with Magnus Hirschfeld (1914) "the pathological conception of inversion has entirely disappeared; homosexuality is regarded as primarily a biological phenomenon of universal extension, and secondarily as a social phenomenon of serious importance". (Havelock Ellis "Sexual Inversion", 1929, pp. 68-74.)

Concomitant with this change of viewpoint regarding the underlying pathology, or rather physiology of this clinical entity, doubts have been expressed regarding not only the efficacy but even the desirability of treatment of these cases of inborn or natural homosexuality. On this point Havelock Ellis has given his opinion that not only is treatment useless from the point of view of changing the sexual outlook of the patient, but it is indeed morally questionable whether the attempt should ever be made to interfere with the natural proclivities of an invert. The endeavour to change the character of an endocrinic homosexual into that of a heterosexual is, in the opinion of some, as futile and as unjustifiable as to seek to suborn a heterosexual to follow unnatural vice. It would appear that the moral outlook of the true invert is a thing that must be accepted, and reconciliation of the conflicting claims of society and the individual, as regards natural homosexuality, can be effected only by a change in the attitude of society toward those of their number who share this anomaly, rather than by attempting to treat by medical means a condition that is virtually unalterable. There can be no question of asking the invert to accept the ordinary standards of heterosexual morality, and any course of therapy which seeks to reverse the fundamental pattern is not only foredoomed to failure, as all the reported cases testify, but is also quite indefensible when regarded in the light of absolute morality: attempted "treatment" or alteration of the basic personality of an inborn homosexual can only be described as a moral outrage.

There are, nevertheless, certain other aspects of fundamental importance which cannot be left unexamined. The question of moral and legal responsibility may not be evaded, merely by simple disclaimer. But the problem of reconciling the demands of the law with the personal rights of the abnormal but not vicious individual is not so difficult as would at first sight appear. Leaving aside the private relations of adult homosexuals one with the other, with which outside society can have no moral justification for interfering, the only offence other than blatant indecency that can properly come within the ambit of the aspect of such an investigation as here suggested to inquire—with the assistance of material drawn from suitably selected countries—whether the fact that the social stigma is much less pronounced for women than for men may not in part be due to the absence of legal penalization. Is it not conceivable that, in the course of time, indignation and stigma would be greatly reduced if the legal ban were lifted? To conclude this part of my argument: If the factor of moral indignation is seen in its true perspective, there are no adequate reasons left why homosexual activities should be regarded as anti-social and be punished, unless they involve the corruption of young people or are committed for financial gain or so as to endanger public order. A reform of the present law on such lines, in conformity with the laws of Switzerland and Poland, seems to be desirable. The argument that homosexual activities mean biological waste and should be punishable in the interest of a constructive population policy goes too far and would equally justify the penalization of masturbation, voluntary childlessness and of many forms of birth control.

(*b*) The suggested legal reform might be opposed on the ground that the exceptions for which punishment should in any case be retained would prove so much more frequent than the rule that the reform might not be worth while. This point is obviously a purely factual one on which further statistical information should, and could, be collected by analysing a substantial number of court cases. Special attention should be paid to the following points: age of the parties concerned; their social and family status; their financial relations; circumstances and locality of the offence; formation of social and anti-social groups of homosexuals and their activities, particularly the relation between homosexuality and other, sexual and non-sexual, offences; relation between frequency of homosexual offences, on the one hand, and sex ratio and political structure of the community, on the other.

(*c*) The effect of imprisonment and other types of institutional treatment of offenders, sexual and others, has to be carefully studied. Information on the matter is available mainly from American sources, e.g. Donald Clemmer, "The Prison Community"; Joseph Fishman, "Sex in Prison": "homosexuals who go to prison and homosexuals who are made in prison". Estimates of the actual extent of the evil in institutions of this kind and views on the part played by the factor of detention in the causation or evolution of homosexual tendencies differ widely. In this country, non-official students of the problem have to rely on books by ex-prisoners as the almost only source of information, and an extension of the fact-finding inquiry to this side of the matter—difficult though it will be—seems desirable. Even if the law should be reformed, the problem itself, though on a somewhat smaller scale, will remain since many homosexuals will still be sent to prison for non-sexual offences and some even for homosexual ones. Can nothing be done to relax the sexual strain in penal and reformatory institutions? In Mexico and Brazil, women are permitted to enter the prisons for this purpose, whereas in Columbia well-behaved prisoners may leave the prison twice a month under escort on a sexual visit (see the most recent information in Professor Negley K. Teeters, "Penology from Panama to Cape Horn", 1946, who recommends the second system, with suitable modifications for the U.S.A.). Even if this should not appeal to people in this country, at least in Approved Schools and similar institutions some relaxation of the sexual tension might be achievable by permitting more social contact between the sexes, carefully graded according to age and psychological characteristics. In this direction, too, some further research may well be indicated.

Dr. D. Stanley-Jones: Several schemes for the classification of homosexuality have been suggested, of varying degrees of complexity, and in nearly all there is a division into major groups, that are variously referred to as congenital and acquired, organic and functional, physiological and psychological. The recognition of these quite and primitive kind of sexual outlet, and a large proportion of the men showed other sexual perversions which suggested that a personality factor was present. There seems to be a specific inherited tendency towards homosexuality sometimes. The most important environmental factor in the series was early seduction by homosexual men. More general causes are the racial and social conditions which tend to favour it. Some men temporarily adopt this means of gratification when circumstances prevent heterosexual relations, others when satiated with heterosexual experiences. Many confirmed homosexuals are perfectly potent in normal sexual relations with women. Among adolescents it is often a transitory experience and many adolescent male prostitutes are not true homosexuals and easily give it up. The tendency towards homosexual interest may be first realized at any age, and its overt expression may be released by alcohol, senility, and other mental conditions associated with loss of control. There is no reason to believe that the homosexual urge is stronger than the heterosexual. But the problems of the chaste homosexual may be particularly difficult and complicated. The suggestion that the association of other perversions with homosexuality is due to the fact that homosexuals are a persecuted class and tend to associate with those who are condemned for other reasons is probably only relatively true, since the ordinary offender holds the homosexual in contempt. Moreover, among women homosexuals, in whom the social ban is less significant, other sexual deviations are more frequent than in women of normal sexuality.

Imprisonment, even without psychotherapy, may have a curative effect, but is sometimes ineffective. Psychotherapy as an adjunct to a sentence of imprisonment has a place in the treatment of specially selected cases. Favourable indications for treatment are youth, good personality, a first offence, absence of habit, a real anxiety accompanying overt behaviour, sincerity of co-operation, and good physical and mental health which assists in preventing the release of homosexual activity. It seems necessary that homosexuality in men must be penalized if it leads to the debauching of young people, if it offends against public decency, if it is carried out for monetary gain, or if the homosexual is in any public place for the purpose of prostitution or solicits to the annoyance of passengers.

Dr. John C. Mackwood: The cases that come to my notice in Wormwood Scrubs Prison are selected ones; all these are seen by me though not all are further treated. They are by no means a medical selection for many come through a direction or recommendation of the Courts. Thus a number of cases are treated that otherwise would not have had precedence had a clinical or optimum selection alone been the criterion. Whilst clinical evidence of anxiety-tension is the main indication for treatment some of the over-dependent, separation-anxiety types and certain personality types with little control over the volume of diffuse feeling—"nostalgic" personalities describes them fairly aptly—tend to find psychotherapy too challenging. These individuals are apt to surrender too much to their self-pity and masochistic trends, and cannot face the further release of anxiety under treatment. But they are more than balanced by others who find—when they can no longer retreat from their problems—that they get relief from psychotherapy; and many of these appear to do better than outside prison—certainly the tempo of their progress is often much higher. One finds many cases that have started treatment outside before conviction and broken off of their own accord who do well in prison, and some who have avoided it when it has been advised and available outside prison to take to it with benefit inside. The preponderating number of convicted homosexuals and those for sexual offences of other kinds are of minor degree.

One is primarily struck by the *immaturity* of the *emotional* development of these individuals. In the general run of cases it is not so much the homosexuality that is stressed as the immaturity, and the homosexual content is a symptom of the general law is the sexual seduction of young persons. Now it is a matter of experience that this particular type of offence is rarely committed by the natural invert, whose affections in the first place almost invariably go out toward an adult of his own sex, in exactly the same way as the desires of a normal heterosexual are directed toward an adult, a potential mate, rather than toward a child. The seduction of children bears no direct relation to homosexuality as such, but may properly be called an anti-social perversion, regardless of whether the offence is heterosexual or homosexual. The law quite rightly makes a distinction between heterosexual intimacy between adults and with adolescents, regarding the latter as an anti-social and therefore a criminal offence necessitating segregation; but in the matter of homosexual activity no such distinction is drawn, and the satisfaction of private sexual desires between like-minded adults is classed equally with unnatural offences against children [1]. This attitude runs counter to all considerations of psychology and common sense.

Acquired, functional, or psychological homosexuality falls within an entirely different category from that of true homosexuality. By far the greater number of wrongdoers who are actually charged with homosexual offences are not natural inverts in the medical sense of the term, but merely immature heterosexuals or bisexuals; as a result, the reasonable claim of *bona fide* inverts to a just recognition of their rights as a social minority is gravely prejudiced by the actions of others who in no way can join in this claim, but who by popular misconception and in the eyes of the law are grouped indiscriminately with true homosexuals as criminally minded perverts.

From the therapeutic point of view, moreover, the distinction is amply justified, and the trend of advanced medical thought is in the direction of educating legal and administrative opinion toward a complete separation of the two categories, the true homosexual being rescued from the clutches of a law which sometimes operates with mediæval barbarity [2], and which serves no useful purpose other than to make easy the lucrative calling of the blackmailer, while offenders against young persons, be they heterosexual or homosexual, are regarded as being more in the nature of psychopaths who need and who can respond to suitable therapy.

The psychogenesis of the pseudo-homosexual has been given at length elsewhere [3], and reasons have been adduced for believing that the persistence into adult life of the homosexual tendencies that are natural and indeed universal during adolescence is symptomatic of a failure of development, an arrest of normal psychological growth at the pre-adolescent stage of homosexuality, rather than of the emergence of inborn and unalterable traits that inform the basic pattern of an abnormal personality. From the point of view of treatment the difference is of supreme importance, for in contradistinction to the endocrinic type that is impervious to any form of therapy, the acquired type of homosexuality yields to psychotherapeutic measures, usually with success and often resulting in a complete cure.

Sir Norwood East: It may be misleading to compare homosexuality in the two sexes. Murder and attempted murder are not uncommon results of male homosexuality and are sometimes due to jealousy, but I cannot recall a crime of this type—other than a suicide pact—occurring in women. It is sometimes suggested that as homosexuality in women is not illegal it is unnecessary to penalize it in men. But women lawyers and doctors with special experience of such cases appear to be alarmed at its increase in women to-day. It is convenient to regard homosexuality as being constitutional or acquired. It is usually due to a combination of factors. In a series of 79 homosexual offenders there was a general tendency toward a varied

DISCUSSION ON FURTHER EXPERIENCES WITH CURARE

Dr. Frederick Prescott (*in absentia*, read by **Dr. R. H. Roberts**): *Some aspects of the clinical pharmacology of curare.*—Curare is a crude plant extract obtainable from a number of species of tropical liane; it is of varying composition and totally unfit in its crude state for clinical use. It contains a number of alkaloids, some of which paralyse skeletal muscle by a myoneural block, others with a central convulsant action, and others with a lissive or relaxing action on spastic muscle. It is therefore incorrect to use the term curare when referring to a preparation employed to block neuromuscular conduction. Clinically the only alkaloid of interest in preparations of curare is *d*-tubocurarine chloride, which is occasionally misnamed curarine, which is quite a different alkaloid. In clinical doses *d*-tubocurarine chloride has practically no action other than the property of paralysing skeletal muscle by blocking conduction at the myoneural junction.

Two preparations obtained from crude curare are available for clinical use. One is *Intocostrin*, a purified curare extract obtained from the South American liane *Chondrodendron tomentosum*. This preparation owes its curariform action, i.e. ability to produce a myoneural block, almost entirely to the *d*-tubocurarine chloride present. Pure *d*-tubocurarine chloride is available stabilized as a solution containing 10 mg. per ml. under the name Tubarine. Both intocostrin and *d*-tubocurarine chloride are free from the undesirable side effects of some of the alkaloids in crude curare. Intocostrin is standardized in units of a standard preparation of curare (0·02 gramme per ml.) and not by its content of *d*-tubocurarine chloride. This has sometimes caused some confusion in dosage when changing from one drug to the other. Assayed by the rabbit head-drop crossover method 6·67 units of intocostrin are equivalent in activity to 1 mg. of pure *d*-tubocurarine chloride. There is some difference of opinion, however, whether this ratio holds in clinical practice. I have always considered that clinically the ratio is more like 3·0 to 3·3 units of intocostrin to 1 mg. of the pure alkaloid, but it is difficult to make an exact comparison in anæsthetized subjects, as one cannot be certain of the part played by the anæsthetic and one has no absolute measurement of relaxation in the unconscious subject.

There have been many conflicting statements made on the pharmacology of curare preparations. This is because sometimes a preparation of unknown potency and composition has been used and has been referred to as "curare", sometimes the writer has used intocostrin and sometimes *d*-tubocurarine chloride; moreover the experimental animals have included all those found in the pharmacological laboratory as well as man; the dosage has varied enormously; sometimes the drug has been given with an anæsthetic, and sometimes without; and the route has varied. Little wonder is it that statements on "curare" are so contradictory.

d-Tubocurarine chloride belongs to a group of compounds known as quaternary ammonium salts, which, in general, exhibit the property of paralysing neuromuscular conduction at the myoneural junction. According to Gross and Cullen (1945) the curariform neurotic personality disorder. For instance, all these individuals are philanderers and this is their greatest risk, for they involve each other in a high percentage of cases that come to prison. But this philandering is itself a sign of immaturity and is not essentially different from the philandering of the immature heterosexual.

These immature personalities, in selected cases, respond well to treatment in prison.

Difficulties and disadvantages in prison.—There are a considerable number of handicaps to treatment in prison that are inherent in the build-up of the machinery for holding prisoners during their sentence. One of the greatest of these is lack of space, outside the cells, for the outlet of energy in a healthy manner. Another is the obvious drawback of the many hours of isolation for the isolated personalities.

One of the greatest improvements has been the building of a New Ward—we have carefully avoided calling it a *psychological* ward, and we term the cases under treatment *exploratory* cases—where all kinds under treatment live and sleep together. It is an asset of the utmost value and has enabled us to start Group Treatment. When cases under treatment can be observed closely in the ward and in relation to each other, both in and out of the Group Session, there are obvious advantages: one has treatment and observation *in vivo* rather than *in vitro*, and the duller mentalities can respond to concrete situations in a way that they would be unable to do with the more abstract and introspective methods of treatment.

Prison is not only a potentially homosexual atmosphere but also a very definitely actual one, where one gets many homosexuals migrating into groups. It might be thought that this would operate unfavourably in treatment, but one finds in practice that the homosexual element in a group does not weigh it down. I have one such Group Treatment with 5 homosexuals out of 9, and it is the homosexuals who are most often at variance in the subjects that crop up—and in a healthily aggressive manner.

The signs of improvement that appear to be reliable are the following: (1) The individual mien and bearing of the prisoner and his behaviour generally to the prison regime. (2) The inter-relations of the individual to the other members of the group. (3) The liberation of energy. This is often quite outstanding and is extremely difficult to provide with a suitable field for its healthy motor discharge.

We are able to send many men out of prison with a new orientation and wanting to face up to life in a realistic manner. Follow-ups are obviously extremely difficult for the discharged prisoner wants his prison history to be a sealed book.

On this social aspect of the problem an interesting point emerged in a Group discussion. It was the opinion of a mixed group, under treatment, that of the hardships in prison life: Around 70% could be attributed to the treatment of prisoners by prisoners. Around 25% were due to the routine prison regimen. Around 5% were due to the personality difficulties of the Warder Staff.

In untreated prisoners I think the allocation would be into three more or less equal categories. So that the difference in treated cases is highly significant. This is a tribute to the prison staff at Wormwood Scrubs. But the outstanding significance of this allocation is the treatment of man by man, and it goes right to the heart of the social problem. It is still all too true that many a prisoner finds his real punishment begins after his discharge from prison. Society throws up these cases and it must be willing to find a place for them.

Many things point to the necessity for the Prison Commission to start a Social Welfare Service operating in the prisons and providing for the prisoner from the day he goes outside. Important as it is for the man to get regular work, I think the provision for his leisure life is equally important in preventing his return to prison. It is all too easy for him to drift back to his undesirable acquaintances.

a sense of choking and shortness of breath, although controlled respiration was given throughout the experiment. There was no loss of consciousness, no clouding of the sensorium, no change in visual acuity and smell. The sensations of pain and touch were normal, memory was unimpaired and the electro-encephalogram and electrocardiogram were unaffected. It was, therefore, concluded that *d*-tubocurarine chloride has no significant central stimulant, depressant or analgesic action in man. These observations confirm those of Kellgren *et al.* (1946) and Prescott *et al.* (1946). It would appear from this that the unconsciousness produced in surgical patients by Whitacre and Fisher (1945) by injecting very large doses of intocostrin was due to anoxia.

According to Cole (1946) and Perlstein and Weinglass (1946) there is a lethal dose of intocostrin even under controlled respiration. In experiments on dogs Cole found that the fatal non-anoxic dose was 23·3 units per pound; this is far greater than would ever be used clinically (maximum 0·7 unit per pound). He states that such large doses affect the cardiovascular system and produce a fall in blood-pressure, although Gray (1946) states that *d*-tubocurarine chloride, even in large doses, has no effect on the cardiac output or venous pressure in the dog heart-lung preparation. The cause of death in the dogs was obscure, but it was probably not due to any interference with oxidation systems in muscle or nerve (Featherstone and Gross, 1947). In man intocostrin and *d*-tubocurarine chloride appear to have no effect on the cardiovascular system in clinical doses. Anæsthetic deaths due to intocostrin and *d*-tubocurarine chloride have been reported, but post-mortem findings have been published in only one case. In two cases death occurred several hours after the injection, and in both of them there was massive pulmonary collapse.

Do curare-like drugs cause bronchospasm? West (1935) refers to bronchospasm in dogs produced by a curare extract of unknown origin, and Cole (1946) reported difficulty in inflating dogs immediately after injecting large doses of intocostrin. A histamine effect on the bronchi cannot be excluded, as Comroe and Dripps (1946) have described the formation of histamine-like wheals after injecting intocostrin and *d*-tubocurarine chloride intracutaneously in man, and the production of histamine has also been observed after the injection of *d*-tubocurarine chloride into animals (Schild, 1947). I believe there is a danger of bronchospasm in man if the patient is lightly anæsthetized or conscious, and if the dose of the curarizing drug is on the low side, e.g. 15 mg. *d*-tubocurarine chloride. I have seen it occur in a conscious volunteer injected with this drug and in three mental patients who were very lightly narcotized with pentothal. The most effective treatment in these three cases was to administer more pentothal or more *d*-tubocurarine chloride.

In the dog it is stated (Gross and Cullen, 1945) that *d*-tubocurarine chloride causes relaxation of the smooth muscle of the small intestine, due in part to a direct action on the effector cells of the muscle. In the patient submitted to surgery the effect of the drug cannot be separated from that due to the drugs used for premedication and anæsthesia. In operations under cyclopropane or gas and oxygen supplemented by a curarizing agent the gut appears contracted (Griffith, 1945; Prescott *et al.*, 1946), but Gray (1946) states that with barbiturate anæsthesia this does not often occur.

d-Tubocurarine chloride and intocostrin are rapidly metabolized after administration. Some of the drug is excreted by the kidneys, either unchanged or in a form still capable of curarizing. Urine obtained within an hour or so after the administration of 30 mg. of *d*-tubocurarine chloride in man has a curarizing action. This rapid elimination suggests that slow administration by an intravenous drip is unsatisfactory. This has been confirmed by slowly administering a curarizing dose of *d*-tubocurarine chloride (30 mg.) to a volunteer over a period of half an hour (1 mg. per minute). Paralysis was incomplete, and ten minutes after receiving the drug the subject was able to sit up. The same dose given rapidly intravenously produced respiratory paralysis (Prescott *et al.*, 1946). If curarizing drugs are given by an intravenous drip a dose sufficient, or nearly sufficient, to curarize must be given; then curarization may be maintained by the drip. There is some difference of opinion whether a curarizing dose of drug should be given all at once intravenously owing to the danger of respiratory paralysis. A committee appointed by the Medical Research Council suggests that not more than 10 to 15 mg. of *d*-tubocurarine chloride should be administered at once and that after a pause to observe the effect on respiration another dose can be given subsequently. Some authorities, e.g. Gray and Halton (1946) and Knight (1946) recommend the use of fractional doses of a curarizing drug and a barbiturate, which are given intermittently throughout the operation. It should be remembered that the buffered solution of *d*-tubocurarine chloride cannot be mixed together with a soluble barbiturate in the same syringe as precipitation occurs. Two separate syringes must be used.

There is just one further pharmacological property of intocostrin and *d*-tubocurarine chloride that is of clinical interest: they both produce salivation. It is therefore advisable drugs act anywhere in the nervous system where acetylcholine is the chemical mediator. The paralysing action of the preparations used clinically is relatively brief as they are rapidly eliminated or destroyed. In man the order in which the muscles are affected after curarization is, as Lucas points out, in the order of their phylogeny. The muscles supplied by the cranial nerves are affected first (face, neck), then those of the limbs, back muscles, abdomen, intercostals, and finally the diaphragm. After intravenous administration an effect on the eye muscles can be perceived within a minute, but the peak of curarization occurs in three to five minutes. If respiratory paralysis is going to occur it will do so within 7-10 minutes of intravenous injection. Recovery of muscle function occurs in the reverse order to which it is lost. After therapeutic doses the limbs can be moved after 30-45 minutes, but residual paralysis of the ocular muscles, causing ataxia, may last for several hours. Patients who have had curare-controlled electrical convulsion therapy appear to recover more rapidly, e.g. they can walk an hour afterwards (Hobson and Prescott, 1947).

The curariform action of intocostrin and *d*-tubocurarine is reversed by prostigmin and eserine, and also in the isolated muscle by washing out with saline. In man I have never been impressed with the action of prostigmin as an antagonist of curarizing drugs in the doses recommended, i.e. 1 to 2 mg. According to Dr. Trevan (personal communication) the action of 30 μg. of *d*-tubocurarine chloride is reversed by 10 μg. of prostigmin in the guinea-pig. If a comparable ratio applies to man at least 10 mg. would be required to reverse the dose of *d*-tubocurarine chloride that produces diaphragmatic paralysis. Cole (1946) in his experiments on dogs was unable to reverse the effect of large doses of intocostrin with prostigmin. Ephedrine is said to potentiate the action of prostigmin (Koppanyi and Vivino, 1944), but this has not been confirmed in man. It is also necessary to give atropine when prostigmin is administered to prevent the stimulating action of the latter on the parasympathetic nervous system. It is an apparent paradox that acetylcholine and prostigmin can, in high concentrations, exert a curariform effect and that curare-like drugs can, under certain conditions, produce muscular contraction (McIntyre and King, 1943).

The antagonism of curariform drugs and prostigmin would be easy to understand if it could be shown that the former could increase the activity of cholinesterase, the enzyme that hydrolyses acetylcholine. The literature on this is most conflicting, the bulk of the evidence suggesting that *d*-tubocurarine chloride has a slight inhibiting action on cholinesterase (Harris and Harris, 1944). Curare-like drugs form a block at the myoneural junction possibly by combining with the receptor substance in the muscle. They do not interfere with the production of acetylcholine.

Acetylcholine appears to be a chemical mediator necessary for the transmission of nerve impulses through the ganglia of the autonomic nervous system, and the view is now held that, in the experimental animal at any rate, curariform drugs are capable of acting anywhere in the nervous or muscular system where acetylcholine is the chemical mediator. There is also evidence that they block peripheral response to vagal stimulation (Mautner and Luisada, 1941).

That ether has a curariform action was noted as far back as 1914. This was confirmed in 1943 by Gross and Cullen, who showed that ether intensified the action of *d*-tubocurarine chloride in the dog. They also showed that pentothal had a curariform action, but only in very high blood concentrations. Clinically it is important when giving curare-ether anæsthesia to limit the dose of the curarizing drug to one-half to one-third that used with other anæsthetic agents.

There is considerable difference of opinion on the effect of curare-like drugs on the central nervous system in animals. Crude preparations used in the earlier studies apparently had a convulsive action on the cerebrospinal axis. Fegler (1942), employing crude curare preparations in anæsthetized dogs, concluded that curare first stimulates and then depresses the respiratory centre, and Cohnberg (1946), using a number of animals, states that *d*-tubocurarine chloride and intocostrin stimulate the central nervous system in a number of species and produce convulsions in rats. According to Pick and Unna (1945) the dose of *d*-tubocurarine chloride just sufficient to paralyse the skeletal muscle of the frog has no effect on the electro-encephalogram, although a larger dose (4 mg./kg.) does; they suggest that the drug blocks the synapses of the central nervous system. More recently McIntyre *et al.* (1946) claimed that *d*-tubocurarine chloride in doses insufficient to abolish respiratory movements produced central depression in dogs as shown by the electro-encephalogram. An experiment was recently performed on a human volunteer given 75 mg. of *d*-tubocurarine chloride over a period of forty-five minutes (Smith *et al.*, 1947). This dose is two and a half times that likely to produce complete respiratory paralysis. The subject was given artificial respiration immediately so that any effects produced could not be attributed to anoxia. The blood-pressure and pulse-rate underwent no significant change. There was, however, I have found tubarine valuable in the relief of *laryngeal spasm* but the dose which will produce the ideal result of quiet spontaneous breathing is variable. Roughly, an adult will need 10 mg. in the first plane of the third stage of anæsthesia and 5 mg. in the second plane.

I anæsthetized a tall red-headed young man for a sublabial antrostomy. He had a healed tuberculous focus in the apex of the right lung and a basal bronchiectasis following influenzal pneumonia three years previously. He produced 2 drachms of sputum daily. He had, also, a high arched palate, protruding teeth and an underslung lower jaw. Pentothal 1 gramme failed to relax his jaw, so cyclopropane was added. Attempted laryngoscopy produced severe laryngeal spasm which made it impossible to give more cyclopropane. Tubarine 10 mg. intravenously gave immediate relaxation of the cords and chest wall and he started to breathe quietly. Laryngoscopy was achieved with some difficulty, he was intubated and his trachea sucked out at leisure before continuing. There were no further complications during operation or recovery.

I gave another man, weighing 175 lb., pentothal 0·5 gramme followed by nitrous oxide, oxygen and ether. He moved at a premature incision. Rushed introduction of ether caused much coughing and a persistent stridor which would not respond to any of the usual remedies. After twenty minutes, with anæsthesia in the second plane, I injected tubarine 5 mg. into the external jugular vein. He was quiet in twenty-five seconds, with shallow breathing and a tendency to cyanosis. Tracheal tug was well marked from ten to twenty minutes afterwards. There was an expiratory wheeze, probably bronchial, from twenty-two to twenty-seven minutes and at thirty-one minutes stridor returned.

Tubarine does not always prevent laryngeal spasm.

I gave a man, aged 56, pentothal 1 gramme and tubarine 10 mg. He was not apnœic. Attempted nasotracheal intubation with a laryngoscope (he was edentulous) produced severe laryngeal spasm and some cyanosis. This was relieved by spraying cocaine on to the cords down the laryngoscope. Although the cords were in spasm, the pharynx and jaw were well relaxed and I had an excellent view.

I have noticed frequently that where tubarine is used with pentothal there is less tendency to apnœa than would have been expected with the same dose of pentothal alone. I wondered whether the effect of pentothal might be due not merely to medullary depression but to an active reflex inhibition of respiration which is prevented by the tubarine.

I have previously decried [1] the use of tubarine for bronchoscopy and œsophagoscopy but I must retract. Bronchoscopy is made to look easy at the hands of the relatively inexpert. Œsophagoscopy with pentothal alone is a dangerous operation owing to the difficulty of maintaining a clear airway. With tubarine as well I have had no anxiety. The airway remains clear and the patient breathes quietly. The passage of the œsophagoscope through the relaxed pharyngeal sphincters is made much more easy and therefore, I think, less traumatic. I use, in adults, tubarine 15 mg. with pentothal as required, the dose varying from 0·4 to 1 g.

The effects of tubarine on the *cardiovascular system* are not quite clear to me. The skin vessels are commonly dilated, the face is often seen to be flushed and bleeding is increased. Pallor is not a common accompaniment of blood-pressure fall but I have once noted it in a man with normal blood-pressure.

From a group of blood-pressure charts I found a serious drop (systolic at 80 mm.Hg or less at the end of operation) in seven. These included an excision of rectum, two prostatectomies, one hysterectomy, an amputation through the hip-joint accompanied by severe hæmorrhage, and two upper abdominal operations, in one of which the pre-operative pressure was only 90/50. In 17 the blood-pressure remained steady. One was an amputation through the thigh, 6 were operations in the lower abdomen including 3 colectomies, and 10 were upper abdominal. 11 showed a rise in blood-pressure at the end of the operation, all upper abdominal. One of 7 in the first group, 7 of 17 in the second and 8 of 11 in the third were on carbon dioxide absorption, suggesting that deficient absorption may have been a factor. On the other hand, the rising proportion of upper abdominals may mean that curarization was more complete and tidal volume of respiration less adequate.

It has been suggested, and I have thought myself, that the steadiness of blood-pressure and pulse-rate in upper abdominal operations must be due to some protective action of curare against noxious stimuli. On the other hand, good muscular relaxation gives good access and trauma may be negligible. Equally good results may be had with pentothal, nitrous oxide and intercostal nerve block without splanchnic block.

Surgical stimuli can, undoubtedly, produce a cardiovascular reaction. In abdominal operations the usual form is that of blood-pressure fall accompanied by slowing of the pulse. In one gastrectomy operative stimuli overcame the depression caused by a relative overdose of opiates with pentothal. The blood-pressure stabilized at 20 mm.Hg. above the pre-operative level.

I have found, almost invariably, a fall in blood-pressure with retropubic prostatectomy, in one case to a level far below any I have seen in a similar operation. (A rise occurred within a few minutes of the intramuscular injection of ephedrine ½ grain.) The fall may accompany or follow the enucleation. In one case the pulse fell from over 80 to round 40 for 35 minutes (pentothal 0·35 gramme followed by nitrous oxide and ether: no clinical anoxæmia); four hours later there was pulsus alternans with a regular rate of 100. In another case the enucleation was anticipated with a further injection of pentothal; here the fall was less marked.

for the patient to be atropinized (atropine sulphate, gr. 1/100 to 1/50) if these drugs are given. In the case of patients undergoing curare-modified electrical convulsion therapy the atropine is given intravenously at the same time as the curarizing drug (Hobson and Prescott, 1947).

Finally there is one maxim to be followed whenever a curarizing drug is used: Keep the patient breathing.

Dr. Geoffrey Organe: *Further experiences with* d-*tubocurarine chloride.*—Some years ago I produced a number of case records carefully selected to show that perfect results could sometimes be achieved in spite of prolonged anæsthesia. To-day my records are selected to show that the results of using *d*-tubocurarine chloride in anæsthesia are not always all that could be desired. I do not want to convey the impression that I would wish to abandon its use, particularly as Dr. Prescott and I did the first experimental work on the preparation now known as tubarine. I do feel, however, that our early clinical reports have been coloured with roseate enthusiasm.

My equanimity was first disturbed by the development of what seemed an unduly large number of serious *post-operative chest complications.* We have followed them with some care in 86 patients having abdominal operations. It seems to be a fairly general experience that the frequency of any complication increases with the care of the follow-up. My figures must, therefore, be discounted to some extent for comparison.

There were, among these 86, 24 patients with major and 15 with minor chest complications—a sobering experience. Of the first group 12 developed lobar collapse, usually bilateral, one bronchopneumonia, one a subphrenic abscess with pleural effusion, one a pulmonary infarct and 9 a cough with fever and much sputum. I have tried to relate these to the accompanying anæsthetic agent or to the technique of its administration, without success. All are incriminated: Ether, cyclopropane, nitrous oxide, pentothal, semi-closed and closed. There seems to be no relation to the degree of respiratory depression at operation or to extreme degrees of cardiovascular depression. The only significant factor was tracheal intubation. In a group of 59 having upper abdominal operations, 11 of 15 patients intubated developed chest complications compared with 20 of 44 not intubated. The only explanations that occur to me are a tracheitis and the possibility of a reflex bronchospasm due to the presence of the tube in the trachea. I have no evidence of either. I have only once seen a patient with symptoms suggestive of bronchospasm and his recovery was uncomplicated. The incidence is higher in men than in women; it is higher, too, with upper abdominal than with lower abdominal operations. All 12 cases of lobar collapse were in a group of 36 men having upper abdominal operations.

One patient died of bronchopneumonia, one of the original disease, and one was later found to have early bronchiectasis. The others appeared, at the time of their discharge (which was not delayed in any case), to have recovered completely.

I should add that, using small doses of tubarine, we rarely assist respiration.

It is suggested by some that intocostrin is unreliable. I have used both tubarine and intocostrin in considerable quantity and still say that, dose for dose, I am unable to detect any significant difference in effect between the two substances. The effects of both vary from patient to patient according to many factors; but then so do the effects of pentothal, and many other drugs. This has to be taken into account always.

One of the most significant aspects of the advent of curarization is the possibility it offers in abdominal surgery of reducing the number of spinal anæsthetics administered. There are, however, a few operations in which spinal is still the better method as, for example, in abdomino-perineal excision of the rectum, where maximal relaxation is vital. Few anæsthetists will deny that for the degree of relaxation it produces, spinal anæsthesia is still unequalled. It is, however, attended by the serious danger of infection unlike intravenous injections. The sterility of the modern preparations of spinal anæsthetics can be relied on but a very exacting aseptic technique is called for. This is difficult for the anæsthetist to encompass in these times of shortage of nursing staffs. The hazard of other central nervous system sequelæ has been practically eliminated since the introduction of nupercaine, but the grave danger of meningitis can be readily appreciated by observing the steady increase in reported series of cases which has accompanied the great increase in popularity of spinal anæsthesia in recent years.

All now agree that the lighter the plane of anæsthesia the less the damage likely to be inflicted on the patient. Curare can be used satisfactorily in second plane anæsthesia, and sometimes even in first plane anæsthesia. Myanesin is even more advantageous in that it is usually adequate in first plane anæsthesia. Here is another advantage of curarization—the elimination of the need for deep soakings of the patient in general anæsthetics to obtain adequate relaxation.

Stress has been laid on the advantage of curare to facilitate laryngeal intubation. I have been disappointed with it in this respect. I still prefer a rapid intubation following a carefully judged dose of pentothal; for it is only when curare and pentothal combined are used in doses which to my mind are unwisely big that intubation is really likely to be facilitated. I feel that initial doses of the order of 15 mg. of tubarine plus 0·5 gramme pentothal which means in effect 15 mg. given whilst the patient is in third or fourth plane anæsthesia albeit temporarily, and which frequently produce complete *flaccid* respiratory paralysis, are not ordinarily justifiable. I have found 10 mg., or even 5, of tubarine frequently adequate as an initial dose for the production of muscular relaxation after the patient has been stabilized in light second plane anæsthesia, and these doses rarely if ever produce diaphragmatic paralysis or more than fleeting intercostal paralysis. On the other hand even 15 mg. of tubarine plus 0·5 gramme pentothal is not infrequently insufficient properly to relax the vocal cords. The same argument in equivalent doses applies to intocostrin.

A number of house surgeons have spoken to me of the shock-like state that they have to deal with on occasions following the administration of curare. Twice has this been followed by a shock-like death. The doses of curare in some of those cases were higher than I personally have found wise. I have not myself seen this condition, but I consider it may be due in great part to a profound weakness of the respiratory muscles and loss of tonus (comparable to that seen in the apparently drowned) which causes not only anoxia even with "aided respiration" owing to the loss of elastic recoil but also a deficiency in the respiratory pump mechanism which is of such importance in maintaining an efficient filling of right heart. It is for this reason that I deprecate the use of big doses of curare, such as 20 to 30 mg. of tubarine to produce spectacular results; preferring the doses 7 to 15 mg. of tubarine to produce reasonable and adequate relaxation and to keep the alternative spinal technique still in reserve for selected cases. I have not observed the shock-like state in any of my own cases. Myanesin, on the other hand, does not cause intercostal or diaphragmatic paralysis and I have not seen the shock-like state following its use, nor have the house surgeons above referred to.

SUMMARY

(1) Curarization has come to stay, and I think that myanesin will supersede curare for this purpose, because of its far greater margin of safety (the dosage of curare is agreed to be very critical) and its simple organic synthesis.

(2) Although it would be an enormous advance if the need for intrathecal injections could be entirely dispensed with, to be able to reduce them to a minimum is a great advantage.

(3) Although I very rarely use ether, I am glad that I need no longer employ third or fourth plane general anæsthesia with *any* agent.

(4) Neither curare nor myanesin seems to me to be worth while to facilitate intubation.

(5) Finally both substances need more caution in their administration than would appear to be exercised at present if a really splendid advance in the science of anæsthesia is not to run the risk of falling into disrepute.

I have anæsthetized 3 patients for amputation through the thigh with only pentothal 0·5 gramme and nitrous oxide, using tubarine to hold them on the operating table. One showed an asphyxial rise of blood-pressure, due to shallow breathing, with accompanying extrasystoles. One showed a sharp transient fall in systolic and rise in diastolic pressure at the moment of severance. All three were exceptionally well after operation.

Pulse irregularities have been not uncommon. In one prostatectomy the pulse was steady until the onset of hæmorrhage from the prostatic bed when there developed signs of a sluggish peripheral circulation, with extrasystoles—presumably due to coronary anæmia. In another patient, undergoing gastrectomy, cyanosis was accompanied by a drop in pulse-rate from 60 to 34 and back within one minute.

Pulse-rate varies but is commonly steady in spite of wide alteration in blood-pressure. It may rise or fall with blood-pressure fall. The interpretation of these varying reactions is not clear to me.

Venespasm is a common accompaniment of severe blood-pressure fall with most anæsthetic agents but is much less common where tubarine is used. In one case, although blood-pressure and pulse-rate were normal, the maximum rate of blood drip was only 40/min. Within five minutes of injecting tubarine 5 mg. the rate rose to 175/min. At the end of operation there was a severe fall in blood-pressure with change of posture. At this point, although the blood-pressure was at shock level (55/35), the blood transfusion dripped freely at 180/min.

In one patient with a low pre-operative blood-pressure (75/55) there was no change during anastomosis of the colon, lasting one hour.

There are two other cases of interest I should like to mention:

A man, aged 41, with perforated gastric ulcer, developed respiratory obstruction after pentothal 0·5 gramme and tubarine 15 mg. Attempted artificial respiration blew gas down the relaxed œsophagus through the gastric perforation into his open abdomen. Laryngoscopy showed a large piece of inspissated mucus obstructing his vocal cords. This was removed, a tracheal tube introduced, and all was well.

The other had his rectum removed and had been for nearly two hours in a steep Trendelenburg position. On the next day his pulse was 160/min., temperature 101° F. and respirations quickened. Breathing was distressed and bubbly. There was impaired percussion note and air entry at the left base, with generalized râles. Radiography showed collapse of the lower lobe with congestion on the other side. I bronchoscoped him and sucked out a lot of frothy mucus from the left side, the right being clear. There was no obvious clinical improvement and he died on the following day. At post-mortem he was found to have an acute perforated ulcer in the œsophagus with another in the stomach. Gastric contents had entered the left pleural cavity and partly digested the left lung. There was a large amount of fluid in the right pleural cavity.

If I have made it clear that, because one is using tubarine, one must neglect none of the precautions usually undertaken with major operations I have accomplished my purpose.

Many of my records have been taken, without permission, from my colleagues. The arduous task of follow-up was undertaken by Dr. Ian English.

1 ORGANE, G. (1946) *Proc. R. Soc. Med.*, 39, 636.

Dr. Barnett Mallinson: *Some general aspects of the technique of Curarization.*—There are a few general points that come to my mind as a result of nearly three years' experience of the technique of curarization.

There are many methods, all with their own special disadvantages of producing muscular relaxation. The latest one seems to require a concise label. For the purpose of the present discussion I propose to refer to the "Technique of Curarization of Muscles" or more shortly just to "Curarization" when I mean the production of muscular relaxation during light general anæsthesia by the intravenous injection of either curare or substances having effects similar to it.

There seems to be little doubt that the technique of curarization has very great value and should take its place amongst the rapidly increasing resources of the anæsthetist *provided that great caution is used in the selection of cases and in the dosage and manner of administration of curare to them in these early days.* For it is early days even in reference to curare itself, whilst the new substitute myanesin is as yet in its infancy.

Using curare, one is impressed with its potency and its efficiency, but on reading and hearing about curare one is impressed with the number of deaths which have occurred: too many amongst even the few thousand administrations which can have, as yet, taken place in this country. Before adopting any new technique I made it a rule to study with an acknowledged expert and, if possible, to use it under his supervision before attempting it alone. To assure that curarization takes the place it certainly deserves—I commend this course to any colleague of moderate experience proposing to employ it for the first time.

It is suggested by some that intocostrin is unreliable. I have used both tubarine and intocostrin in considerable quantity and still say that, dose for dose, I am unable to detect any significant difference in effect between the two substances. The effects of both vary from patient to patient according to many factors; but then so do the effects of pentothal, and many other drugs. This has to be taken into account always.

One of the most significant aspects of the advent of curarization is the possibility it offers in abdominal surgery of reducing the number of spinal anæsthetics administered. There are, however, a few operations in which spinal is still the better method as, for example, in abdomino-perineal excision of the rectum, where maximal relaxation is vital. Few anæsthetists will deny that for the degree of relaxation it produces, spinal anæsthesia is still unequalled. It is, however, attended by the serious danger of infection unlike intravenous injections. The sterility of the modern preparations of spinal anæsthetics can be relied on but a very exacting aseptic technique is called for. This is difficult for the anæsthetist to encompass in these times of shortage of nursing staffs. The hazard of other central nervous system sequelæ has been practically eliminated since the introduction of nupercaine, but the grave danger of meningitis can be readily appreciated by observing the steady increase in reported series of cases which has accompanied the great increase in popularity of spinal anæsthesia in recent years.

All now agree that the lighter the plane of anæsthesia the less the damage likely to be inflicted on the patient. Curare can be used satisfactorily in second plane anæsthesia, and sometimes even in first plane anæsthesia. Myanesin is even more advantageous in that it is usually adequate in first plane anæsthesia. Here is another advantage of curarization—the elimination of the need for deep soakings of the patient in general anæsthetics to obtain adequate relaxation.

Stress has been laid on the advantage of curare to facilitate laryngeal intubation. I have been disappointed with it in this respect. I still prefer a rapid intubation following a carefully judged dose of pentothal; for it is only when curare and pentothal combined are used in doses which to my mind are unwisely big that intubation is really likely to be facilitated. I feel that initial doses of the order of 15 mg. of tubarine plus 0·5 gramme pentothal which means in effect 15 mg. given whilst the patient is in third or fourth plane anæsthesia albeit temporarily, and which frequently produce complete *flaccid* respiratory paralysis, are not ordinarily justifiable. I have found 10 mg., or even 5, of tubarine frequently adequate as an initial dose for the production of muscular relaxation after the patient has been stabilized in light second plane anæsthesia, and these doses rarely if ever produce diaphragmatic paralysis or more than fleeting intercostal paralysis. On the other hand even 15 mg. of tubarine plus 0·5 gramme pentothal is not infrequently insufficient properly to relax the vocal cords. The same argument in equivalent doses applies to intocostrin.

A number of house surgeons have spoken to me of the shock-like state that they have to deal with on occasions following the administration of curare. Twice has this been followed by a shock-like death. The doses of curare in some of those cases were higher than I personally have found wise. I have not myself seen this condition, but I consider it may be due in great part to a profound weakness of the respiratory muscles and loss of tonus (comparable to that seen in the apparently drowned) which causes not only anoxia even with "aided respiration" owing to the loss of elastic recoil but also a deficiency in the respiratory pump mechanism which is of such importance in maintaining an efficient filling of right heart. It is for this reason that I deprecate the use of big doses of curare, such as 20 to 30 mg. of tubarine to produce spectacular results; preferring the doses 7 to 15 mg. of tubarine to produce reasonable and adequate relaxation and to keep the alternative spinal technique still in reserve for selected cases. I have not observed the shock-like state in any of my own cases. Myanesin, on the other hand, does not cause intercostal or diaphragmatic paralysis and I have not seen the shock-like state following its use, nor have the house surgeons above referred to.

SUMMARY

(1) Curarization has come to stay, and I think that myanesin will supersede curare for this purpose, because of its far greater margin of safety (the dosage of curare is agreed to be very critical) and its simple organic synthesis.

(2) Although it would be an enormous advance if the need for intrathecal injections could be entirely dispensed with, to be able to reduce them to a minimum is a great advantage.

(3) Although I very rarely use ether, I am glad that I need no longer employ third or fourth plane general anæsthesia with *any* agent.

(4) Neither curare nor myanesin seems to me to be worth while to facilitate intubation.

(5) Finally both substances need more caution in their administration than would appear to be exercised at present if a really splendid advance in the science of anæsthesia is not to run the risk of falling into disrepute.

I have anæsthetized 3 patients for amputation through the thigh with only pentothal 0·5 gramme and nitrous oxide, using tubarine to hold them on the operating table. One showed an asphyxial rise of blood-pressure, due to shallow breathing, with accompanying extrasystoles. One showed a sharp transient fall in systolic and rise in diastolic pressure at the moment of severance. All three were exceptionally well after operation.

Pulse irregularities have been not uncommon. In one prostatectomy the pulse was steady until the onset of hæmorrhage from the prostatic bed when there developed signs of a sluggish peripheral circulation, with extrasystoles—presumably due to coronary anæmia. In another patient, undergoing gastrectomy, cyanosis was accompanied by a drop in pulse-rate from 60 to 34 and back within one minute.

Pulse-rate varies but is commonly steady in spite of wide alteration in blood-pressure. It may rise or fall with blood-pressure fall. The interpretation of these varying reactions is not clear to me.

Venespasm is a common accompaniment of severe blood-pressure fall with most anæsthetic agents but is much less common where tubarine is used. In one case, although blood-pressure and pulse-rate were normal, the maximum rate of blood drip was only 40/min. Within five minutes of injecting tubarine 5 mg. the rate rose to 175/min. At the end of operation there was a severe fall in blood-pressure with change of posture. At this point, although the blood-pressure was at shock level (55/35), the blood transfusion dripped freely at 180/min.

In one patient with a low pre-operative blood-pressure (75/55) there was no change during anastomosis of the colon, lasting one hour.

There are two other cases of interest I should like to mention:

A man, aged 41, with perforated gastric ulcer, developed respiratory obstruction after pentothal 0·5 gramme and tubarine 15 mg. Attempted artificial respiration blew gas down the relaxed œsophagus through the gastric perforation into his open abdomen. Laryngoscopy showed a large piece of inspissated mucus obstructing his vocal cords. This was removed, a tracheal tube introduced, and all was well.

The other had his rectum removed and had been for nearly two hours in a steep Trendelenburg position. On the next day his pulse was 160/min., temperature 101° F. and respirations quickened. Breathing was distressed and bubbly. There was impaired percussion note and air entry at the left base, with generalized râles. Radiography showed collapse of the lower lobe with congestion on the other side. I bronchoscoped him and sucked out a lot of frothy mucus from the left side, the right being clear. There was no obvious clinical improvement and he died on the following day. At post-mortem he was found to have an acute perforated ulcer in the œsophagus with another in the stomach. Gastric contents had entered the left pleural cavity and partly digested the left lung. There was a large amount of fluid in the right pleural cavity.

If I have made it clear that, because one is using tubarine, one must neglect none of the precautions usually undertaken with major operations I have accomplished my purpose.

Many of my records have been taken, without permission, from my colleagues. The arduous task of follow-up was undertaken by Dr. Ian English.

REFERENCE

1 ORGANE, G. (1946) *Proc. R. Soc. Med.*, 39, 636.

Dr. Barnett Mallinson: *Some general aspects of the technique of Curarization.*—There are a few general points that come to my mind as a result of nearly three years' experience of the technique of curarization.

There are many methods, all with their own special disadvantages of producing muscular relaxation. The latest one seems to require a concise label. For the purpose of the present discussion I propose to refer to the "Technique of Curarization of Muscles" or more shortly just to "Curarization" when I mean the production of muscular relaxation during light general anæsthesia by the intravenous injection of either curare or substances having effects similar to it.

There seems to be little doubt that the technique of curarization has very great value and should take its place amongst the rapidly increasing resources of the anæsthetist *provided that great caution is used in the selection of cases and in the dosage and manner of administration of curare to them in these early days.* For it is early days even in reference to curare itself, whilst the new substitute myanesin is as yet in its infancy.

Using curare, one is impressed with its potency and its efficiency, but on reading and hearing about curare one is impressed with the number of deaths which have occurred; too many amongst even the few thousand administrations which can have, as yet, taken place in this country. Before adopting any new technique I made it a rule to study with an acknowledged expert and, if possible, to use it under his supervision before attempting it alone. To assure that curarization takes the place it certainly deserves—I commend this course to any colleague of moderate experience proposing to employ it for the first time.

Dr. John Halton: This milestone in anæsthesia must not become a tombstone; but it will unless the physiological factors concomitant on its use are fully understood and recognized by those who employ this useful aid to anæsthesia.

Gray has shown conclusively that *d*-tubocurarine chloride, in clinical dosage, has no toxic action on the heart nor has he found there to be any poisonous effect on the liver or kidneys. It is rapidly excreted and danger lies only in its paralysant action on the mechanism of respiration. Prescott, Organe and Rowbotham, together with other independent workers, have proved conclusively that doses not exceeding 15 mg. given to a conscious patient reduce, very considerably, the tidal exchange; this fact becomes of vital importance when the subject is anæsthetized and the respiratory centre made less sensitive to stimuli. Those who employ this drug must learn a new conception of administration, it is not enough that the patient is just breathing. The respirations must be "aided" from the moment of injection until the curare effect has passed off. This may not coincide with the termination of the operation.

Intravenous thiopentone, in clinical dosage, is relatively innocuous and is rapidly eliminated but there is irrefutable evidence to show that it is a potent poison to the heart muscle in the presence of anoxæmia, with or without cyanosis. The combination of *d*-tubocurarine chloride and thiopentone without full oxygenation can therefore be extremely dangerous and is positively lethal to those in whom myocardial function is already embarrassed.

My colleague Cecil Gray and I have been using this drug, in combination with thiopentone and cyclopropane, for two years and have employed it in over 2,000 cases with but one fatal result. We believe that the secret of this form of administration lies in the following fact: These agents potentiate each other to a remarkable degree and this should be played upon, giving just as little of each one as is required to meet the surgical demands and the state of the operation.

Dr. L. O. Mountford, after hearing Dr. Gillies' report of a case of fatal bronchospasm following curare, expressed surprise at Dr. Mallinson's preference for intubating the trachea under pentothal anæsthesia, and recorded a fatal case of bronchospasm following an attempt at intubation under pentothal alone.

In order to try and eliminate such tragedies, he now cocainized the larynx and trachea prior to the use of either the curare or pentothal technique. Provided the local anæsthesia was carried out thoroughly, spasm appeared to be prevented, but inadequate local anæsthesia might be followed by spasm.

Dr. H. B. Wilson: In children I have used myanesin in a series of acute abdomens in order to obtain good muscular relaxation.

The technique employed is to give a general anæsthetic, gas–oxygen–ether, to level of lower first plane, or at most upper second plane of third stage of anæsthesia. When peritoneum is reached, myanesin is slowly injected intravenously. Relaxation comes on rapidly (usually in about circulation time) and persists for seven to twelve minutes when it passes off quite suddenly. A further dose of myanesin, usually half the initial dose, brings back relaxation for a period of fifteen to twenty minutes.

Clinically, no change has been noted in respiration or circulation following myanesin. I have had no thrombosis of veins and recovery from anæsthesia has been rapid and unaccompanied by post-operative complications.

Dr. Massey Dawkins: The benefits conferred on surgeons and anæsthetists by curare are obvious but in the case of the patient it is probable that curare does more harm than good. In a series of some 300 cases which have come under my observation, the mortality rate has been about twelve times greater than that of chloroform. In 50 gastrectomies relaxed with curare the incidence of collapse of the base of the lung, confirmed by X-ray, has been 20%. Bleeding has been excessive and I have been asked to refrain from giving curare on that ground alone by two of my surgical colleagues.

Dr. Cecil Gray: I have recently completed a careful examination of a large series of cases, and I have been able to arrive at some authoritative conclusions. I must state that with one exception I have yet to hear of any accident following the use of this drug which could be blamed on any unforeseen property or side action. In all the cases of accident which have come to my notice, including those under my care, the administrator has been at fault, not necessarily culpably for the technique of its use is still developing. This applies also to the occurrence of post-operative or indeed operative complications. The incidence of chest complications will, it is true, be high if the patient has been inadequately ventilated during the operation or if he is returned to the ward whilst still curarized.

Dr. A. C. Forrester: After using curare in some 500 cases in Glasgow, the marked improvement noticed in the general condition of severely shocked abdominal cases led me to try curare in a short series of non-abdominal shocked cases. Tubarine was used in one of these cases requiring amputation of the leg, following a street accident. This patient had been treated for shock for some hours, and although he had had two pints of plasma and one pint of whole blood, his blood-pressure would not rise above 86/68. As the limb was turning gangrenous immediate operation became a necessity. During preparation for operation in theatre, nitrous oxide and oxygen (30%) was given and the systolic pressure became stabilized at 94 mm.Hg. Within five minutes of giving 10 mg. tubarine the B.P. had risen to 120/88, and the patient left the theatre with a B.P. 115/82. He looked well and made an uninterrupted recovery. This and similar cases confirm statements made elsewhere that curare protects against shock.

If the curarization is allowed to wear off while the anæsthetic is still very light, a condition clinically resembling shock is produced. This lack of curare can be easily demonstrated by the difficulty of inflating the lungs. If more curare is given the patient's general condition immediately improves. One of my cases was a hemicolectomy. Anæsthesia was 0·5 gramme pentothal with nitrous oxide and oxygen and a trace of trilene (2 c.c. per hour given in a Rowbotham's chloroform bottle) with 20 mg. tubarine. After about forty minutes the effect of the curare passed off and the B.P. quickly fell to 80/70. The lungs were inflated with difficulty at this stage. Within five minutes of giving a further 10 mg. tubarine the pressure returned to 140/90. In my opinion this explains many of the reported cases of shock with curare. In other words, to prevent shock one must either produce deep general anæsthesia or adequate curarization. If the operation is nearly finished it is probably more advisable to deepen the anæsthesia so as to obviate the possibility of respiratory depression when the patient has returned to the ward.

(Two charts were shown at the Meeting illustrating the condition of these 2 cases.)

Dr. John Gillies referred to an article by Ranyard West in the *Journal of Physiology*, 91, 437, 1938, in which "The Action of Curarine on the Respiratory Mechanism" was investigated experimentally.

He described the features of a recent personal experience where a patient had died three and a half hours after operation for which *d*-tubocurarine alone was used. The patient, aged 8 weeks, had vomited repeatedly since three days after birth and was in poor condition. At operation no pyloric hypertrophy was found but there were adhesions extending from the second part of the duodenum to the liver and lateral abdominal wall. Separation of the adhesions proved difficult and as kinking of the duodenum still persisted a posterior gastro-enterostomy was performed.

An intravenous injection of *d*-tubocurarine chloride was administered slowly until a total of 5 mg. had been reached. A profound effect of total paralysis of muscles, including the diaphragm, was achieved. It had been intended to keep the child unconscious by means of cyclopropane but this was judged to be unnecessary particularly as there was already an indication of insensitivity when a vein had been cut down upon earlier for the introduction of an intravenous drip.

Throughout the operation which lasted forty-five minutes controlled ventilation of the lungs with oxygen was carried out. Good oxygenation was maintained as evidenced by the colour of the gut. The pulse, visible in the mesenteric vessels, was regular and the rate was steady at 110 per minute. Thirty minutes after closure of the abdomen spontaneous contractions of the diaphragm started but pulmonary exchange being still inadequate the administration of oxygen by compression of the rebreathing bag was continued. On several occasions the mask was removed from the patient's face and a remarkable alteration in pulse-rate occurred. From a rate of 120 the pulse fell to 20 within one minute. On reapplication of the mask and inflation of lung the pulse-rate was restored to 120.

On the third occasion when this sequence of events was demonstrated inflation of the lung was difficult and the heart stopped finally. Post-mortem examination showed collapse of both lungs which presented the appearance of fœtal lungs and did not float.

In the laboratory the clinical events just described were reproduced exactly in a curarized dog, with the exception that the animal recovered completely.

In view of the accidents that have happened during the clinical use of preparations of curare and the post-mortem findings in such cases Dr. Gillies hoped that anæsthetists using this agent would study carefully all the published experimental work.

Controlled Respiration by Means of Special Automatic Machines as Used in Sweden and Denmark. [*Abstract*]

By E. TRIER MOERCH, M.B., B.S., M.D.Copenhagen

MOST operations in the chest cavity can be performed under general, local or spinal anæsthesia without artificial ventilation. However, because of the danger associated with paradoxical respiration, pendulum-air and mediastinal movement, some form of artificial ventilation instead of spontaneous breathing is preferable, at least in major and lengthy intrathoracic operations.

The problem of differential pressure respiration was thoroughly investigated by H. Moelgaard in Copenhagen 1908–1915 and by K. H. Giertz in Stockholm from 1913 to 1916. Giertz showed that artificial ventilation by rhythmic insufflation was superior to the constant differential pressure breathing of the Sauerbruch type.

Starting from Giertz's observations, the Swedish surgeon Frenckner evolved the "Spiropulsator", an air-driven machine, which, during inspiration, fills the patient's lungs with the anæsthetic mixture, and, during expiration, allows the lungs to empty themselves by means of their elasticity, without any resistance.

Since 1933 Frenckner, in collaboration with the Swedish surgeon Crafoord and the engineer Anderson, of the Swedish firm "AGA", has designed for major thoracic operations an anæsthetic apparatus which gives rhythmic ventilation under positive pressure. This "Frenckner-Crafoord-Anderson" apparatus is a combination of the Frenckner Spiropulsator and an "AGA" anæsthetic apparatus built partly on new principles.

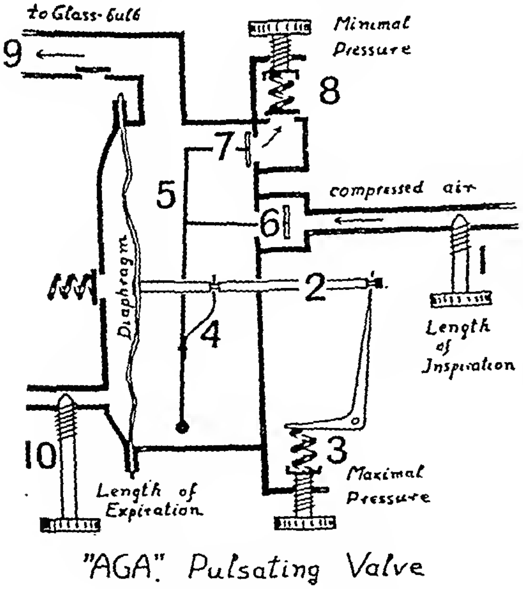

FIG. 1.—The Frenckner "Spiropulsator".

The "Spiropulsator".—Compressed air from an electrically driven air-compressor is led (1) in the main chamber of the valve. As the pressure here increases it presses a diaphragm towards the left (*see* fig. 1). The diaphragm moves a bar (2) towards the left, but the spring (3) tries to move the bar towards the right. As the pressure of air in the valve grows the bar (2) moves towards the left; it presses on the spring (4), the weight-arm (5) moves towards the left and the valve (6) closes while the valve (7) opens. The outlet (9) is connected by a rubber tube to a glass bulb which is airtight and surrounds the breathing bag of the anæsthetic apparatus.

Action of the spiropulsator upon the anæsthetic gases.—When the pressure in the spiropulsator rises, the pressure in the glass bulb rises at the same time, the breathing bag is compressed by the air and the anæsthetic mixture is pressed towards the patient's lungs (inspiration). When the pressure has reached a certain height, which is determined by the position of the screw (3), the diaphragm pulls the arm (5) over

Dr. Halton has done most useful service by emphasizing once again the need for "aided" respiration in all cases which have received tubocurarine. Figures for the incidence of these complications mean little, for so many factors other than the anæsthesia play a part. I am convinced that the use of *d*-tubocurarine by virtue of the light anæsthesia employed must materially reduce post-operative morbidity provided always that the basic physiological facts are borne in mind.

Regarding shock, it has been claimed by some that tubocurarine reduces its incidence, by others that it predisposes to collapse. It is also said that it actually has a protective function; this I do not believe, but the absence of deep anæsthesia enables the patient to recover more quickly from and to compensate better for any circulatory changes which may occur.

Bronchospasm we have never seen. West's work, which is responsible for the fear of this complication, was done with curarine, not tubocurarine, and was performed on dogs. Different species of animals are notoriously variable in their reactions to these substances and until this work has been repeated using pure tubocurarine it would seem of little value.

There is no evidence of increased predisposition to post-operative ileus in these patients. It seems that in a series of over 1,000 chest cases we should have seen one case—in fact we have not.

Finally, I must mention a case to which I have referred where an unforeseen action of tubarine caused the death of a patient.

A patient, aged 40, was bronchoscoped for a suspected carcinoma of the bronchus. The usual technique of anæsthesia was employed and 15 mg. of *d*-tubocurarine (tubarine) was followed by 0·5 gramme of thiopentone. Respiration was abolished and remained absent. He was artificially respirated from the beginning and at no time was there any cyanosis. After half an hour 5 mg. of prostigmin with atropine was given with no result. This was repeated after a further half an hour when a little diaphragmatic movement became apparent, but disappeared after five minutes. The response to further doses given one hour and forty-five minutes and two hours and forty-five minutes after the induction of anæsthesia was similar. After this last dose, however, the diaphragmatic respiration continued, but did not improve in amplitude. All this time his circulatory condition had not shown any change from the satisfactory state in which the procedure was started. Three-quarters of an hour after the last injection of prostigmin he suddenly regurgitated blood-stained abdominal contents in large quantity, some of which entered the bronchial tree. A bronchoscopy was immediately performed and suction instituted. However, the patient's condition deteriorated from this moment and he eventually died five hours and fourteen minutes after the induction of anæsthesia. This case was clearly an exaggerated reaction to a normal dose of tubocurarine—a true idiosyncrasy. That the prolonged respiratory depression was not due to any idiosyncrasy to the barbiturate would seem to be indicated by the fact that there was a small but transient response to the injections of prostigmin. There was no history of any myasthenic symptoms nor was there any thymic tissue found at autopsy. However, there was a very extensive involvement of the left main bronchus by carcinoma. This rendered the whole of the left lung functionless. The right lung showed evidence of the aspiration of a large amount of blood-stained fluid which had undoubtedly reduced the aerating surface of this lung below the minimum required to support life. In the stomach and small intestine there were numerous small punctate hæmorrhages which accounted for the blood-stained stomach contents.

The condition was similar to the hæmorrhages found by Cole (*Anesthesiology*, 1946, 7, 190) in dogs poisoned with a very large dose of intocostrin.

The two main dangers of tubocurarine appear to be its use by the inexperienced and the occurrence of regurgitation of stomach contents. This is an insidious "flow back" of the stomach contents due to the abnormal relaxation of the œsophageal muscle and sphincters.

Dr. Barnett Mallinson, in reply to Dr. G. S. W. Organe: I have not had any venous thromboses with myanesin in my cases so far. As, however, pentothal occasionally causes this complication, if too strong a solution has been used, possibly on occasions thrombosis may have occurred in a vein which had also received pentothal.

In reply to another speaker: An account of post-operative respiratory complications in comparable series of cases with and without curare has been published (Mallinson, *Anæsthesia*, 1946, **1**, 17).

In reply to Dr. Massey Dawkins: As to the value of curare I would suggest that the period of experiment and assessment may occupy a long time yet, but that in time the opposite ends of the pendulum swing will approximate in curare finding its niche. Cyclopropane, after all, remained controversial and experimental for a considerable number of years before taking its present established place.

so the valve (6) shuts off the inlet of compressed air and valve (7) opens for the outlet of the air.

The pressure in the pulsator now drops to the minimum pressure determined by the screw (8). The pressure round the breathing bag decreases accordingly and the bag expands because of the recoil of the lungs (expiration). As the pressure on the diaphragm decreases, the spring (3) will pull the bar (2) towards the right, the arm (5) goes to the right, valve (7) closes and valve (6) opens, compressed air streams in again and a new inspiratory phase starts.

By means of the four screws we can alter (*a*) the maximum and (*b*) the minimum pressure, the length of (*c*) inspiration and (*d*) expiration.

The anæsthesia is started in much the same way as in England; a preliminary injection of morphine-scopolamine is given, and local anæsthesia of the throat and larynx is carried out with cocaine or pantocaine. Pentothal or similar preparations (such as evipan, the Swedish barbiturate narcotal, or more often the Danish preparations citodan or narcodorm), nitrous oxide-oxygen and ether or cyclopropane forms the anæsthetic. When the anæsthesia is quiet and some time before the pleural cavity is opened, the spiropulsator is started. After a few minutes, the respiration becomes controlled and is taken over by the machine.

We start the spiropulsator as nearly as possible at the same speed as the patient's spontaneous respiration, but if it is correctly adjusted the spiropulsator automatically finds the rhythm of the patient's respirations. If the patient expires against the spiropulsator, the pressure inside this will rise very quickly and the latter will "click over" to the expiratory phase.

Crafoord has used this machine for several hundred major thoracic operations. In Copenhagen we have used it for about 150 cases.

The "Respirator" designed by the writer.—Having learned the rather complicated method in Stockholm from Crafoord and his anæsthetist (Doctor T. Gordh), I have used it in Copenhagen with excellent results for years. During the war, however, it was almost impossible to import Swedish machines, and as in any case, the machine seemed unnecessarily complicated, I started some experiments in 1940 to adapt the gas-oxygen machines in Denmark (mostly McKesson Nargraf) on similar lines and at the same time to simplify the working principles.

The final machine which I thus evolved contains an electrically driven piston-pump which is inserted into a closed circuit instead of the breathing bag (fig. 2).

An electric motor acts via a worm gearing and a friction clutch on a crank, the pitman of which is connected to one of the arms of a two-armed lever. The other arm of this lever moves via a piston-rod the piston of a single-cylinder pump up and down.

The speed of the pump (i.e. the frequency of the controlled respiration) is regulated by means of a variable electric resistance, mounted in its own box, connected with the anæsthetic apparatus only by a wire (fig. 3), so that one can stand where convenient and watching the frequency of the patient's active respiration adjust the speed of the controlled respiration accordingly.

The clutch is inserted in the slowly moving axle beyond the worm gearing. The friction in the clutch can be conditioned as desired.

The pitman is made of two parts ordinarily in connexion, but which can be disconnected if the supply of electricity should fail (as happened several times during the war) or if something else should happen to the motor. If so, one can continue giving controlled respiration either by working the arm up and down by hand or by the foot or by squeezing the breathing bag by hand.

The pitman is connected to the lever in such a way that the connecting point may be moved along the latter while the machine is working. If the connexion is moved

In the Danish machine the gases are pumped in during inspiration and sucked out during expiration.

Advantages of the automatic machines are the same as of controlled respiration by other means. In addition:

(1) The ventilation can be maintained at a sufficient and fixed level, more accurately than by manually controlled respiration.

(2) The ventilation can easily be changed, little or much, either in frequency and/or depth.

(3) The nerve-impulses from the operation field arise at constant intervals, as in normal respiration: this has presumably a certain importance in diminishing the neurogenic shock from the operation and in maintaining the normal tone of the circulatory medullary centre.

(4) The respiratory part of the circulation, i.e. the venous return of blood to the heart, is supported by the changing pressure inside the thoracic cavity, presumably mostly where positive pressure alternating with suction is applied, as in the Danish machine.

(5) During a thoracotomy when an automatic machine is used, the respiratory movements are very small and take place in an exactly regular rhythm. This is a great help to the surgeon and makes his job easier.

(6) During these extensive and dangerous operations the anæsthetist has much to do. Besides guarding the patient and running the anæsthetic he must watch the transfusion and use his general skill to counteract anything which might disturb the smooth course of the operation. The automatic machines allow the anæsthetist more freedom; he can, without decreasing the ventilation, move from the head of the patient if his help is needed elsewhere in the theatre. He will also have more time for making records.

(7) The ventilation can be recorded exactly, which is of interest both clinically and scientifically.

ACKNOWLEDGMENT

I am indebted to Dr. Crafoord and Dr. Gordh of Stockholm, to the two thoracic surgeons in Copenhagen, Professor E. Husfeldt and the chief surgeon Dr. Tage Kjaer, for all their help; to Dr. phil. O. M. Henriques, the chief of the Finsen laboratory, where the blood estimations were undertaken, and to Major O. Lippmann who has undertaken the technical part of these experiments.

Skin Temperature as a Clinical Aid During Anæsthesia. [*Abridged*]

By J. CLUTTON-BROCK, M.B., D.A.

THIS is an account of some purely empirical observations on the use of a skin thermometer during anæsthesia.

I have used a skin thermometer on a great many surgical patients, including most bad risk cases, for rather more than three years and have come to rely more and more on these readings together with those of the blood-pressure, &c., as an indication of the patient's general condition and his need for resuscitative measures.

away from the axis of the lever, the stroke of the piston will decrease until a minimum of 500 c.c. is reached: if the connexion is moved towards the axis, the stroke will increase up to 1,000 c.c.

One-half of the lever is curved. If the lever were wholly straight, the piston would only reach the bottom of the cylinder in one position of the connexion. With the lever bent as a part of a circle concentric with the crank, the piston will reach the bottom of the cylinder whatever the position of the connexion of the pitman (that is, with all stroke-volumes). The dead space will thus be as small as possible.

The cylinder is a simple one without any valves. The pressure of the gases delivered from the pump can be read on a combined pressure and vacuum gauge and varies from about +8 mm.Hg during inspiration to about −3mm.Hg during expiration.

Just above the breathing bag is a mechanism which enables one to disengage the bag from the closed circuit and, instead, engage the respirator.

The whole respirator is built on a little trolley which can be placed a metre or so away from the anæsthetic machine. This distance, plus earthing, ensures against explosion risk.

The anæsthesia is induced as already described. When the respiration is to be controlled, one can either compress the bag until active movements of respiration have ceased and then switch on the respirator, or switch the respirator on straight away. The latter is in fact the easier manœuvre, the motor is started before it is connected to the closed circuit, and the speed adjusted to the speed of the patient's respiration. The clutch is then loosened and the respirator switched into the closed circuit instead of the breathing bag. After the lapse of some minutes, the respirator takes over the respiration of the patient.

If during this time the speed of the respirator does not exactly coincide with the speed of the patient's respirations, the difference is eliminated by the clutch. As a matter of fact it is astonishing how little it matters if there is a difference between these two frequencies. After a short fight the patient gives up and the respirator wins.

Safeguards are already present in the McKesson machine against too-violent action of the respirator, that is either too much suction or too much compression.

The minimum pressure.—If one places the pressure dial on the McKesson machine between "Off" and "O" mm.Hg, the suction will be very little—about 3 to 5 mm.Hg. It can be read on the manometer of the respirator and adjusted on the pressure dial of the McKesson apparatus.

The maximum pressure is limited by the usual McKesson expiratory valve, set to the desired pressure—about 8 to 10 mm.Hg. The McKesson rebreathing bag is opened fully, but the spring is set to say 10 mm.Hg, thus acting as an elastic "buffer" against unexpected sudden changes in pressure.

The McKesson oxygen-percentage-dial is set to a high figure, about 50%, so that if (and when) the respirator sucks from the anæsthetic machine the oxygen content of the gases supplied will be on the safe side.

Apart from these adjustments the McKesson machine with closed circuit is used in the usual way with a continuous supply of basal oxygen, about 300 to 500 c.c. per minute.

Since November 1942 this respirator has been used in 300 cases of major thoracic operations, such as lobectomies, pulmonectomies, ligations of ductus arteriosus, diaphragmatic hernias and transthoracic resections of the upper part of the stomach. The anæsthesias have been quiet, the patients' condition good and the working conditions for the surgeon excellent since the controlled respiration gives such a quiet field.

Differences between the Swedish and the Danish machines.—In the Swedish machine the anæsthetic gases are forced into the patient's lungs during inspiration, but escape during expiration passively by means of the elasticity of the lungs and the thorax.

DISCUSSION ON THE TREATMENT OF TOXIC GOITRE

Mr. J. E. Piercy (*Surgeon i/c Thyroid Clinic*): Primary thyrotoxic goitre offers no difficulty in diagnosis and we find thiouracil invaluable for increasing safety of operation in these patients. It has eliminated the necessity for stage operations in the very severe cases although it increases the technical difficulties.

We feel that the secondary nodular thyrotoxic goitre which leads insidiously to cardiac damage culminating in paroxysmal or established auricular fibrillation is the type which most needs recognition, particularly the apparently non-toxic nodular gland with few symptoms other than tiredness, irritability and occasional palpitation, often with a basal metabolic rate within normal limits.

There is a very great difference clinically between primary and secondary toxic goitre, and I have yet to find a patient with a nodular goitre giving a history suggestive of primary Graves' disease earlier in life. The importance of this must be appreciated when we find that 22% of 1,000 patients with nodular goitres had developed auricular fibrillation by the time they were sent for operation—40% between the ages of 50 and 60, and 30% between 40 and 50. Of these 220 patients 78% were discharged with normal rhythm after operation, either occurring spontaneously, or after a short course of quinidine. They do not include the many patients with minimal thyrotoxicosis, some showing signs of pressure symptoms only, who developed a transient post-operative fibrillation. These were at the point of developing paroxysmal or established fibrillation before operation and this should not be looked upon as a complication of the operation but as evidence that they were at a late stage in the disease.

Our procedure is one of close collaboration between physician and surgeon and carefully organized team-work. The pre- and post-operative procedure depends solely on the individual merits of each case. There can be no uniformity in regard to the pre-operative period of rest and iodine or in the type of operation performed.

We feel that ligation of the inferior thyroid arteries lessens the possibility of recurrence because we have had none to our knowledge in 550 patients treated in the past seven years, whereas in the previous seven years 750 operations were performed and the vessels were not ligated and 6% of these patients had recurrences. A recurrence in secondary toxic goitre is often due to the fact that the opposite lobe was not explored and to its being really a case of continued growth in the unexplored lobe.

In the ordinary way when we assess a patient's condition, we include rough estimates of the state of his peripheral circulation. We feel the temperature of his skin and note his colour. It has been shown that temperatures within a range of 5° C. above or below that of the examining finger will not be appreciated as either warm or cold [1]. Variations in the skin temperature, however, give a reasonably accurate idea of any changes in the state of the peripheral circulation.

The technique is simple, a mercury in glass thermometer is used. This is made without a constriction and reads from 80° to 107° F. The bulb is in ring form and partly enclosed in a reflecting hemispherical case, making with the patient's skin a reasonably airtight fit, thus avoiding changes in the readings due to draughts, &c.

The thermometer is attached by elastoplast to the patient's forehead. This position is chosen because the skin of the forehead shows least response to environmental changes of temperature [2].

There is considerable individual variation in the skin temperature of the face in normal patients [2], so, within limits, changes in temperature rather than absolute readings are considered to be of significance.

The constriction of the vessels of the skin is one of the compensating factors in shock, and I think a measurement of this vasoconstriction is, to a close approximation, a measurement of the degree of shock present.

The skin temperature of the patient's face usually rises with the induction of any anæsthetic, the absence of this vasodilatation apparently having a grave prognostic significance [3]. After this initial rise, it will remain steady unless shock occurs when it may fall. A fall of 1° F. or less is of minor significance, but 3° or more shows, I think, a considerable degree of shock.

The variation in skin temperature bears very little relation to that of the blood-pressure. A very considerable fall in blood-pressure may occur without a fall in skin temperature, the fall in blood-pressure being due perhaps to a high spinal, large quantities of local anæsthetic solution, changes in position of the patient, changes in the percentage of the anæsthetic gases, or any other cause producing sluggishness of the circulation without true shock. In one case the patient's blood-pressure fell to 40 mm. systolic and 20 mm. diastolic after a high spinal for a combined synchronous excision of the rectum. The blood-pressure remained at this level for more than one hour.

Provided that there has been no fall in skin temperature, I have never found any harm come to a patient whatever his blood-pressure. When, however, the blood-pressure and skin temperature have fallen together, the patient has been critically ill and needed energetic resuscitation.

In some cases a sustained blood-pressure, or even a rise, has been seen with a fall in skin temperature. This is not uncommon, presumably the vasoconstriction which causes the fall in skin temperature also sustains the blood-pressure. The patient in these cases has been shocked but has compensated well for his shock; however, it is important to realize that the condition of shock is present and that the patient requires careful watching.

By taking skin temperatures we can distinguish between falls in blood-pressure due to shock and falls due to other causes of little significance. With skin temperature and blood-pressure readings together the patient's need for resuscitation can be better judged.

DISCUSSION ON THE TREATMENT OF TOXIC GOITRE

Mr. J. E. Piercy (*Surgeon i/c Thyroid Clinic*): Primary thyrotoxic goitre offers no difficulty in diagnosis and we find thiouracil invaluable for increasing safety of operation in these patients. It has eliminated the necessity for stage operations in the very severe cases although it increases the technical difficulties.

We feel that the secondary nodular thyrotoxic goitre which leads insidiously to cardiac damage culminating in paroxysmal or established auricular fibrillation is the type which most needs recognition, particularly the apparently non-toxic nodular gland with few symptoms other than tiredness, irritability and occasional palpitation, often with a basal metabolic rate within normal limits.

There is a very great difference clinically between primary and secondary toxic goitre, and I have yet to find a patient with a nodular goitre giving a history suggestive of primary Graves' disease earlier in life. The importance of this must be appreciated when we find that 22% of 1,000 patients with nodular goitres had developed auricular fibrillation by the time they were sent for operation—40% between the ages of 50 and 60, and 30% between 40 and 50. Of these 220 patients 78% were discharged with normal rhythm after operation, either occurring spontaneously, or after a short course of quinidine. They do not include the many patients with minimal thyrotoxicosis, some showing signs of pressure symptoms only, who developed a transient post-operative fibrillation. These were at the point of developing paroxysmal or established fibrillation before operation and this should not be looked upon as a complication of the operation but as evidence that they were at a late stage in the disease.

Our procedure is one of close collaboration between physician and surgeon and carefully organized team-work. The pre- and post-operative procedure depends solely on the individual merits of each case. There can be no uniformity in regard to the pre-operative period of rest and iodine or in the type of operation performed.

We feel that ligation of the inferior thyroid arteries lessens the possibility of recurrence because we have had none to our knowledge in 550 patients treated in the past seven years, whereas in the previous seven years 750 operations were performed and the vessels were not ligated and 6% of these patients had recurrences. A recurrence in secondary toxic goitre is often due to the fact that the opposite lobe was not explored and to its being really a case of continued growth in the unexplored lobe.

Our mortality at the Thyroid Clinic on thyrotoxic goitres is 1·3% since 1932, but in recent years it has been a fraction of 1%. I have personally had three deaths in my last 500 cases, two of them from pulmonary embolism occurring on the ninth and tenth days.

No patient however toxic and emaciated or whatever the severity of cardiac damage is considered inoperable but we feel that perhaps the ones needing most consideration are those with an associated mental derangement.

Complications.—No thyrotoxic crisis has been seen for some years. Symptoms due to injury of the recurrent laryngeal nerve occurred in 21, or nearly 2% and all but one of these was of a transient nature. In the one persistent case the symptoms began three weeks after operation. Thirteen patients developed tetany, generally of a transient nature which quickly responded to intensive calcium therapy. In only three was parathyroid extract necessary and they ultimately became symptom-free. Two patients who developed myxœdema still require thyroid treatment but others of a mild degree have later recovered their metabolic balance by regeneration of the remaining thyroid tissue.

Results.—In the average patient a return to normal or near normal health can be expected, whilst a large measure of recovery can be anticipated even in severely toxic patients and in those with complications. Thyrotoxicosis commonly occurs in the highly-strung, sensitive type of person and though thyroid balance may be regained by operation, the constitutional make-up is not altered. It is generally recognized, however, that the nursing profession is an exceptionally arduous and exacting one and the fact that of 67 nurses who underwent partial thyroidectomy all returned to full duty is an indication of the effectiveness of the operation.

We have not used thiouracil at our clinic as treatment so I cannot pretend to have any experience of it as such. I am, perhaps, biased therefore as my only experience of the drug, apart from pre-operative and diagnostic use, is from those many cases of thiouracil failure and intolerance, sent to us for operation from hospitals both in London and in the Provinces. These patients were many and varied, males and females with primary and nodular goitres, some having had the drug for as little as three weeks and some up to two years. The majority had improved but treatment had been stopped for various reasons, including leucopenia, nausea and vomiting, thrombocytopenia, attacks of tetany, œdema of legs with urticaria, increasing size of gland and vomiting, leucopenia with præcordial pain, recurrence of symptoms while under treatment, lack of response to thiouracil, continued auricular fibrillation with evidence of heart failure, and failure to co-operate with the physician.

All of these patients had been treated in hospitals under medical supervision, one of them for as long as one and three-quarter years, and I am certain that every effort had been made for a successful trial before the patients were sent to us for operation.

In surgery, not only is the thyrotoxicosis dealt with rapidly, once and for all, but also the goitre, which is liable to cause pressure symptoms, to be subject to hæmorrhage, occasionally to become malignant, and even by its mere presence to cause endless worry and anxiety. Moreover, the risk of future auricular fibrillation is practically removed.

To my mind surgery offers a more certain and more rapid cure than does thiouracil and the mortality is no greater.

Dr. W. R. Trotter: *The treatment of toxic goitre by thiouracil.*—In the experimental animal the primary effect of administering thiouracil is that the production of thyroid hormone ceases. As a consequence the metabolic rate falls and signs of myxœdema eventually appear. What has been achieved is, in effect, a pharmacological thyroidectomy, differing only from the surgical operation in that its effects may be reversed by discontinuing the drug at any stage in its administration.

A secondary result of the administration of thiouracil to an experimental animal is hyperplasia and hypertrophy of the thyroid gland. This is believed to be due to an excessive secretion of the thyrotropic hormone of the pituitary, provoked by the low level of circulatory thyroid hormone.

Physiological experiment therefore leads us to expect that if this drug is given to a patient with a toxic goitre it will be possible to reduce or abolish the manifestations of thyrotoxicosis. But since there is no evidence that thiouracil has any permanent effect on the thyroid it is to be expected that if the drug is discontinued the symptoms will immediately recur, unless by that time a natural remission of the disease has taken place. We shall certainly not expect any reduction in the size of the goitre and shall not be surprised to find that it becomes larger. We shall also not expect any amelioration of exophthalmos or ophthalmoplegia, since there is reason to believe that they are not the result of thyrotoxicosis as such.

It is obvious that the practical utility of the drug will depend, first, on its ability to control the symptoms of thyrotoxicosis; secondly, on its toxicity; and, thirdly, on the frequency with which natural remission occurs. If thiouracil is to supplant surgery as the standard treatment of toxic goitre it must be shown that it can control thyrotoxicosis as effectively as thyroidectomy and that it is no more dangerous than the operation. If these postulates can be fulfilled then thiouracil is clearly a useful method of tiding a patient over a relatively brief phase of thyrotoxicosis, but it would still not be a very acceptable form of therapy if it had to be continued for a lifetime. Most patients would probably prefer to swallow pills for a limited period rather than undergo a major operation; but they would probably prefer the operation to the prospect of remaining under close medical supervision for the rest of their lives. Much therefore depends on the natural course of the disease.

For the most part the theoretical forecasts have been confirmed by clinical experience. The only major exception has been the enlargement of the goitre which might be expected to occur regularly during thiouracil treatment but which in fact appeared in only 8% of our cases. Usually, but not invariably, when the goitre enlarges symptoms of myxœdema also appear. Lowering the dose of thiouracil abolishes the signs of myxœdema, and the gland reverts to its previous size. It seems that in order to cause enlargement of the goitre one has to give a dose greater than that which is necessary to control the thyrotoxicosis. In other words, when enlargement of a goitre occurs during thiouracil treatment it is simply an indication of overdosage.

The control of thyrotoxicosis by thiouracil which is theoretically to be expected obtains also in practice. The short-term effects of this drug are too well known to need further description. Only in cases which have had much iodine do we fail to get a well-marked response within a few weeks of the start of treatment. However, iodine can also produce a prompt response when given to a thyrotoxic patient for the first time, and it is clearly necessary to show that the control exercised by thiouracil can be maintained for long periods. Some results recently published by Professor Himsworth, Dr. Morgans and myself (1947, *Lancet* (i), 241) seem to suggest that this is in fact the case. Two series of patients were compared over a period of thirty months: 93 were treated by subtotal thyroidectomy, and 65 with thiouracil. The latter were treated initially in hospital with thiouracil or methyl thiouracil in a dosage of 600 mg. daily. They then continued as out-patients on 100 mg. daily. This was later reduced to 50 mg. daily or 50 mg. on alternate days, according to their progress. The method of assessment of results was to find out what proportion, in each series, could be considered "apparently cured" at different stages up to thirty months. This term means that the patients were free of all thyrotoxic symptoms and had pulse-rates of 80 or less. It will be seen that about one-third of the cases in both series attained this standard throughout the period of observation. The remainder either had slight symptoms, such as occasional palpitations, or their pulse-rates were a little over 80. In both series all patients obtained considerable benefit from their treatment and had resumed their normal occupations. It was also found that the average weight curves of the two series ran closely parallel. We concluded from these observations that thiouracil maintains its control for periods of up to thirty months, and that that control is of the same order of efficacy as that produced by thyroidectomy.

We have been able to study 29 patients who have been kept under observation for six months or more since thiouracil was stopped (fig. 1). When more time has elapsed we are clearly going to get valuable information from studies of this type about the natural course of the disease. Although the numbers are few and the time of observation short there are already some points of interest to be observed. The duration of the course of thiouracil varied from four to thirty-two months, the average being sixteen months. In 7 patients symptoms recurred after intervals of five to twenty-nine months from the time of stopping treatment (average fourteen months). Since the symptoms did not return immediately it seems likely that these were true recurrences of the disease, and not merely the result of stopping treatment too soon. Our policy is to continue treatment until the patient has remained symptomless on the minimum dose (50 mg. on alternate days) for at least three months, and this seems to be a safeguard against too early cessation of treatment. It may be remarked that in some other published series, in which high relapse-rates are reported, the majority of relapses have occurred within one or two months of the end of treatment, which clearly had been terminated too soon.

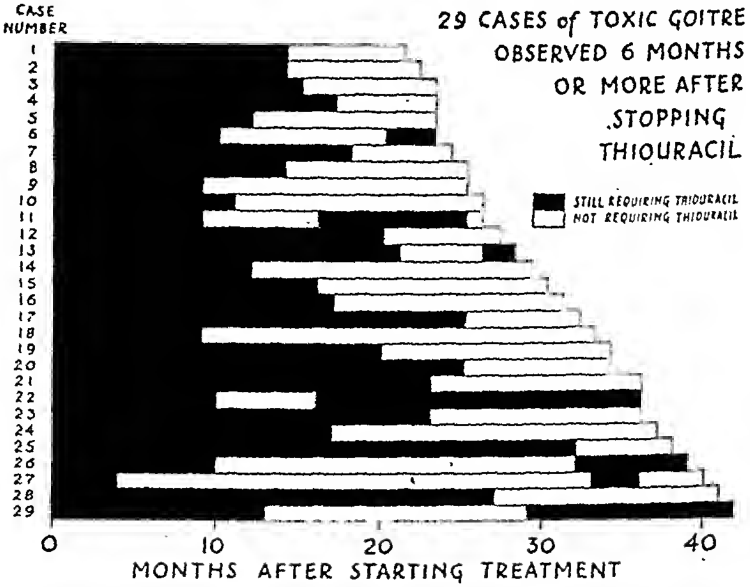

Fig. 1.

Our experience shows that in some cases a natural remission can be expected to set in within a year or two of the patient first coming under treatment. How durable this remission will be remains to be seen. From the obvious well-being of some of these patients at periods of a year or more after the end of treatment, and from the way in which their goitres have shrunk, one may well expect that in some at least the remission will be permanent. There is therefore reason to believe that in a proportion of patients with toxic goitre the disease becomes extinct within a year or two. Such patients need to have their thyrotoxicosis kept under control for this relatively short period, and the administration of thiouracil is a simple and satisfactory way of exercising this control. What we need now is some way of distinguishing this type of case from those whose disease persists for many years or who show a continued tendency to recur.

We think therefore that thiouracil is capable of controlling thyrotoxicosis and that the disease is one in which natural remission occurs often enough for a remedy of this kind to have its uses.

The common complications of thiouracil therapy are skin rashes, drug fever and leucopenia. However, these conditions do not amount to much more than a nuisance and at their worst may lead to discontinuance of thiouracil. Agranulocytosis is a very different matter. Its high death-rate and unexpected onset make it one of the most alarming conditions to be encountered in medicine. It is the cause of all the recorded deaths from thiouracil. There is at present no known way of preventing agranulocytosis, but alertness and promptitude in diagnosis and treatment will do much to prevent it being fatal. It is very necessary that patients on thiouracil should be warned to report at once if they develop fever or a sore throat and that they should immediately discontinue the drug. In such an event a blood-count must be done immediately and if no polymorphs are present penicillin should be started at once. If a patient with agranulocytosis can be protected from infection during the critical period he will probably survive.

But although agranulocytosis is alarming it is fortunately rare. The large series of cases, amounting to several thousands, collected by Moore, F. D. (1946, *J. Amer. med. Ass.*, **130**, 315), and by van Winkle and others (1946, *J. Amer. med. Ass.*, **130**, 343), show that the death-rate due to thiouracil amounts to about 0·5% of all cases treated. These figures include the early cases when agranulocytosis was not anticipated, and not all the patients with agranulocytosis were treated with penicillin. The present day mortality-rate is therefore probably less. Hence it may be said that the mortality-rate of thiouracil is at least as small as that of thyroidectomy in the hands of an expert surgeon.

In summary, thiouracil can be said to be a safe and effective method of keeping thyrotoxicosis under control. It has no curative action and therefore is only useful in cases in which the disease is not likely to last an inordinately long time. So far as our early experience goes it looks as if a fairly large proportion of cases of toxic goitre will be found to fall into this class.

If this new agent is to be compared with the well-established method of subtotal thyroidectomy it is clear that the comparison must depend on two circumstances: first, the type of surgery with which it is to be compared, and secondly the type of case which is being treated.

Subtotal thyroidectomy can be a very difficult operation. The safety with which it can be performed depends not only on the skill of the surgeon and his team, but also on his familiarity with the operation. By the time a surgeon has done several hundred thyroidectomies we can safely assume that his mortality-rate has fallen to the region of 1% or less. Most general surgeons do not acquire this degree of experience and their mortality is correspondingly higher than that of their colleagues who have made a special study of the operation. It follows that thyroidectomy in the hands of an expert is about as safe as treatment with thiouracil, but that thyroidectomy by surgeons without much experience of the operation is less safe than thiouracil—in some cases much less safe. In places where specialized surgery is not available, therefore, a physician may be well advised to treat all his cases with thiouracil, in the expectation that by so doing he will be saving lives.

When expert surgery is available we can afford to exercise more discrimination. Here surely the aim should be to learn to distinguish the short-term from the long-term cases. By the long-term cases I mean those patients whose thyrotoxicosis seems likely to last many years and for whom thyroidectomy would be a more appropriate remedy. We have, for example, under our care a man of 57, whose thyrotoxicosis began first in 1917. A partial thyroidectomy was performed and he remained well until 1933 when the symptoms returned. He has now been under treatment with thiouracil continuously for two years. So long as the dose is maintained at 100 mg. daily he remains well, but thyrotoxic symptoms have appeared on the three occasions when it has been decreased below this level. It now seems as if he will need thiouracil for many years—perhaps indefinitely. This is a case in which a further thyroidectomy might have been a more appropriate treatment.

In toxic nodular goitre, too, we are dealing with a condition in which natural remission is unlikely, for the symptoms seem to be related as much to the patient's age and cardiac state as to the state of the goitre itself. In these patients an element of mechanical obstruction is very common and there are therefore double grounds for supposing that they are best dealt with by thyroidectomy.

As a contrast I will quote the case of a woman aged 42, who started treatment in April 1944. Initially she had an easily palpable diffuse goitre and unilateral lid retraction. The initial sleeping pulse-rate was 110, and the B.M.R. + 53%. She made a good response in the first month of treatment and was afterwards maintained free of symptoms on 50 mg. daily, and then on 50 mg. on alternate days. Thiouracil was stopped after treatment had continued for nine months in all. She has been observed for a further two years since then. She says she has never felt so well in her life. Her goitre is no longer visible and scarcely palpable; and the lid retraction has gone. She has gained 2½ stones in weight, and her pulse-rate at the last six attendances has varied between 68 and 80. It seems to me that thiouracil in such cases is the best form of therapy.

Dr. A. M. Nussey: My remarks are based on experience in 75 cases treated with thiouracil in the course of three and a half years. I would like to emphasize that anyone attempting to treat cases of thyrotoxicosis with thiouracil should follow them right through, for years, if need be.

After a preliminary B.M.R., white cell and polymorph counts, every patient is given the choice of surgery or medicine and, if thiouracil is preferred, is warned of the possible dangers. I used to admit patients for at least a week, and longer if such complications as congestive heart failure and auricular fibrillation were present, but now practically all, with exception of the so-called thyro-cardiacs, are treated as out-patients, and those who are gainfully employed are allowed to go on working while the treatment is progressing. They are seen at weekly intervals twice or three times, then every other week, then every third week and finally, while the treatment lasts, not less than once in every four weeks. At such a visit the patients are assessed in a general way, white cell and polymorph counts are done, the neck measured and weight recorded. In the light of experience I now treat all patients for not less than eight months, even if they respond very rapidly. After treatment stops they are followed up every two months and then once every three months, and with few exceptions, their co-operation has been very good. At present I have thirty patients, half of whom had severe or very severe symptoms and the other half moderate or mild, who had remissions for not less than five months after periods of treatment varying from three to fifteen months, the average being about seven months. Four of those had relapses which necessitated more than one course. Ten have been free of symptoms for longer than two years, the longest being two years nine months, and eleven for more than a year. On the other hand one of my first patients has had to have thiouracil with short remissions for over three years. Relapses, which are often preceded by emotional stress, do, as a rule, respond to further courses of treatment.

Dosage.—I generally start with 0·1 gramme of methyl thiouracil q.i.d. and after two, three or four weeks reduce it to 0·1 gramme t.i.d. Then further reductions are made to 0·05 gramme q.i.d., t.i.d., and b.d. and quite a number of my patients are maintained on 0·05 gramme daily.

With thiouracil the thyroid gland softens slightly, and only rarely does it become smaller. In many patients there is a slight enlargement, and in some of the early ones, where we used larger doses than we are accustomed to do now, the neck swelled up considerably, though the process was found to be reversible when the dose of the drug was reduced. The neck measurements already mentioned serve as a rough guide, but of course some of the increase in circumference is often due to the quite appreciable gain in weight observed in most cases.

I have not found exophthalmos much affected by the treatment, but in one patient unilateral exophthalmos regressed completely with thiouracil. Seven patients had auricular fibrillation and the rhythm returned to normal in four, one with the aid of quinidine, but in the three others there has been no change. Two patients conceived in the remission stage (one of those had had a stillbirth before thiouracil treatment) and both had healthy children. Another was treated for five months ending six weeks before term and she was delivered of a normal baby.

Complications of a minor type like fleeting macular rashes, enlargement of salivary glands and a tendency to leucopenia were met in about 10% of the patients, but hardly at all in the last twenty. It is fair to point out that with such prolonged treatment all kinds of symptoms may arise, and some may be unjustly blamed on thiouracil. Two serious complications occurred, one in a woman of 59 who developed almost complete agranulocytosis and who eventually responded to intravenous pyridoxine, and another in a female diabetic of 65 who had an intense maculo-papular rash, splenomegaly and fever, without a drop in the white cell count.

Two patients were operated on because thiouracil failed to control the disease fully but in both, after an extensive ablation of the thyroid, further treatment with thiouracil was required. A third was operated on at the patient's request after she suffered a relapse and a fourth is awaiting operation because of her lack of co-operation.

The usual contra-indications to the use of thiouracil are:

(1) Where the patient, for cosmetic or other reasons, expresses a preference for surgery; (2) where the gland exerts pressure; (3) where, in the course of treatment, serious complications arise, such as agranulocytosis and recurring rashes with fever; (4) where the disease cannot be controlled without pushing the drug to dangerous limits; (5) where co-operation by the patient is lacking.

At present I would suggest three years as an arbitrary period for length of treatment, after which only the patient's express wish to avoid surgery would justify further use of thiouracil.

Mr. R. Vaughan Hudson: Thiouracil is a sign-post on the road to medical treatment but is not the complete answer to our problems. It is essential that the effects of thiouracil be fully investigated, and the indication for its use and the knowledge of its limitations made known. On the other hand the random use of thiouracil must be deprecated. The patient should be warned of its uncertainties and of its dangers, and treatment only undertaken by competent physicians, with a knowledge of the vagaries of thyrotoxicosis, who will undertake a full investigation of their patients, and keep them under supervision for a number of years.

Failures of prolonged thiouracil treatment which eventually come to operation render the surgical technical problem much more difficult. Mortality and morbidity in these cases should be credited to the results of medicine rather than be attributed entirely to surgery.

Although a division of the cases into primary and secondary thyrotoxicosis is useful I do not consider that there is any essential difference between the two. For instance in 150 personal cases of arrhythmia, we found that the arrhythmia was due to primary thyrotoxicosis more commonly than to secondary thyrotoxicosis and nodular goitre.

Dr. A. C. Crooke: Improvement in the results of medical treatment of toxic goitre may be anticipated and it is unfair to compare the present results of thiouracil therapy, which is still in its infancy, with surgery, which has, perhaps, reached the peak of its perfection. Rather the results of thiouracil therapy to-day should be compared with surgery in its infancy, when it will be realized how valuable a drug we have to deal with.

New advances are being made and in 1943 Astwood, Bissell and Hughes had reported on the comparison of 220 compounds with thiouracil, 115 of these had detectable antithyroid activity and 15 were more potent than thiouracil. The most active of them were 6-n propyl thiouracil, which was eleven times, and 6-n benzyl thiouracil, which was ten times as active as thiouracil. In 1946 Astwood and Van der Laan reported on the treatment of 100 unselected patients with propyl thiouracil, none of whom had any toxic reactions. If this work is confirmed by others, then we have in propyl thiouracil a drug which is as simple, as safe and as effective for the treatment of thyrotoxicosis as thyroid extract is for the treatment of thyroid insufficiency.

DISCUSSION: TREATMENT OF THE LYMPHADENOPATHIES

Dr. R. Bodley Scott: *Treatment of the primary lymphadenopathies.*—By the ungainly title of primary lymphadenopathy is meant all those disorders which manifest themselves first by enlargement of lymph nodes. Those which particularly call for discussion are the proliferative and neoplastic diseases of lympho-reticular tissue, or what are now often called the reticuloses and the reticulosarcomata. Of the former the commonest examples are Hodgkin's disease, lymphatic leukæmia, lymphoid follicular reticulosis (follicular lymphoblastoma of Brill and Symmers), and lympho-reticular reticulosis (Hodgkin's paragranuloma); of the latter, the lymphoblastic reticulosarcoma (lymphosarcoma).

The therapeutic problems raised by these disorders are numerous, and at the present time unsolved because the cause of none of them is known, and the very nature of the reticuloses is matter for debate. I believe it to be important that the general direction of treatment of these disorders should rest with a physician and not with the practitioner of some specialized form of therapy.

It may be stated at the outset that, as the cause of these diseases is unknown, there is for them no curative, or even logical, treatment. Trousseau's comment that a diagnosis of Hodgkin's disease is a sentence of death is as depressingly true now as it was in 1866, and can be extended to most of the other diseases under consideration.

The long tale of discarded remedies indicates a sorry record of therapeutic failure, and in Hodgkin's disease particularly a number of methods of treatment have been used which have now only a historical interest. These are, in the main, measures which assumed that the disease had an infective origin: vaccines prepared from the diphtheroids isolated from lymphadenomatous tissue by Bunting and Yates; immune sera against these bacteria, and against emulsions of diseased lymph nodes; sensitized vaccines of supposed virus bodies obtained from such emulsions; homologous serum from other patients with Hodgkin's disease; extracts of spleen; suprarenal extracts;

and Coley's fluid. The demi-monde of immunotherapy has been fully explored and its products found ineffective. Likewise the pharmacopœia has been ransacked: quinine, trypan blue, benzol, iodine—in organic and inorganic combination, cerium, manganese, gold, iron, bismuth, mercury, and antimony have all been recommended and duly discarded.

At the present time our ignorance of their causation forces us to apply the same general principles of treatment to the many different histological types of reticulosis and reticulosarcoma. The two therapeutic aims commonly pursued are to destroy the pathological tissue and to preserve the patient's general health.

It is assumed that the patient will benefit if the enlarged lymph nodes can be induced to shrink to normal size and the pathological cells in them destroyed. To effect this the destructive agent commonly used is X-radiation. There is little evidence, however, that life is prolonged by such measures. It is difficult to obtain satisfactory statistics for these diseases because the histological criteria for diagnosis are not yet agreed, and because no untreated control series is available. In respect of Hodgkin's disease, however, the series of Baker and Mann (1939) is comparable with that of Desjardin and Ford (1923); in the former radiotherapy was adequate, in the latter the authors state that many cases had no radiotherapy and in none was it satisfactory, even by the standards of twenty-three years ago. The graph of survival (fig. 1) in the two series shows no appreciable difference until the percentages for those living after five years are reached when the figures are 19% and 7·9%; however, this difference is not significant, its standard error being 5·8. There is, therefore, little reason to suppose that radiotherapy, judged to be "adequate", prolongs life in Hodgkin's disease. For other types of reticulosis and for reticulosarcoma similar figures are not available, but there is no reason to suppose that they would show any striking difference.

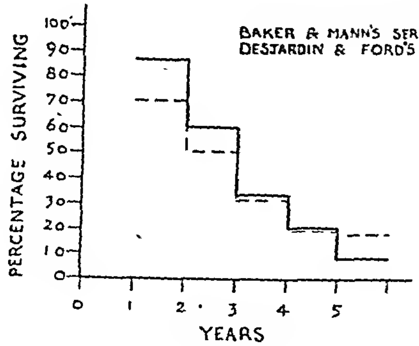

FIG. 1.—Percentage of patients with Hodgkin's disease surviving at the end of yearly periods.

No one would deny that radiotherapy is often followed by improvement in all these disorders, but this is transitory. Enlarged nodes disappear, fever vanishes, pruritus is controlled, and the patient's general health, for a time, shows great benefit.

From the point of view of treatment it is convenient to divide reticulosis and reticulosarcoma into two broad groups, depending on whether the disease is localized to one or two contiguous groups of lymph nodes, or is virtually systematized throughout the lympho-reticular tissue. Into the first category fall Hodgkin's disease, lympho-reticular, and many of the less common reticuloses and reticulosarcomata; into the second, lymphatic leukæmia, lymphoid follicular reticulosis, and lymphoblastic reticulosarcoma. This division, is, of course, not absolute and variations occur in both directions, but it is true to say that the majority of the first group start as localized disorders, while the majority of the second are generalized *ab initio*. It is clear that this peculiarity has important bearings on treatment: in the former irradiation of one group of nodes is all that is required, in the latter the whole body may demand treatment.

In the first group radiotherapy yields results which are temporarily satisfactory, and, with possible exceptions which I will discuss later, it is at present the treatment of choice. The situation in the second group is different: the patient may have no symptoms arising from the nodal enlargements which are often discovered by chance. This is especially true of chronic lymphatic leukæmia in the elderly, a disorder which is often revealed by a blood-count done for some other reason; the lymph-node enlargement being found only when the blood-count invites a search. In the latter half of life this disease is often virtually benign; it may run a course of ten or twelve years. I have recently seen a patient who has remained in good health without treatment for nine years. Radiotherapy can control some symptoms, there is no evidence that it prolongs life, and it is irrational to prescribe it until symptoms exist. No patient is distressed because his blood contains more than the usual number of lymphocytes, and however much satisfaction the physician may derive from restoring the count to normal there is no reason to suppose the patient benefits from the alteration. In this type of case irradiation should be withheld until local masses cause pain or disfigurement or until anæmia demands intervention. In lymphoid follicular reticulosis again the place of radiotherapy is less certain than it formerly seemed; many of these cases terminate by sarcomatous change, but the disease progresses slowly until this occurs. It is the impression of many clinicians that irradiation may accelerate this metamorphosis. Thus if irradiation is employed, caution is advisable and it seems wise to defer it until symptoms become insistent. In lymphoblastic reticulosarcoma the course is rapid, radiotherapy usually has to be applied by the "bath" method, and the remissions it produces are short-lived and few; nevertheless it is, at present, the best method available of palliating the patient's discomforts.

Surgery in the treatment of these diseases has been decried in the past, but Baker and Mann in 1939 noted that two cases in their series had continued without recurrence ten and twelve years respectively after total extirpation of the affected lymph nodes. This procedure is clearly applicable only to those in whom one superficial group of nodes is diseased, that is to certain of the first category. Suitable cases are rare for in 80% of the common cervical type of Hodgkin's disease there is radiological evidence when the patient is first seen of enlarged mediastinal nodes. I have seen complete freedom from recurrence for four and eight years after surgical excision of the affected nodes, the first in Hodgkin's disease and the second in lympho-reticular reticulosis. In such cases I now recommend surgery but it will be some time before its exact value and indications can be appraised.

Chemotherapeutic attempts to reduce the size of the enlarged nodes began with Billroth's introduction of arsenic in 1871. It has been used consistently since then, in organic and inorganic forms. Its value is hard to assess. The older clinicians were loud in its praises, but it is sometimes difficult to avoid the iconoclastic suspicion that they were easily pleased. Arsenic, seldom, if ever, diminishes the size of the lymph nodes, but it is often reported to have a beneficial effect on the patient's general health.

Recently interest has been aroused by reports from the United States of the use of compounds of the nitrogen mustard series in these disorders. The substance most extensively employed has been methyl-bis (beta-chloroethyl) amine hydrochloride. It is given intravenously in doses of 0·1 mg. per kg. body-weight daily for four con-

and Coley's fluid. The demi-monde of immunotherapy has been fully explored and its products found ineffective. Likewise the pharmacopœia has been ransacked: quinine, trypan blue, benzol, iodine—in organic and inorganic combination, cerium, manganese, gold, iron, bismuth, mercury, and antimony have all been recommended and duly discarded.

At the present time our ignorance of their causation forces us to apply the same general principles of treatment to the many different histological types of reticulosis and reticulosarcoma. The two therapeutic aims commonly pursued are to destroy the pathological tissue and to preserve the patient's general health.

It is assumed that the patient will benefit if the enlarged lymph nodes can be induced to shrink to normal size and the pathological cells in them destroyed. To effect this the destructive agent commonly used is X-radiation. There is little evidence, however, that life is prolonged by such measures. It is difficult to obtain satisfactory statistics for these diseases because the histological criteria for diagnosis are not yet agreed, and because no untreated control series is available. In respect of Hodgkin's disease, however, the series of Baker and Mann (1939) is comparable with that of Desjardin and Ford (1923); in the former radiotherapy was adequate, in the latter the authors state that many cases had no radiotherapy and in none was it satisfactory, even by the standards of twenty-three years ago. The graph of survival (fig. 1) in the two series shows no appreciable difference until the percentages for those living after five years are reached when the figures are 19% and 7·9%; however, this difference is not significant, its standard error being 5·8. There is, therefore, little reason to suppose that radiotherapy, judged to be "adequate", prolongs life in Hodgkin's disease. For other types of reticulosis and for reticulosarcoma similar figures are not available, but there is no reason to suppose that they would show any striking difference.

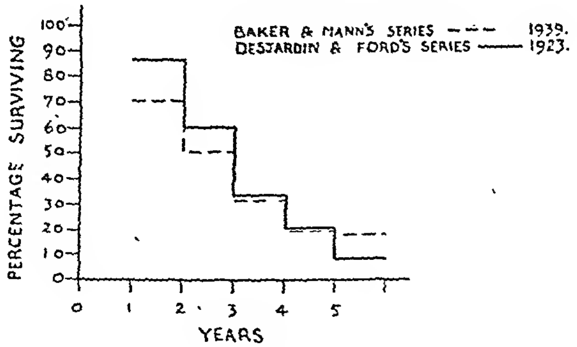

FIG. 1.—Percentage of patients with Hodgkin's disease surviving at the end of yearly periods.

No one would deny that radiotherapy is often followed by improvement in all these disorders, but this is transitory. Enlarged nodes disappear, fever vanishes, pruritus is controlled, and the patient's general health, for a time, shows great benefit.

From the point of view of treatment it is convenient to divide reticulosis and reticulosarcoma into two broad groups, depending on whether the disease is localized to one or two contiguous groups of lymph nodes, or is virtually systematized throughout the lympho-reticular tissue. Into the first category fall Hodgkin's disease, lympho-reticular, and many of the less common reticuloses and reticulosarcomata; into the second, lymphatic leukæmia, lymphoid follicular reticulosis, and lymphoblastic unhappy patients but they make it a little more tolerable. The benefits of radiotherapy are undoubtedly great, but I believe that this powerful weapon is sometimes used uncritically. When I see a patient in the terminal cachexia of Hodgkin's disease the thought often passes through my mind "how much of this is due to the disease process and how much to prolonged and intensive irradiation?"

Professor M. J. Stewart: As to the effects of irradiation I had a case of Hodgkin's disease of the Pel-Ebstein type under observation some twenty years ago. The patient had himself kept a record for nearly two years of his night and morning temperature. Following the diagnosis of the disease after biopsy, he was sent to the Radium Institute in London for radiotherapy. This had very satisfactory results, practically all the superficial glands disappearing and the general state being much improved. Later, anæmia developed and there were signs of mediastinal involvement. The point of particular interest in the case was that in spite of the well-marked effect of the radiotherapy on the lymphadenopathy, the Pel-Ebstein phenomena continued, though in an altered form. There was some lowering of the temperature generally, but the bursts of "pyrexia", lasting four or five days, consisted of great *downward* fluctuations, the peaks rarely rising more than a degree or a degree and a half above normal.

Dr. E. Lipman Cohen: It has been reported that thorium X varnish has been useful in the symptomatic treatment of mycosis fungoides, it may also be of use in the relief of pruritus in Hodgkin's disease.

Professor D. W. Smithers: As the question of the treatment of mycosis fungoides by nitrogen mustard, methyl-bis (beta-chloroethyl) amine hydrochloride, has been raised, it is of interest to note that one such patient has been treated in this way at the Royal Cancer Hospital without any demonstrable effect.

Though X-ray therapy in the lymphadenopathies is only palliative, in some instances, at any rate, it is a very efficient means of palliation, and there can be little doubt that it does in some cases prolong life. One has only to see a case of giant follicular lymphadenopathy (lymphoid follicular reticulosis) with a large pleural effusion, and in a very poor state of general health, returned to normal life for a period sometimes of many years, as has already been pointed out, for this to strike one very forcibly.

The function of radiotherapy would seem to be that of relieving symptoms and returning the patient to a reasonable state of health for a while, and so giving opportunity for other methods of treatment to be used in the hope that some curative agent may be found.

Nothing has yet been said at this meeting about the use of radioactive isotopes. Perhaps there may be some future in the combination of chemotherapy on the lines now being investigated in combination with radioactive isotopes.

Surgeons still seem to have a not unnatural reluctance to remove regional lymph nodes in a generalized condition. The percentage of cases which have lymph node enlargement confined to one region, and which are amenable to surgery when first seen, is not large. I believe that a few cases have been treated with hyperpyrexia in this country, but so far I have heard of no favourable reports on this treatment.

secutive days. It appears to have a selective action on hæmopoietic tissue affecting, like X-irradiation, the lymphocytes first and most profoundly and the erythropoietic cells least. There is usually nausea and vomiting about four hours after the injection and anorexia for the four days on which the drug is administered. The leucocyte and platelet counts fall, reaching a minimum about fifteen days after the first dose, subsequent rise is rapid and usually complete by the twenty-fifth day; a small decrease in the erythrocyte count and the hæmoglobin level is also seen. One of my patients developed a scattered vesicular eruption fifteen days after the injection which lasted a week; a dermatologist regarded this as a sensitization effect. Other toxic effects are rare and there seem to have been no fatalities attributable to the drug.

Reports are guarded but the results in Hodgkin's disease appear better than in the other conditions in this group, and there are cases recorded which had become radioresistant but in which nitrogen mustard has induced temporary remission; it is, however, not curative. Even more impressive results have been obtained in mycosis fungoides.

My own experience of this compound is limited to its use in six recent cases: in these the immediate effects have been reduction in size of nodes, relief of severe abdominal pain in one, disappearance of fever in one. Its value remains to be assessed, but there are innumerable related compounds, one of which may prove to have a more selective action. If the effects of nitrogen mustard prove comparable to those of radiotherapy it will offer great advantages in the brief duration of treatment, the ease of administration, and the manner in which all diseased tissue is accessible to its action.

Another recently introduced chemotherapeutic agent is urethane. Of the diseases under discussion chronic lymphatic leukæmia is the only one in which it has a significant effect, and here the results are inconstant. A fall in the lymphocyte count and an improvement in the patient's general condition are often obtained but, although the enlarged lymph nodes decrease in size, they do not disappear. It can at best be regarded as an ineffectual form of symptomatic treatment.

I have discussed the main methods which are used in attempts to destroy the new formations which mark these diseases. The second aim of treatment is to maintain the patient's general health and control symptoms. It has been said that the patient is usually much benefited in the second respect when the first has been attained. But there comes a time in every case when the cachectic stage of the disorder begins: in those patients who have been irradiated palpable lymphadenopathy may no longer exist, there is progressive loss of weight, anæmia, weakness, fever, and particularly in Hodgkin's disease, obstinate pruritus. Radiotherapy is no longer effective and the resources of the physician are greatly taxed to make the patient's life tolerable.

Blood transfusion may control the anæmia in the more indolent cases, and may allow the patient to leave his bed. There are occasional instances where the salient symptom is hæmolytic anæmia or thrombocytopenic purpura secondary to the splenomegaly; in some of these splenectomy is justifiable as it may give the patient another year or more of fair health.

Pruritus is a particularly difficult problem. It often disappears when the local lesions have been adequately irradiated but in the later stages this form of treatment is no longer possible. Local applications are seldom effective. In some cases benadryl by mouth has given relief.

There is unfortunately no difficulty in showing that in these diseases the methods of treatment available to us are only symptomatic; they do not prolong life for these unhappy patients but they make it a little more tolerable. The benefits of radiotherapy are undoubtedly great, but I believe that this powerful weapon is sometimes used uncritically. When I see a patient in the terminal cachexia of Hodgkin's disease the thought often passes through my mind "how much of this is due to the disease process and how much to prolonged and intensive irradiation?"

I believe that a few cases have been treated with hyperpyrexia in this country, but so far I have heard of no favourable reports on this treatment.

Dr. J. D. N. Nabarro: With regard to the use of the nitrogen mustards I have had the opportunity over the last ten months, under the direction of Professor H. P. Himsworth at University College Hospital, of using the "bis" salt in a number of cases. Six of these were previously untreated cases of Hodgkin's disease, the diagnosis being confirmed in each one by biopsy. In two there was no response to a single course of injections, in one the response was very slight, one is too recent to report and the other two showed satisfactory remissions. The first of these was a young woman with cervical and mediastinal glands, whose symptoms were abolished and general condition improved over a period of nine months, although the glands showed little change. She then had a relapse clinically and this was treated by deep X-ray therapy because the initial course of injections had been attended by such severe nausea and vomiting. The second satisfactory case was of particular interest, the patient was a middle-aged man with enlarged cervical glands and a very large liver and spleen. He ran a fever up to 102° F. and had a hæmoglobin level of 58%. After a course of injections his fever subsided by crisis and his hæmoglobin rose in three months to 100%. He had a febrile relapse two months later and his hæmoglobin fell to 57%, after another course it rose in two months to 90%. Unfortunately, he developed a bronchopneumonia shortly after from which he died. In this case, one not very suitable for X-ray therapy, nitrogen mustard produced two good remissions and enabled the patient to live an active life for some months.

There is no doubt that some cases of Hodgkin's disease show a definite response to this drug, but we have as yet no criteria on which we can foretell the result of treatment.

DISCUSSION ON THE PRESENT STATUS OF INFECTIOUS DISEASE CONTROL IN CONTINENTAL EUROPE

Dr. Ian Taylor: The district for which I was responsible in Germany covered a distance of 50 or 60 miles north and south of the City of Hanover. Infectious disease control was only one of the many and varied duties which had to be carried out. It is convenient to discuss the subject under five headings:

(1) Environmental factors.
(2) Ascertainment of cases.
(3) Isolation and treatment.
(4) Action taken on notification.
(5) Specific prophylaxis.

(1) Environmental Factors: The city of Hanover had a pre-war population of about half a million. 60% of the dwellings in the city were either heavily damaged or totally destroyed, and most of the rest of the town had suffered some damage. The centre was just a heap of rubble, with only the main military routes cleared. Another sizeable town in the area, Hamelin, suffered about 12% of total damage. By comparison there was very little damage in the smaller towns and rural areas, except to bridges and main roads.

The total population of the area, about a million, and already considerably in excess of what it had been before the war, steadily increased after the war with the influx of refugees from other parts of Germany and New Poland, with the result that the average living space had shrunk when I left to 6·2 sq. metres (only about 70 sq. ft.) for living, eating and sleeping. I believe that the figure is now even smaller; and have recently heard that in spite of the fact that the city had been declared a black spot which could not receive refugees, they have now decided that it must receive a further increase of 10% in its population. The floating population of refugees, and to some extent residents, were frequently accommodated in huge concrete air-raid bunkers, some of which were below ground level, and which often held 3,000 or more persons. These places were quickly singled out as potential health hazards, and attempts made to prevent overcrowding and provide ventilation and health services.

There can be no doubt that a high proportion of the Germans are very hungry, and undernourishment is a factor that has to be considered by health workers in the British Zone.

In the city there were 600 breaks in the main sewers apart from minor damage to drains. In rainy weather they overflowed and the basements in certain areas became flooded.

Dr. J. D. N. Nabarro: With regard to the use of the nitrogen mustards I have had the opportunity over the last ten months, under the direction of Professor H. P. Himsworth at University College Hospital, of using the "bis" salt in a number of cases. Six of these were previously untreated cases of Hodgkin's disease, the diagnosis being confirmed in each one by biopsy. In two there was no response to a single course of injections, in one the response was very slight, one is too recent to report and the other two showed satisfactory remissions. The first of these was a young woman with cervical and mediastinal glands, whose symptoms were abolished and general condition improved over a period of nine months, although the glands showed little change. She then had a relapse clinically and this was treated by deep X-ray therapy because the initial course of injections had been attended by such severe nausea and vomiting. The second satisfactory case was of particular interest, the patient was a middle-aged man with enlarged cervical glands and a very large liver and spleen. He ran a fever up to 102° F. and had a hæmoglobin level of 58%. After a course of injections his fever subsided by crisis and his hæmoglobin rose in three months to 100%. He had a febrile relapse two months later and his hæmoglobin fell to 57%, after another course it rose in two months to 90%. Unfortunately, he developed a bronchopneumonia shortly after from which he died. In this case, one not very suitable for X-ray therapy, nitrogen mustard produced two good remissions and enabled the patient to live an active life for some months.

There is no doubt that some cases of Hodgkin's disease show a definite response to this drug, but we have as yet no criteria on which we can foretell the result of treatment.

provision for diphtheria in the shape of a special hutted hospital of 100 beds outside the town, and these beds are fully used. Even so, I gathered that they regard it as quite normal for a considerable proportion of diphtheria cases to be nursed at home.

The treatment of cases in hospital suffered considerably from the shortage of drugs and dressings. Treatment of diphtheria and antitoxin dosage differed little from that in this country.

Sulphonamides of all sorts were extremely short after the capitulation, owing to the fact that industrial production was curtailed. We issued sulphonamide on the strict understanding that the drug would be used for the treatment of venereal disease only. It was naturally difficult for the Germans to understand why sulphonamide could not be issued also for the saving of life in other diseases, and this situation resulted in a number of heartbreaking interviews in the office. But it was a matter of high policy, and had to be accepted.

Penicillin was not available for Germans, although in the spring of 1946 a quantity was released, again on the understanding that it was for the treatment of sulphonamide-resistant gonorrhœa.

(4) Action taken on Notification: The organization required for investigation of the source of infection in local outbreaks was sadly defective. This was due, in part, to the fact that there were no persons on the staff of the public health departments of the exact status and training of our sanitary inspectors. Most of the sanitary inspection as such was left to the various branches of the police. It is true that each Kreis had one or two men on the staff who were known as "disinfectors" but their duties, as far as I could discover, were limited to what the name implies. The detailed enquiry into the circumstances of infection fell to a great extent upon the M.O.H. in person. Many of them were strangely apathetic in the matter, even when cases of typhus arose, and in the early days it was only because we were continually on their tail that they were stimulated to the necessary action in disinfestation of contacts. It became necessary at a later stage to require the M.O.H. to give us within twenty-four hours a full report on each case of typhus, giving particulars of the presumed source of infection, and the action taken with contacts, and we were thus able to check the fact that action had been taken. In view of the extreme importance of immediate and thorough dusting of typhus contacts, we issued a quantity of D.D.T. fairly early on to each Kreis, and the Kreis disinfector was given instruction in its use.

In addition to the M.O.H. there were, in certain widely separated places, so-called "Hygienic Institutes", which were bacteriological laboratories doing a certain amount of public health work. They were supposed to have a function in the investigation of epidemic diseases, but the areas they covered were far too large for any real activity except in the immediate locality. This remoteness from practical reality was shown up very clearly when I heard that the professor in charge of the laboratory in Hanover, whose area of influence included that part of the country in which Belsen is situated, was able to persuade the authorities that he had no knowledge of what was going on there.

Almost the first serious trouble to occur after arrival was a considerable outbreak of poliomyelitis in a town of 10,000 inhabitants. I think that the unusual course that was taken in putting the town into complete quarantine did help to limit the infection to that town.

(5) Specific Prophylaxis: *Diphtheria.*—Immunization against diphtheria was not compulsory under the Nazis, although there was power to make it so locally as deemed necessary, and only certain districts had done so.

The figures for the British Zone for September 1946 show that diphtheria morbidity was 45·4 per 10,000 per week, which is between three and four times the pre-war September figure which averaged 13·6 from 1928 to 1938. In my own area during the period July to December 1945 the average was 27·35 per 10,000.

In reconciling the level of diphtheria with the supposedly high degree of inoculation it is worth while taking note of certain facts. In 1945 when I called for a report on diphtheria immunization in the area it emerged that the last general inoculation had taken place in 1943 (two years previously) when 37,000 school children and 35,000 children under 6 had been inoculated. Of this total of 72,000 children, only 58,000 received the second injection. The following year they switched over to combined diphtheria and scarlet fever immunization, and only 628 children were inoculated—this in a community that had more than 5,000 births each year. These figures are an interesting commentary on totalitarian methods in practice. It seems to be the old story of relying more on periodic mass attack on the population than on arrangements for systematic treatment of the individual child, with the usual resulting

The water in the city came from four waterworks. Two of these drew their water from the River Leine, and the water from these was chlorinated normally. Two others took water from wells in a peat bog about 25 km. north of the town and the Germans were very proud of the purity of this supply. In view of the impossibility of guaranteeing freedom from pollution in the damaged distribution system we had to insist on chlorination. They were very reluctant to institute it, and took it almost as a personal insult to their intelligence. However in February 1946, when the worst floods in living memory occurred, and the River Leine, with a normal width of 30 ft. in the centre of the town, became a raging torrent a quarter of a mile wide, submerging parts of the town, severing communications, isolating some of the hospitals, and incidentally submerging two of the waterworks, it was a great comfort to know that whatever was happening in the pipes and drains below ground, no water was being delivered from the two waterworks that were still functioning without being superchlorinated.

Soap was extremely scarce and poor in quality. No coal was available for producing hot water in the home. These two factors, coupled with the existing overcrowding, were probably responsible for the high incidence of scabies, although the degree of infestation with pediculosis was less than one would have expected.

The background of undernourishment and overcrowding presented a very black picture when one considered the risk of spread of typhus, a disease that was constantly being introduced by refugees coming from the East.

The process of denazification of the medical services, although necessary, undoubtedly lowered the general level of public health work and the standard of skill in the specialties in the large hospitals. There was a surfeit of doctors of mediocre attainments, but first-class specialists were hard to find.

(2) ASCERTAINMENT OF CASES: At the time of the fall of Germany there was no organized system of collection of infectious diseases intelligence relating to the German population. The reason for this lack was the complete disorganization of civilian telegraphs, telephones and road and rail transport.

We put into operation at once a scheme whereby the Burgomaster or Landrat in each county district had to supply to the local Military Government administrative officer each week a statement of the number of cases and deaths from infectious diseases in the area in the previous week. These were sent up by Military Government courier to our office, where they were consolidated and sent on to higher levels, with copies to the heads of the medical services of the local British troops. For a long time these were the only returns for infectious diseases available, and formed the basis of the consolidated returns circulated centrally by UNRRA and the Ministry of Health.

Attempts were, however, made to put the responsibility for collecting information on to the German machine as soon as possible. But even when I left Germany in April 1946 I was still able to get a weekly consolidated statement forty-eight hours before my opposite number in the German administration, as he was still being hampered by inadequate civilian communications.

The return included the usual notifiable diseases. Additions to the list that were made by us at various times were venereal diseases (by sexes), influenza, pneumonia, and scabies.

Orders were given that cases of typhus, smallpox, plague, cholera, and relapsing fever, besides being included in the weekly list, were to be the subject of an immediate telegraphic report. Typhus was the only one of these diseases which occurred, and the system worked quite well, although at the beginning there was some confusion over the German word "typhus" and more than once I made a fifty-mile car journey to investigate a case of typhus which on enquiry turned out to be typhoid. By a later order, louse-borne typhus, when referred to, was always followed by the German term "fleckfieber" and this innovation worked remarkably well in preventing confusion.

(3) ISOLATION AND TREATMENT: In the Hanover district it was customary for cases of infectious diseases to be received into special infectious blocks in the municipal general hospitals. The standard of isolation accommodation varied in different districts, but normally was of the standard provided in England at the end of the last century. An exception to this was the infectious section of the City hospital at Hanover, which was more pretentious, and included a modern block of single-bedded cubicles. This had been a very good block until it was practically put out of action by Allied air raids.

An interesting sidelight on the present incidence of diphtheria is that whereas in Hanover the city municipal hospital has 400 infectious diseases beds, they have had to make emergency

Dr. H. Stanley Banks: *Experiences in South Italy, Jugoslavia and the U.S. Zone of Germany.*—In spite of my having spent twenty-one months in Continental Europe, I fear that any information I can give on infectious disease control will be incomplete and only approximately correct. This is the result of the incredible state of disorganization of the countries concerned, of their paucity of trained staffs, of the absence of wartime and post-war records, and of the extreme difficulties of communication and transport.

SOUTH ITALY: *Typhus fever* was effectively snuffed out by the use of D.D.T. in the Naples outbreak of January 1944; *typhoid fever* was relatively abundant in the civil population and very rare among the well-inoculated troops; *bacillary dysentery* was abundant in both and controlled. in the Army, only partially by hygienic measures and largely by early treatment with sulphonamide drugs; *smallpox* flared up in several villages and small towns—these were quarantined and put out of bounds to troops for several months; *malaria* was controlled by the new method of adult mosquito control (as distinct from larval control) by D.D.T. spraying of certain buildings where mosquitoes are found. On these subjects much has already been written. A few moments might, however, be devoted to *diphtheria* in the forces in Italy. The amount of mild and moderate tonsillar diphtheria, cutaneous diphtheria and diphtheritic neuritis following missed cases encountered in the forces, was, I think, somewhat of a surprise to the Army Medical Authorities. At the Army Physicians' Conference in Rome in January 1945 many of the medical specialists exhibited some confusion and uncertainty as to the pathogenesis and treatment of diphtheria. Even the use of antitoxin was not always thoroughly understood. Several of the American physicians, in particular, admitted that, prior to this, they had never seen a case of the disease. It was evident that medical inexperience of diphtheria was a far from negligible factor in the problem.

The prevalence of diphtheria in the field raised the question of prophylaxis by mass Schick testing and immunization of the whole of the British forces in the area. This was rejected, however, as a practical impossibility. The question has been discussed by Brigadier J. S. K. Boyd (1946) and the conclusion reached that Schick testing and immunization should be done at the recruiting stage, and not in the field. I understand, however, that the relatively small New Zealand and Canadian forces did manage to achieve active immunization in the field. We must here pay tribute to the prescience of G. Ramon (1945). He secured, largely by personal influence, the active immunization of the French Army against diphtheria as early as 1936. This measure paid handsome dividends when hundreds of thousands of French prisoners of war were subjected to severe diphtheria infection in prisoner of war camps in Germany and experienced a very small morbidity as compared with that of Belgian prisoners of war in the same camps. The failure to immunize the British Army against diphtheria at the recruiting stage before or during the war appears to have been a major omission in an otherwise remarkably well-planned Army programme of prophylaxis against disease.

JUGOSLAVIA.—Let me sketch in outline the background of the picture. It is a country grossly despoiled of its medical and hospital equipment; so short of doctors and nurses that in places there was only one doctor to about 30,000 of population; the medical administration is poor, sketchy and completely subservient to political ideas and political bosses; and yet we have here a virile peasantry and people accustomed to hard conditions and often bearing extreme privations without complaint. Wherever I went, I visited the hospitals. They were overcrowded and lacking in food, clothing and equipment to a degree difficult even to imagine. In the Civil Hospital, Split, an adapted building, there were, in February 1945, literally 400 cases in 250 beds. In the State General Hospital, Belgrade, in April 1945, there were literally 850 patients in 500 beds. That means that in each ward of 12 to 16 beds there were two or three beds each with two occupants. Every child's bed, of course, contained two children, "tops and tails"; a number of women's beds were similarly "doubled"; but it was an incredible sight to see two sick men side by side in a narrow hospital bed, spending their days and nights balanced precariously just inside the rails. In most hospitals there were very few blankets or sheets, just coats or scrap-up bed clothing brought in by the patients themselves; no X-ray films, no rubber gloves, little or no anæsthetics, few needles, syringes, instruments, drugs or even sutures.

Smallpox.—The control of smallpox in Jugoslavia is very efficient owing to universal vaccination at the age of 3 months or thereabouts and universal re-vaccination at 6 years and again on entering the Services. The disease has been completely absent from the country since 1930. The vaccination scheme has perforce been suspended since 1941. The vaccinations in the rural areas are carried out by village hygiene teams of lay workers who undergo a few weeks' whole-time training in this and other practical hygiene measures at the District Hygiene Institutes. In May 1945 two cases of smallpox were reported but the diagnosis was

difficulty in assessing the mass immunity of the population at any given time. It is noteworthy also that the prophylactic in use in that district was a combination in one injection of alum precipitated diphtheria toxoid with alum precipitated scarlet fever toxoid.

On the other hand, the fact that diphtheria immunization may be taking effect in Germany is suggested by a considerable rise in the average age of attack, a phenomenon which we have come to associate, rightly or wrongly, with the development of some degree of mass immunity in the child population. It may well be that the present high level of diphtheria in Germany is due to a mixture of patchy immunization technique and enhanced virulence and infectivity of the organism.

Typhus.—A number of vaccines were in use in the early period. I believe that Weigl's vaccine was being made in Hamburg, but saw nothing of its use. The commonest vaccine was a mouse-lung vaccine. The main threat of typhus after the initial clear-up was the stream of refugees coming from the New Poland. All who came through the transit camps had been properly dusted with D.D.T. both there and on the journey. Such cases as occurred were almost without exception infected outside the British Zone, and the threat was therefore greatest to public health officials and hospital staff who might become directly involved in handling these imported cases. It was therefore decided to immunize this special group of health workers. This decision coincided with reports of the infection of certain hospital workers who had been vaccinated, and in subsequent vaccination only egg-yolk vaccine was used.

Smallpox.—Smallpox vaccination is on a firmer footing than diphtheria immunization. It is compulsory for all in infancy. The only exception is when the health of the child would be prejudiced by vaccination, and vaccination is not excused in these cases, but merely postponed. Conscientious objection is not allowed. Re-vaccination of older children between the ages of 10 and 12 years is also compulsory. I cannot help feeling that although there is not much to admire in present-day Germany, we can envy the vaccinal state of their population.

Intestinal diseases.—During my stay in Hanover enteric fever was occurring at the rate of about 20 cases per million per week. The great majority of the infections were typhoid fever, with a sprinkling of paratyphoid A. These cases arose sporadically. Other districts in the Zone were experiencing a considerably higher incidence, and in certain places localized outbreaks of considerable proportions were reported, which raised the suspicion of infection of rural water supplies.

Dysentery figures were much lower than those of typhoid, which was surprising in view of the overcrowding and shortage of soap and hot water. At no time did we have the difficulties with dysentery that were described by the public health officers from Berlin at a previous meeting (*Proc. R. Soc. Med.*, **40**, 89).

In view of the high general incidence of typhoid and the unsatisfactory sanitary background, a general inoculation of the population with TAB was ordered and was in progress when I came home. From this distance I suppose that it is possible to question its wisdom. When in the midst of the problem, however, with high enteric incidence, grossly defective public and domestic hygiene, with little prospect of immediate improvement in environmental conditions, the case seemed very strong. As might be expected, reports from some districts that incidence has been reduced have been accompanied by statements that certain individuals incubating the disease had been killed by inoculations.

It may be said that infectious disease control in the circumstances described will remain a nightmare for health workers in the Zone for a long time to come.

Wholesale chlorination of main water in the larger centres and the use of D.D.T. to control imported typhus have probably played a very great part in success so far achieved.

Immunization against various diseases may also have played some part.

Good fortune has also played a not inconsiderable part, and a widespread outbreak of respiratory disease in the malnourished, overcrowded population, with such poor hospital facilities, so inadequately supplied with medicaments, would tax resources to the utmost.

The problem of tuberculosis, which is now coming to the stage when it can be treated as a priority, will undoubtedly present enormous difficulties.

In conclusion I feel that I cannot do better than quote the words of Geddes Smith in his admirable and fascinating book, "Plague on Us", published in America in 1940:

> "The lords of Europe are fighting again. Masses of men are bombed out of their homes and cities, hounded into exile, driven hither and thither, in a greater dislocation of ordered living than any rational man would have thought possible. Such a world is in peril of pestilence. It is early to boast."

Dr. H. Stanley Banks: *Experiences in South Italy, Jugoslavia and the U.S. Zone of Germany.*—In spite of my having spent twenty-one months in Continental Europe, I fear that any information I can give on infectious disease control will be incomplete and only approximately correct. Smallpox.—The control of smallpox in Jugoslavia is very efficient owing to universal vaccination at the age of 3 months or thereabouts and universal re-vaccination at 6 years and again on entering the Services. The disease has been completely absent from the country since 1930. The vaccination scheme has perforce been suspended since 1941. The vaccinations in the rural areas are carried out by village hygiene teams of lay workers who undergo a few weeks' whole-time training in this and other practical hygiene measures at the District Hygiene Institutes. In May 1945 two cases of smallpox were reported but the diagnosis was

not confirmed. Nevertheless, an attempt was made to get the machinery of vaccination going again. I had the task of organizing the import by air of half a million doses of vaccine from the Middle East. In spite of the clearest instructions, however, most of this material was wasted owing to inadequate storage in the hot weather. In Belgrade there was a 30% take, but in Macedonia, where storage conditions were very primitive, only a 1% take was obtained. I saw no case of smallpox in Jugoslavia. The immunity of the country from smallpox may be, I think, fairly attributed to the highly vaccinated and re-vaccinated state of the population. No accurate data exist as to the prevalence of post-vaccinal encephalitis.

Typhus fever.—All the indications pointed to typhus fever as the greatest epidemic danger to post-war Europe. This disease has been endemic in Jugoslavia, particularly in Bosnia, since the first World War. In 1942-43 there was a flare-up with some thousands of cases reported in the country. In the first few months of 1945, some 5,000 to 7,000 cases were reported per month, and even as late as June 1945 the figure for the month was 1,000 cases. In the twelve months from January 1945 to January 1946 no less than 40,000 cases were reported in Jugoslavia. The disease was, therefore, at this time just held in check and no more. Most of the cases during the war occurred in and around the area of operations of the Jugoslav Army. There is evidence that the disease was controlled to a considerable extent by the simple methods employed by the hygiene sections of the Jugoslav Army. These consisted chiefly in the regular use of the Serbian barrel steam disinfector for soldiers' clothing, a method introduced by Zinsser during the Serbian epidemic of 1915. Control became easier when D.D.T. was brought into the country by the U.S. Typhus Commission in February 1945. By January 1946, nearly ½ million pounds of D.D.T. powder had been delivered to Jugoslavia by the Typhus Commission and UNRRA. But the bulk of this was too late for the rush of refugees that passed through the country during the two or three months following the end of the war. Typhus control in Europe at this period was almost entirely due to the D.D.T. disinfestation stations which were set up by the Army at various points on the frontiers of Germany and Austria.

A noble attempt to mass-inoculate the whole population of Bosnia with anti-typhus vaccine was commenced in May 1945 by the Typhus Commission, and continued under the supervision of the medical staff of the Hygiene Institute of Sarajevo. The inoculations were done by no less than 170 teams of four or more lay workers who had each received some two weeks' training. The scheme was interrupted several times by lack of materials and also by poor staff work at the Ministry of Health in Belgrade. It is estimated, however, that some 800,000 of the two million inhabitants of Bosnia received one or more inoculations. These anti-typhus inoculations were believed to have three main effects: (1) reduction of the mortality of the disease (even in old people) to almost nil; (2) reduction of morbidity and therefore also of the number of infective persons; and (3) reduction of the number of infective lice. This experiment was never completed and did not succeed in its object of eradicating the endemic foci of typhus in Bosnia. Nevertheless, thanks to this and to the liberal use of D.D.T. for disinfestation during the winter succeeding the war, the danger of epidemic typhus spreading from Jugoslavia to the rest of Europe was completely overcome. In this achievement it is hardly to be doubted that D.D.T. deserves the major share of the credit.

Tuberculosis.—Throughout Europe the problem of tuberculosis is probably the greatest in the whole field of public health. The incidence and death-rates of tuberculosis in Jugoslavia are very comparable to those recently estimated for Poland by Marc Daniels (1946). In 1944, the deaths from all forms of tuberculosis in the town of Split were at the rate of 300 per 100,000 population, the same figure as that for Lodz in Poland. In the whole of Croatia, T.B. deaths were estimated in July 1945 at 400 per 100,000 population or about eight times the death-rate from tuberculosis in Britain. This represents more than a twofold increase over Jugoslavia's pre-war tuberculosis death-rate which was one of the highest in Europe. An attempt was made to obtain data from a mass radiography survey. After tremendous trouble by UNRRA officials a set of limited power was obtained from Italy and put in the charge of an excellent technician. The Jugoslav authorities, however, with typical Jugoslav recklessness, insisted on running the machine far in excess of its capacity, with the result that it was wrecked in a week. This is the reason for the complete absence of data from mass radiography in Jugoslavia.

Hardly any effective control of tuberculosis is being exercised in Jugoslavia. Clinic, hospital and sanatorium services are grossly inadequate. Poverty and underfeeding are general throughout the country as well as in the hospitals. Nothing less than a substantial rise in the standard of living of the whole population is likely to bring about an improvement.

Venereal diseases.—In Bosnia syphilis is said to be prevalent to the extent of 10% of the population. No exact estimate is, however, possible, owing to the absence of reliable sampling surveys. Dr. Grin of the Sarajevo Hygiene Institute believes that the disease is not only venereal, but frequently transmitted by the use of common food utensils among families and units containing members with acute nasopharyngeal and oral lesions. Knowing the habits of the peasantry, I think this may be quite a likely source of infection.

Intestinal diseases.—As in Italy, *bacillary dysentery* is endemic. In summer practically everyone in Jugoslavia has several attacks of it. Those of us who were able to obtain supplies of sulphaguanidine controlled our attacks by its regular use at the first onset of diarrhœa. The Jugoslavs, in 1945 at least, just suffered until they acquired enough natural immunity to tide them over until the next attack.

Typhoid fever is also very rife. Our six-monthly T.A.B. inoculation was, without doubt, the source of our personal immunity. The worst area is probably Macedonia, since there hygiene is the most primitive. Water supplies, usually springs and shallow wells, are in bad repair. The privy and open well often exist in the same yard. The sewage is often carried in the street gutters. Morbidity from intestinal diseases in Macedonia is estimated at 30% and mortality at 10%. No effective help could be given with this problem by the UNRRA sanitary engineering section, owing to lack of co-operation from the Ministry of Health. The latter's policy was entirely dominated by the political and military factors in the situation.

Malaria.—At a conference of malariologists in Belgrade in April 1946 it was estimated that there were 1,200,000 cases of malaria in the country per annum. In Macedonia over 30% of the population of one million suffer from malaria. Again, no effective help could be given with this problem because the authorities would neither allow proper surveys to be made nor allocate skilled staff to operate the plant which, in the beginning, was supplied. In Greece, UNRRA supplied aeroplanes for spraying marshy land with D.D.T. The Jugoslav authorities demanded aeroplanes also, but as there was every reason to think that the planes would have been used for military purposes, they were not supplied. And so, although UNRRA sent a strong sanitary engineering section into the country, and were prepared to supply large quantities of anti-malaria materials, it proved impossible to make any effective contribution to anti-malarial work, owing to the intransigent attitude of the Government.

Nursing.—Six highly skilled U.S. and British public health nurses laboured for over a year in the country trying to organize the training of nurses. Their labours were in vain. Finally, it was arranged to provide fellowships for training of 20 nurse-teachers in U.S.A. The 20 candidates were selected by the Government (with, of course, the usual political considerations in mind). Out of the 20, visas were allotted to 18 and the other two were refused. The Jugoslav authorities were so incensed at this refusal that they called off the whole scheme. Thus the nursing contribution of UNRRA to infectious disease control ended in failure.

UNRRA supplies.—In spite of such rebuffs, by September 1946 UNRRA, under the leadership of a Russian chief of mission, had imported into Jugoslavia no less than two million tons of supplies, including vast quantities of medical and hospital supplies. The whole of this was a free gift to the Jugoslav Government. Acknowledgment took the form of the usual elaborate feast to the UNRRA officials, but (to quote the official report) "the foreign policy of the Government forbade all public recognition of this unprecedented gift".

GERMANY: I can make only very brief reference to the U.S. Zone of Germany. Infectious disease, except tuberculosis, among the displaced persons is remarkably low, thanks to regular inoculations against diphtheria, smallpox, typhus and typhoid fevers, to regular D.D.T. dustings and to a reasonably good diet, which is supposed to include approximately 1,000 calories from fresh meat, milk, eggs, &c. On the other hand, large epidemics of *typhoid fever* occur among German civilians. In one district of Bavaria from September to November 1946, there were 2,500 cases of typhoid reported among German civilians, while there were only 8 cases among the thousands of displaced persons in the area—another tribute to the preventive effects of regular T.A.B. vaccine.

Tuberculosis is worst in the Jewish camps, although the incidence is now much less than it was at the close of the war. Mass radiography in the Jewish camps shows a rate of about 2% active tuberculosis based on examination of 35 mm. film only. This figure would probably be considerably reduced after hospital observation of doubtful cases. Tuberculosis hospital and sanatorium provision is of course inadequate, but probably less so for both D.P.s and civilians in Germany than in many other countries in Europe.

Dr. F. R. Curtis: *Venereal disease control in Denmark, Sweden and the British-occupied Zone of Germany.*—In Denmark and Sweden prior to 1939 there had been a steady fall in the incidence of syphilis and gonorrhœa since 1919-20. In both countries notification of venereal diseases and compulsory treatment had been the law for many years and had become an accepted part of the social fabric. The figures in the table (*v.i.*) can, therefore, be considered reliable.

Between 1939 and 1944 syphilis in Denmark increased almost eightfold, while in Sweden the increase was threefold. The difference may reasonably be attributed to the much greater wartime disturbance of social conditions in Denmark associated with occupation by German troops.

It is also worthy of note that the increase in gonorrhœa in both countries from 1939 was much less than the increase of syphilis, being approximately 2·5 times for Denmark and 1·5 for Sweden.

Both countries emerged from the war convinced that the increased incidence of gonorrhœa and syphilis was but a transient wartime phenomenon and that their well-tried control measures would once more exert their pre-war power as soon as social disturbances subsided.

The British-occupied Zone of Germany presents a very different picture. Here there was no pre-existing system of efficient control of venereal diseases. Little or no use was made of the free public clinic. Practically the only cases treated in hospitals were prostitutes who were sent there by the police, whose responsibility it was to supervise prostitutes and brothels. Naturally a certain number of patients attended the skin and V.D. out-patient departments of the University Hospitals because they were attracted by the prestige of the Professors but could not afford to pay for private treatment.

The local authorities in Germany were under no compulsion to appoint venereologists to supervise the operation of control in their areas, though some states, e.g. Thuringia, took steps to make such appointments with on the whole very favourable results. The fact that so much venereal disease was treated privately made epidemiological work difficult if not impossible for the public health authorities. Nominally there was a professional, but not legal, obligation on every doctor seeing a fresh infection to endeavour to bring the infectious source under treatment. If he failed, he was supposed to furnish particulars to the Medical Officer of Health, who, after failing to achieve success by means of correspondence, could do no more than hand the matter over to the police. To a very large extent the whole system failed to work and except in relation to the regular medical examination of prostitutes it was not surprising to find that the health visitor and social service worker had no place in the scheme of venereal disease control.

The problem of Military Government and then of Control Commission for Germany was first to implement those parts of the German law on venereal disease which were sound but had been somewhat neglected and later to add provisions which would force the local public health authorities to take effective action and at the same time ensure that the British public health officers were able to exercise effective supervision.

During the first year of occupation many parts of the British Zone were inadequately supplied with sulphonamides for all purposes. This led, in the case of gonorrhœa, to a sort of rationing system by which all cases got a little but few got enough. The results in the way of asymptomatic infectiousness and sulphonamide resistance can easily be imagined. The German venereologists admitted that 40% of cases of gonorrhœa were resistant to sulphonamides.

In an endeavour to reduce this reservoir of gonococcal infections as quickly as possible penicillin was obtained from the United Kingdom, since the Germans had never produced penicillin themselves. As they had no experience of penicillin treatment arrangements were made for the leading venereologists to visit the British Army V.D. treatment centres, and they were made responsible for training their colleagues. At the same time, to avoid as far as possible leakage of penicillin to the black market it was made mandatory that cases of gonorrhœa should be treated only in certain specified University or Municipal hospitals.

One of the early preoccupations of public health officers was the possibility of considerable numbers of cases of venereal diseases amongst displaced persons. I made a survey in the summer of 1945, visiting camps containing altogether about 60,000 such persons which represented approximately 10% of the total in the area. From inspection of the case-books at the sick bays in the camps and from detailed talks to the medical personnel in charge it became evident that, though in many instances conditions were highly favourable to the spread of venereal diseases, there was in fact a negligible incidence amongst displaced persons. This was confirmed by numerous UNRRA medical officers not only in the area under survey but also in other parts of the British Zone.

The rates for England and Wales are calculated from Tables A and B on pages 272 and 273 of Report of the Chief Medical Officer of the Ministry of Health, 1939-45.

RATE PER 10,000 OF TOTAL POPULATION

	England and Wales		Denmark		Sweden		Germany (British Zone)
	1939	1944	1939	1944	1939	1944	1946
Gonorrhœa	7·4	6·5	21·8	58·5	19·4	32·0	46·7
Syphilis	2·8	3·8	1·3	10·2	0·7	2·1	19·8

The rates for Denmark and Sweden are obtained from page 33 of Hartmann's "The Girls they Left Behind", Copenhagen, 1946.

The rates for British Zone of Germany are calculated from figures in a paper published in the *British Journal of Venereal Diseases*, 1947, 23, 20.

(1) It must be remembered that the figures given for England and Wales are for attendances at treatment centres only and exclude Services cases as well as gonorrhœa and syphilis treated privately.

(2) The conditions in Germany, owing to the absence of so many men of military age as prisoners of war, approximate to those obtaining in England and Wales in 1944. It is of interest that in both England and Wales and Germany in 1944 and 1946 respectively the incidence of venereal diseases was greater in females than in males as judged by the returns. This occurred for the first time in England and Wales since the records had been kept. It is of course almost certainly related to the preponderance of young women over young men at the relevant times.

(3) The figures for gonorrhœa in Denmark and Sweden are far higher than those in England and Wales. In the former countries notification is the law, whether cases are seen privately or at public clinics. It would be premature to conclude that gonorrhœa is a less common disease in England and Wales than in the Scandinavian countries until appropriate action has been taken to implement the recommendations of the Ministry of Health Medical Advisory Committee that "some form of regular return which would provide information about the number of patients treated by private practitioners should be adopted" (Page 71, Chief Medical Officer's Report on the State of the Public Health during Six Years of War).

(4) The very low ratio of gonorrhœa to syphilis in British Zone of Germany should be compared with the corresponding ratios for Denmark and Sweden.

(5) It is noteworthy that in Denmark and Sweden between 1939 and 1944 there has been an increase in syphilis disproportionate to that in gonorrhœa, and that the disproportion is far greater in Denmark, which was occupied, than in Sweden which was not. If there were any reliable figures available it would probably be evident that the same disproportion occurred in Germany. Certainly the leading German venereologists were convinced of such disproportionate increase in their own spheres of influence.

Dr. J. Balfour Kirk said that the spraying of houses with D.D.T. as a method of malaria control had been advocated by de Meillon and Park Ross in Natal some twelve years ago. Russell and Knipe employed it with conspicuous success in certain villages in India. The method had also been put into effect in Mauritius in 1941 as a means of protecting from malaria a large camp of Jewish immigrants, and also at Takoradi on the Gold Coast in 1942. In those experiments pyrethrins or an extract of pyrethrum made with kerosene oil had been used, as well as dusting with a fresh pyrethrum powder. D.D.T. by itself, owing to its delayed action and to the fact that it was not repellent, was unlikely to be entirely satisfactory in house-spraying. Possibly a more effective mixture would be D.D.T. and pyrethrins.

Dr. Kirk remarked that the danger of a European pandemic of communicable disease arising from localized outbreaks in more backward countries such as those of the Balkans or Eastern Europe, was not really great, because these countries had been largely deprived of means of rapid transport. Although their health departments had been very seriously disorganized, they were probably sufficient to deal with local outbreaks. The danger might arise if rapid international transport were re-established before the various health departments were sufficiently organized to deal with country-wide outbreaks.

The success of the UNRRA Displaced Persons Operation in Germany during the winter of 1945-46 in keeping to remarkably low levels the incidence of communicable disease in the camps Dr. Kirk attributed to the fact that the danger had been adequately anticipated by Military Governments and UNRRA, and that such preventive measures as were practicable had been very thoroughly applied throughout and in good time.

Dr. Milosh Sekulich said that in Jugoslavia to-day, a doctor was never sure of his position in the community unless he was a "party man". There was no question to-day of introducing a new system—a National Medical Service—because national medical service was gradually introduced between the two great wars. Doctors were engaged in this national medical scheme both on a whole-time and part-time basis, the latter being allowed private practice, and thus retaining their identity as "family doctors".

Prior to 1918, Jugoslav doctors were educated abroad, but, from then onwards, three medical schools were created and over three thousand doctors were trained. Over three hundred new institutions were set up for work on preventive medicine, and over three hundred hospitals, clinics and other institutions were opened for curative medicine. As a result of this medical progress in Jugoslavia between the two great wars, the fight against infectious diseases was increasingly successful. Diseases like smallpox were quite unknown in the country, while typhoid, typhus and diphtheria were progressively reduced. The fight was very difficult, and, in spite of all efforts, endemic typhus and syphilis remained virulent in some parts of the country until the present time.

It is interesting to note that the pre-war semi-dictatorships favoured the development of medical service, and many new laws were created to this end. Under the Communist totalitarianism of to-day, medical work was far from being successful in spite of the enormous help given by UNRRA. The Communist Government of Jugoslavia received as a gift from UNRRA the equivalent in value of six years' national budget, yet unfortunately almost daily pathetic letters from that country were received, asking for even a few grains of aspirin.

Common Cold.

Interim Report on a Transmission Experiment. [*Abstract*]

By Doctors C. H. Andrewes, W. H. Bradley, D. K. M. Chalmers and F. Fulton
(*Common Cold Research Unit, Harvard Hospital, Salisbury.*)

THIS meeting was held on May 2, 1947, at the Common Cold Research Unit, Harvard Hospital, Salisbury, where for about a year, under auspices of the Medical Research Council and the Ministry of Health, an investigation into the ætiology of the common cold has been undertaken. Successive groups of volunteers have accepted isolation for ten to fourteen days to be tested with the common cold virus.

Members of the Section and others visited the isolation quarters and later heard a review of the present position of the experiment and saw a film of the Unit which had been produced by the Central Office of Information. Dr. H. J. Parish, the Chairman, pointed out that the common cold was reputed to be responsible for the loss of 40 million man-days per year, but this was the first time the Section had discussed the subject.

At the time of Dunkirk, Harvard University in America sent to this country a number of field and laboratory workers to assist in the control of epidemics. A group of prefabricated buildings formed the hospital at Salisbury and the Harvard Unit grew into a team of more than 100 doctors. The hospital became an E.M.S. hospital for both civil and military cases of communicable diseases. The course of the war prevented the full benefit of the studies from being reaped, but the result of some of the work was published in the reports for the war years of the Chief Medical Officer of the Ministry.

With America's entry into the war the hospital passed into the hands of the U.S. Army and became the central laboratory for the American Army Medical Corps in the European theatre. The laboratories were extended and special research units were established. The place rapidly acquired a reputation as one of the foremost laboratories devoted to preventive medicine. In 1944 the central laboratory was transferred to the Pasteur Institute in Paris. In May 1945 the American military authorities withdrew from the hospital which now remains an important link between the United States and Great Britain on the one hand and between Harvard University and its Faculty of Medicine and the British Ministry of Health and the Medical Research Council on the other.

The hospital was built specifically as an institute for the study of communicable diseases. In 1946 it was decided to adapt it for a long-term research into the ætiology and transmission of the common cold.

The first requirement is to discover a method of studying the virus of the common cold which cannot at present be handled in the laboratory by existing techniques. Human volunteers are therefore employed as indicators of the presence of cold-producing agents, but it is hoped that eventually a substitute will be found for the human volunteers.

It has been known for more than thirty years that a cold can be transmitted from one person to another by means of bacteria-free filtrates, and that such colds are transmissible in series. It is also known that chimpanzees—but no other kind of animal—can also be infected. A claim to have cultivated the virus in a tissue culture medium is not yet confirmed. The most likely working hypothesis is that the filtrable agent which can produce transmissible colds in series is a virus.

The primary objective is to find some substitute for the human volunteer, some laboratory method by which to recognize the presence of the virus. An attempt is being made, first of all, to adapt to the study of the cold a number of virus techniques which have been developed during the last fifteen years. Concentrated attempts are being made to grow the virus in fertile eggs because about sixty different viruses have been studied in this way, and in about 75% success has been obtained by one or other technique. Attempts are being made to grow the agent in the egg and to use human volunteers to decide whether the experiment is getting anywhere. The problem is not one which can be solved quickly.

It has been suggested, particularly by recent work in America, that there might be some infections simulating the common cold but with a much longer incubation period than two or three days. If this is so the technique in use at the research unit is open to serious criticism, but the possibility is recognized. To allow a fortnight or more for long incubation periods would seriously curtail the speed of the research.

Volunteers are isolated on the assumption that they are likely to pick up colds by contact with other people. No stringent precautions are taken to prevent the infective agent reaching the volunteers by means of inanimate objects, such as newspapers and milk bottles: these are not believed to be serious sources of danger. The system of controls is such as to give some indication if these precautions are inadequate. A full-blown cold is not difficult to detect clinically, but there are bound to be many intermediate conditions. To avoid a bias in any trial, certain volunteers receive normal egg fluids or other materials known not to contain cold virus and nobody but the laboratory workers knows what is given to any volunteer. Twenty-four people—12 pairs—are taken at each trial. Two of the pairs receive negative control material and, in most trials, two positive control material. This leaves 8 pairs for the material to be tested. Something like 50% of the people are resistant to the material, so that to test any one material it is necessary to take at least four subjects, two pairs, as a minimum. There must be no disappointment if progress is rather slow. Other angles of approach are possible in the future—a study of the individual resistance of the patient, epidemiological studies, air hygiene, climatology and orthodox bacteriology, but it is felt that orthodox bacteriology has been studied rather more than other aspects.

At the Unit itself, the task is to provide the bacteriologists with human subjects in isolation under such standard conditions as are practicable and then to make the clinical assessment on which to base the result of the experiment. The age limit for volunteers is 18 to 40—after school age and before the setting in of the chronic catarrhal conditions of later life. People with asthma, hay fever, sinusitis, or a history of pulmonary tuberculosis are excluded. There is almost complete freedom for volunteers except that they must not mix with other people. A distance of 30 feet is regarded as beyond the reach of cross-infection. Each trial lasts for ten days. After a communal lunch on arrival, the volunteers are given a preliminary talk, undergo a medical examination of life insurance standard (but including an X-ray examination of the chest and sinuses) and then go into quarantine for seventy-two hours to exclude incubating colds. Materials believed to contain virus or materials known not to contain virus are instilled into the nose, 0·5 ml. into each nostril, with the subject maintaining the supine position for two minutes followed by the prone position for one minute.

Clinical assessment begins on the fourth day of the trial and continues throughout the remainder of the trial. The matron records pulse and temperature daily on a chart. The

criteria of each assessment are subjective and objective. Each volunteer reports any symptoms he or she may have. The appearance of the fauces is noted and especially the evidence of what can be blown out of the nose on to the handkerchief.

It may well be that the experimental cold induced in the Unit is not the same thing clinically as the cold seen outside. For one thing there should be less secondary infection. The induced colds vary from the doubtful abortive cold to abundant rhinitis. The most common incubation period is two to three days, but a few colds develop after five or six days, which is the limit of the period of observation ; therefore the present period of observation is not ideal, although the majority of colds probably exhibit themselves within that time. It does not appear significant whether the subject has had a cold during the previous month or has had no cold for six months.

Material for transmission experiments is collected from suitable subjects, packed in solid CO_2, sent to the laboratory and centrifuged. The filtrate is cleared of all bacteria and then stored. The first problem is to determine whether it is possible to go on storing the material indefinitely and still maintain the life of the virus. It has been shown that the filtrate can be stored for at least four and a half months at −76° C. At ordinary icebox temperature, +4° C., activity persists for at least three days. An attempt is also being made to determine the size of the agent responsible. The washings can contain substances of quite different sizes. It cannot be said that the lower limit of size is fixed; the upper limit is fixed but not the lower. The only thing certain is that there is some agent in the common cold filtrates which induces colds in a percentage of people; all other results are tentative.

Teratomas and Mixed Tumours in Animals and their Bearings on Human Pathology. [*Summary*]

By Professor R. A. WILLIS

THE following distinct kinds of tumours should not be confused with one another: (1) Mixed tumours of adult tissues, e.g. of the breast, thyroid and uterus. (2) Embryonic tumours of particular organs, arising in early life from tissues which are still immature, e.g. embryonic tumours of the kidney, liver, and pelvic viscera. (3) Teratomas, composed of a variety of tissues quite foreign to the parts in which they arise.

Tumours of the first class, e.g. mammary fibro-adenoma, contain both epithelial and non-epithelial neoplastic tissues. By serial transplantations of the mammary tumours of rats, several workers have found that the fibromatous component can be separated from the epithelial component and its properties studied, especially its sarcomatous transformation. Informative results might be obtained by similar transplantation of the common mammary fibro-adenomas of dogs, the fibromatous element of which, besides undergoing sarcomatous change, often ossifies or chondrifies; or by similar studies of the rarer mixed tumours of the dog's thyroid, or of other mixed tumours which may be discovered from time to time in animals.

Tumours of the second class also occur in animals, e.g. embryonic renal tumours, believed to be the counterparts of the human ones, are not uncommon in pigs, rabbits and possibly birds. Analysis of the structure and properties of these by transplantation deserves further study. Such tumours not infrequently show aberrant differentiation of their tissues in part.

Teratomas appear, with one exception, to be very rare in animals. The exception is the benign type of teratoma which occurs frequently in the testes of young horses. (Several examples of these were shown to the meeting.) It is a striking fact that, while dogs frequently develop seminomas, interstitial-cell tumours and Sertoli-cell tumours, teratoma of the canine testis has not been described. Ovarian teratomas are very rare in dogs, and also in rodents. But there is great need of analysis of the properties of the various components of these growths by serial transplantation.

criteria of each assessment are subjective and objective. Each volunteer reports any symptoms he or she may have. The appearance of the fauces is noted and especially the evidence of what can be blown out of the nose on to the handkerchief.

The most common incubation period is two to three days, but a few colds develop after five or six days, which is the limit of the period of observation; therefore the present period of observation is not ideal, although the majority of colds probably exhibit themselves within that time. It does not appear significant whether the subject has had a cold during the previous month or has had no cold for six months.

Material for transmission experiments is collected from suitable subjects, packed in solid CO_2, sent to the laboratory and centrifuged. The filtrate is cleared of all bacteria and then stored. The first problem is to determine whether it is possible to go on storing the material indefinitely and still maintain the life of the virus. It has been shown that the filtrate can be stored for at least four and a half months at −76° C. At ordinary icebox temperature, +4° C., activity persists for at least three days. An attempt is also being made to determine the size of the agent responsible. The washings can contain substances of quite different sizes. It cannot be said that the lower limit of size is fixed; the upper limit is fixed but not the lower. The only thing certain is that there is some agent in the common cold filtrates which induces colds in a percentage of people; all other results are tentative.

in both sexes at birth, but are best developed after puberty. They form a ring around the anus, but are most numerous above it; tumours of these glands are most often seen above the anus, but they may occur anywhere around the anus, or even at the base of the tail or the side of the prepuce. The tumours do not form metastases, but they have a vascular stroma and are liable to bleed, and their position exposes them to infection.

Tumours of the circumanal glands occur almost exclusively in males, and Smythe (1945, 1946) has introduced a method of treatment with stilbœstrol which often has satisfactory results; these are, however, sometimes only temporary. The circumanal gland tumour occurs in old dogs, and it is possible that it should not be classed as a neoplasm, but as an example of those hyperplasias of endocrine origin which occur in old dogs, such as hyperplasia of the interstitial cells of the testis or hyperplasia of the prostate.

(3) *Mammary tumours of the bitch.*—This is the commonest tumour we are asked to examine—110 of the 550 tumours mentioned were from the mammary gland. The tumours usually occur in older animals, are often well encapsulated, and may be multiple. They tend to be more frequent in the posterior pairs of mammary glands, and usually grow slowly and intermittently over months or even years.

At least one-third of the 110 tumours were of the mixed type, showing, in addition to the epithelial component, myxomatous fibrous tissue, cartilage, pseudocartilage, and sometimes bone. The cartilage and bone are apparently formed by metaplasia of the stromal connective tissue, and the pseudocartilage by the appearance of interstitial matrix between the epithelial cells. Some have claimed that the pseudocartilage is true cartilage of epithelial origin; for example, Allen (1940) found the material to have the staining and biochemical properties of cartilage, and he considers that the absence of a perichondrium around the pseudocartilage is not evidence of its non-cartilaginous nature, but is merely what would be expected if it was, in fact, of epithelial origin. The myxomatous and other changes appear to affect mainly the intralobular as opposed to the interlobular tissue, and a study of the changes in this tissue during the normal sexual cycle might provide a clue to the significance of the structure of the tumour.

An attempt has been made to assess the nature of 69 tumours from their histological structure: 29 were thought to be certainly benign, and 9 probably so; 10 were thought to be malignant, and 10 probably so; the nature of 11 was doubtful. These figures are probably misleading as to the actual proportion of benign to malignant cases that might be encountered in practice, partly because clinically quite benign tumours may show a disordered histological structure suggesting malignancy. Dobberstein and Matthias (1942) consider that not more than 10% of the mammary tumours of the bitch are truly malignant as shown by the production of metastases, and they show that many of the descriptions of malignant tumours in the literature were based on insufficient evidence of malignancy or of mammary origin.

With regard to the possible ætiology of the mammary tumours of the bitch, they seem to be commoner in those bitches that have bred infrequently or not at all—this recalls the incidence of "pyometra" in the bitch, which is possibly due to a hormone imbalance provoked or accentuated by repeated pseudo-pregnancies. It is possible that retention of milk may account for the more common occurrence of the tumours in the posterior glands, as they are larger and have larger teats and may not be so thoroughly milked out by the pups even when true pregnancy has occurred. Huggins and Moulder (1944) found that the mammary glands of the bitch undergo regional involution, some degree of functional activity often being retained longer in the posterior than in the anterior glands.

One case of what appeared to be a typical mixed mammary tumour was seen in a male dog, and others have been recorded.

The only instance of such a study in a mammal appears to be that of Jackson and Brues who examined the growth of a malignant ovarian teratoma of a mouse through 13 generations of transplants.

REFERENCE

JACKSON, E. B., and BRUES, A. M. (1941) *Cancer Res.*, 1, 494.

Dr. C. L. Oakley showed reconstructions of slices of a teratoma of ovary of a young bitch.

Dr. L. Foulds referred to difficulties in the experimental analysis of mixed tumours. If transplantation succeeded it was probable that even if multiple neoplastic components were present, one would outgrow the others. Primarily simple tumours, however, were observed to become complex during the course of serial transplantation as a result of changes induced by the parenchyma in the stroma or invaded tissues. Dr. Foulds agreed with Professor Willis in placing the teratomata in a group by themselves but thought that the majority of so-called "mixed" tumours were primarily simple tumours with one neoplastic component which had become complex as a result of secondary changes in the stroma or invaded tissues. There was good experimental evidence for the sarcomatous transformation of the stroma in the course of transplantation of mammary carcinomata in mice. At one stage the tumours appeared to be mixtures of sarcoma and carcinoma but subsequently the carcinoma was eliminated and the tumour was then transplantable as a pure sarcoma.

Some Glandular Tumours of the Dog

By E. COTCHIN, M.R.C.V.S.

(1) *The "sweat gland adenoma".*—Visible sweating in dogs is generally confined to the pads of the feet, but this is not due to the absence of glands resembling sweat glands from the general body surface. The dog's sweat glands, unlike those of man, open, except on the pads, into hair follicles and not on to the skin surface (Speed, 1941) and do not normally produce visible sweat; they resemble the apocrine glands in structure.

A few well-defined tumours of the skin of dogs have been encountered which are thought to be of sweat gland origin. They are encapsulated, may be lobulated, and may ulcerate. They consist of epithelial cells resembling basal cells lying in spaces in a fibrous stroma and tending to form long rope-like columns and structures resembling starfish in shape. The latter, which appear to be nodes from which the cell columns radiate, are seen in some other skin tumours, and are composed of a peripheral layer of cells tending to lie at right angles to the stroma and of a central mass of spindle-shaped cells. The cell columns are from one to two cells thick, the cells lying at right angles to the length of the column, and there is no lumen. The arrangement of the cells in the columns, and the relation of the columns to the stroma, are those seen in a developing sweat gland before it has formed a lumen. The name "basal-cell carcinoma" sometimes applied to these tumours is misleading, as, despite the presence of mitoses and the apparently invasive nature of the growth of the cell columns in the stroma within the limits of the tumour capsule, they are not malignant.

(2) *The "anal adenoma".*—This tumour was seen 30 times in a series of 550 dog tumours examined. There are several kinds of glands in the anal region of the dog—the internal anal glands at the junction of rectal mucosa and anal canal epithelium, the glands in the walls of the anal sacs, the local sebaceous and sweat glands, and finally the circumanal glands from which the anal adenoma develops. These circumanal glands are modified sebaceous glands of unknown function. They consist of solid alveolar masses, their ducts usually opening into hair follicles. The alveoli consist of small darkly-staining peripheral cells, and large cytoplasm-rich central cells; in sections, the latter often appear to be separated by canaliculi, and from their supposed method of secretion they have been called "hepatoid glands" by Schaffer (Bolk *et al.*, 1939). The circumanal glands occur only in canines. They are present

It has been demonstrated experimentally for the moth *Tineola biselliella* by E. Titschack, that the greater the body length the greater the span of life. It is probably true generally both for the vegetable and animal kingdoms that in broad terms the longest lived are the large organisms whereas small organisms are generally short-lived. It has been stated that for organisms of comparable size aquatic animals exhibit greater longevity than terrestrial ones, which, if true, may not be without significance. But in connexion with size we may note that the potentially immortal organisms are usually minute but inhabit a liquid environment, a point to which we must revert later. In the small terrestrial organisms a high rate of metabolism is usually a necessary concomitant of the large ratio of surface to volume. In the fruit fly, the span of life has been shown to vary directly with the body weight, and inversely as the rate of metabolism.

Let us consider those plants in which the span of life normally appears quite definite, namely the annuals, which complete their life-cycle in anything from a few months to just over a year. We know experimentally that at least some of these can have their life artificially prolonged by preventing them flowering and fruiting. Indeed, so slender an annual as the sandwort can become perennial under natural conditions which preclude normal reproduction. Here it would appear that the brevity of life is linked with its gaiety and that exhaustion of food resources plays a large part in rendering the organism susceptible to the immediate causes of death. But continuing the analogy of the machine, reproduction is I think only to be regarded as an additional strain, sometimes severe, but that it is far from being the main cause of the limitation of the span of life is shown by the fact that some exotics which we grow here, which do not flower or fruit, though they appear to flourish vegetatively, are not in any degree remarkable for an increased span of life.

No, the secret lies deeper and I think we can come nearer the heart of the problem by considering a few concrete examples. Many species of *Dianthus*, as every gardener is aware, are short-lived perennials. Yet if we take cuttings from the periphery of the plant we can, by repeating the process, prolong the life of the individual apparently indefinitely. Varieties of sugar-cane are propagated by means of the top joints only and Bourbon for instance has been in cultivation for two hundred years or more without loss of vigour. It would appear then as if removal of the younger from continuity with the older parts of the plant had a rejuvenating effect. In the pseudo-annual herbs such as the Enchanter's Nightshade, the same effect is produced by the rapid decay of the older parts at the end of each season. The cultivated potato behaves as a pseudo-annual and except for the greater incidence of virus disease the potato shows no loss of vigour. The prevalence of virus diseases might be regarded as a sign of diminishing vigour in the stock were it not that this is probably not an outcome of changed susceptibility but rather of the vastly augmented opportunities for infection. The giant trees in California are known to attain an age of over 2,000 and possibly 5,000 years, but it must be remembered that the tree develops new living tissue on the outside of the old each year, whilst the heart wood dies from within outwards. Thus no part of the tree actually remains alive for centuries though individual cells may perhaps persist for nearly one hundred years. The anything but robust mycelium of the fairy ring fungus could with equal justice be claimed to attain to a great age, for such rings are known from the downs which from their diameter must be at least 400 years old, but here, as with the tree, a new living zone is added on the outside as the mycelium within dies and decays. Despite this juvenile tissue added without, a common feature of nearly all trees, we find that each species has its normal span of life; this, though subject to variation with the conditions of growth, is a feature that has been shown to depend in part at least on genetic factors.

Let us now turn to the unicellular plants for which it has been claimed that they are potentially immortal. If, for instance, we study the life-cycle of such aquatic plants as the unicellular Chlamydomonads, we find that each individual is capable of growth and division and that the entire living substance of the parent is embodied in that of its vegetatively produced offspring. The same is true of the bacteria, of yeasts, and of many others. In one sense then we can speak of these as potentially immortal organisms. The essential difference here is that the entire substance appears to be potentially immortal whereas in the Dianthus potential immortality is characteristic only of a part, though an appreciable part, of the organism and it is relevant to note that the much more academic concept of potential immortality in the sex cells of sexually produced offspring embodies but a microscopic part of the living material of each successive parent and this, moreover, may undergo change in kind.

It would appear then that continuity of life, except in the unicellular organisms referred to, is dependent upon separation of the newly-formed parts from the old.

Some twenty years ago I called attention to the fact that the root systems of flowering plants could be strikingly checked in their growth by the presence of the root systems of other species. Subsequently, Varma working in my laboratory was able to show that this was due to water soluble substances and there is evidence that though such substances may be important as weapons in the competitive struggle, unless removed they are deleterious also to the producing organisms.

Such antibiotics are now familiar from the special example of penicillin. For our present purpose their significance is the evidence it affords of the production by the living organism, as a by-product

Miss J. O. Joshua: Clinically the anal tumours described by Mr. Cotchin are invariably benign: they occur in a variety of forms, from single circumscribed masses to diffuse involvement of the entire anal rim. This rather supports the suggestion that the condition is a hyperplasia and not neoplasia, as also does the fact that, prior to the introduction of stilbœstrol therapy, treatment of these tumours by simple expression of the contents followed by cauterization of the cavity was successful. An interesting point in connexion with stilbœstrol treatment is that in addition to regression of the tumours there is almost invariably improvement in the general health of the dog, in spite of the fact that the owner has not as a rule complained of general symptoms shown by the dog prior to the initiation of treatment.

The condition occurs in dogs over middle age, in most cases household pets which have had little or no sexual activity; one case had occurred in a popular stud dog which had been overworked during his breeding life; both might, however, be attributed to hormonal disturbance.

With regard to mammary neoplasms in bitches, these again usually occur in bitches which have not bred. in fact I can recall only one case of mammary neoplasia in a bitch which has been regularly bred. The phase of most rapid growth of these neoplasms nearly always coincides with the period of pseudo-lactation following œstrus. Frequently small nodules of tumour tissue have been present for a long period before active enlargement occurs. It is inadvisable to undertake surgical interference during the period of pseudo-pregnancy.

In the small percentage of cases in which there are malignant changes metastasis has often occurred not via the lymph nodes, but direct to the lungs, where multiple highly malignant tumours have developed resulting in rapid death of the patient.

Mrs. M. Mandeville and **Professor A. Haddow** read a paper on "Melanoma Occurring in the Viviparous Fish *Heterandria formosa*, and associated with Sex Reversal".

[*March* 19, 1947]

DISCUSSION ON THE SPAN OF LIFE

Sir Edward J. Salisbury: The problem of the span of life is of both economic importance and great scientific significance. But in this connexion the question immediately arises: Why do organisms die? For those who think of a plant merely as a mechanism concerned with the business of living the analogy with a machine that gradually becomes less efficient with age and is liable to succumb to a variety of causes that add to the strain upon the mechanism is familiar. If the immediate cause of the death of a tree be its uprooting in a storm or its destruction by diseases or pests, it is nevertheless a fact that the saplings commonly survive these trials whereas the old trees perish. If accidents be the immediate cause, impaired vitality is the more remote one.

If we employ the usual, and may I add rather equivocal, meaning which attaches to the phrase "span of life" it is true to say that the maximum longevity of certain plants far exceeds that of the longest lived animals. For example, the Mexican Swamp Cypress that attains perhaps two millenia, or the famous Sequoia Giganteas of California that perhaps attain to over four millenia, are of a different order of life span to that of a fish, such as the famous Pike of Kaiserslautern, which is alleged to have attained an age of 267 years, or of an elephant, or even a tortoise which may attain to over 200 years. But, in fact, we are in reality comparing different things because the tissues of the old animal occupy the same position in space as those of the young, a condition essential to a mobile organism that would be handicapped by an ever-increasing bulk, whereas in the plant there is no such in situ renewal but a juxtaposition of juvenile tissue. Though span of life in a higher animal means something different from that of a higher plant, it will I think be true to say that the distinction is a concomitant of the high degree of differentiation of advanced members of the two kingdoms, the sedentary and mobile habits impose a different type of longevity on each.

for far longer than similar seeds stored in packets in a cupboard, where the metabolic activity is almost certainly greater.

The fact that worker bees during the active season live only four or five weeks compared with up to ten weeks in the inactive season might be held to support the view that the mechanism of living deteriorates with use, but since the rate of production of by-products will increase *pari passu* with the augmented activity this is no more inconsistent with the view here adopted than the well-established diminution in life span with increased temperature that accelerates chemical processes.

Breeding experiments have shown that the span of life is in part at least a genetic phenomenon, but it may well be that this is but an expression of heritable differences in susceptibility to the hypothetical chemical causes of senescence.

Probably no botanical material has been more studied in relation to problems of senescence than detached apples and it is significant to note that one of the two most important factors for the prolongation of the life of apples is checking the rate of metabolism of the living tissues by lowering the temperature and increasing the CO_2 content of the surrounding atmosphere, as in gas storage, both of which may reasonably be assumed to reduce the rate of production of by-products of metabolism. Again, greater longevity can be induced by removal of these same metabolic by-products especially ethylene gas and it is noteworthy that treatment of unripe fruit with even minute traces of this same ethylene collected from ripe fruit will quickly induce symptoms of maturity and old age in the immature apples. It is moreover pertinent to recall that chemical treatment has been known to produce rejuvenation and the use of HCN on Planarians has successfully "put back the clock" again and again with respect to the same individual.

It is suggested that the facts so far known are all consistent with the conception postulated. If the concept be true then the investigation of such by-products, their isolation and the determination of their chemical characteristics, might lead to methods of their neutralization and destruction, to the prolongation of life and perhaps even to the prophet's dream of a millennium when "there shall be no more death" with consequences as fraught with potentialities and dangers as great as those of the atomic bomb.

Dr. John Hammond (*School of Agriculture, Cambridge*): In the higher animals the curve of life begins with a period of growth and development which is followed by one of completed development—the prime of life—and lastly by one of senescence in which the powers of the different functions gradually fail ending in the death of the individual.

Superimposed on this curve of life of the individual as a whole are curves of life of the different individual tissues and organs. An organ such as the mammary gland may have several curves of life during the life of the individual animal (fig. 1). The course of these is influenced by the stage of life of the animal as a whole. In young animals the milk yield does not rise to a high level (due to competition with other tissues for growth substances), but persists for a long time (due to the youth of the animal's tissues). In the prime of life the milk yield rises to a higher level but falls more quickly, while in the downward curve of life the fall off in yield after the maximum is rapid. The various organs and tissues of the body develop in a definite order and it would appear that in the senescence of the individual the first tissues, organs and functions to develop are the last to go.

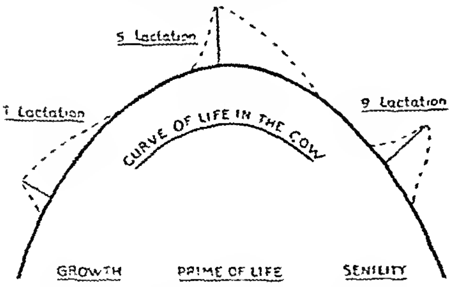

FIG. 1.—Curves of life in the mammary gland.

The duration of life in the various races of animals is very variable and whereas some species are remarkably long lived others die after a relatively brief existence. A sea anemone, belonging to the species *Actinia mesembryantha*, is known to have lived for sixty-six years. Among insects there is an extraordinary variability in the duration of life, some living in a condition of maturity for only a few hours while certain *Hemiptera* are believed to survive for as many as seventeen years. The duration of life is sometimes very different in the two sexes, the queen ant being known to live in some instances for fifteen years whereas the male ant survives for only a few weeks. Reptiles have always been noted for their longevity, a tortoise from the Galopagos Islands being stated to have lived for 175 years. Here long life is associated with a slow rate of living.

of its normal metabolism, of substances which are suppressive of biological activity. Is it on such similar substances that the loss of potential immortality depends? In other words is senescence in plants a condition of increasing auto-intoxication? The effects of increasing temperature in diminishing life span may well be the consequence of more rapid production of by-products relative to their rate of removal.

The fact that many unicellular organisms appear to be potentially immortal may well be due to their large surface in relation to their volume, the liquid media in which they live and in which they move freely.

The well-known experiments of Woodruff on *Paramœcium caudatum*, which he cultivated for 8,000 generations, showed that there was no apparent degeneration or signs of senescence provided that the organisms were continually transferred to fresh nutrient media. Investigations using other organisms have pointed to the same conclusion.

The death which ensues in algal cultures when the medium is unchanged, despite the addition of nutrients, suggests that the senescence is here due to the accumulation of metabolic products which in terrestrial and sedentary organisms must to a greater or less degree accumulate in the body of the organism itself. Is it not possible that the proximal diffusion of such substances away from the actively growing regions of the higher plant leads to an inhibiting accumulation in the older parts of the plant body and thus sows the seeds of ultimate dissolution. The likelihood of such accumulation will depend upon the possibilities for diffusion into the surrounding medium which will be greatest in an aquatic organism of small size whilst for terrestrial plants the contact which the organism makes with the soil may well be a factor. The large increase in such surface of contact of the root system of a higher plant with the soil which is the result of the root hairs may well have a very important significance in relation to water supply when the latter is deficient but abundant root hairs are quite common in species which normally occupy habitats where the absorbing surface is rarely if ever the limiting factor in water supply. It is not improbable that the extended surface of contact provided by the root hairs may have a value in accelerating the removal of toxic products of metabolism and we have, in fact, evidence that water-soluble antibiotics do diffuse outwards in this way. If this were true the trees which should have the greatest longevity would be those with the most extensive root systems penetrating to the levels not densely exploited by the root systems of other species. Whether this is true we have I think no data to test. All we can say is that Nobbe found the areas of the roots in relation to the tops of young trees to be 2 : 1 for Silver Fir, 3 : 1 for Spruce and 5 : 1 for Scots Pine. If similar ratios obtain in the adult trees then the extent of the roots in relation to the living bulk of the trees would seem to correspond roughly to the ages which these species normally attain.

Senescence has by some been held to be a necessary concomitant of differentiation. But though it may well be true that certain types of cell specialization are inconsistent with marked longevity the basis of the wider application of the concept is probably not unconnected with the mistaken view that the potentially immortal types of unicellular organism, because they are morphologically simple are therefore simple in their internal organization and physiology. Indeed, as we know in human mechanisms, the apparently simple is often the most highly differentiated. Moreover it is relevant to note that tissue cultures of meristematic cells are safeguarded against senescence and death only so long as we remove the products of their metabolic activities by renewal of the culture medium. If differentiation retards the rate of such removal it will manifestly become a contributory factor to limitation of the span of life.

Ingle found that the length of life of *Daphnia* could be appreciably increased by dilution of the nutrient medium. Was this because the growth rate was diminished or because removal of by-products was facilitated? On the other hand the span of life of snails has been found to decrease with the number of individuals per unit volume, a fact most readily accounted for by the higher concentration of waste products in the denser populations. The beneficial effects of larger body size are probably due to a similar cause. Again, the persistence of normally short-lived perennials from which the older portions are continually removed may be because in this way the younger portions are protected from the diffusion outwards of the by-products of metabolism that have accumulated in the older plant body.

Again we may recall that many seeds both small and large are known to retain their viability for many years and I have elsewhere furnished evidence that the small seeds of the Pimpernel, which is an annual plant, can retain their viability for more than a century. If we think in terms of the crude machine concept, this does not surprise us for the mechanism that is not working does not wear out; but, equally, it may be that in the absence of active growth there is no production of toxic by-products causing senescence. But that even dormant seeds undergo change is shown not only by their loss of viability with time, but also by the fact that has been demonstrated for a variety of species such as the Antirrhinum, Maize, Barley and Crepis, that there is increased mutation which the ageing of the seed induces. It is noteworthy that seeds under turf which are probably subjected to but slight changes of temperature and an atmosphere of relatively high CO_2 content remain viable

Dr. V. Korenchevsky (*Gerontological Research Unit, Oxford*) discussed the longest span of human life as judged from the records on centenarians in England and Wales. Only the latest data, presumably more reliable, were taken for a period 1930–1945, and subdivided by Dr. Korenchevsky into two sub-periods of eight years each, namely 1930–37 and 1938–45.

These data were obtained from the most reliable source available, the Registrar-General's Statistical Reviews for England and Wales; or, for the latest years, as a personal communication from the Registrar-General's Office at Somerset House, London.

The following conclusions could be drawn from the examination of these data:

(1) In the data recorded in the Registrar-General's Office the certificates of birth of centenarians have not been checked, and therefore their age can be accepted only with some reservation.

(2) According to these data, in England and Wales, per twenty millions of male or female population there were each year on the average 17·7 male centenarians and 71·4 women in the period 1930-1937, and 18·3 men and 83·4 women the latest period of 1938-1945. Their incidence was more or less regular, more women having a long span of life than men. There was a statistically significant increase of female centenarians during the last eight years as compared with a previous period of eight years, whilst a small increase in male centenarians in the last period was not significant.

(3) During these periods the longest human lives were recorded as 109-112 years, which accord approximately with the conclusions reached by previous critical investigators of the span of human life in the periods earlier than 1930. Thus, *theoretically and potentially*, a span of life of 109-112 appears to be possible for every human being. Since, however, the exceptional cases of longevity of human beings have occurred during the present time, when the process of ageing is abnormal, there is some possibility that the span of human life might be further extended, when the process of ageing becomes a normal one.

(4) There are some indications that the genetic factor is one of the causal factors of longevity.

(5) Taking into consideration the primary aim of gerontology to make old age stronger and healthier, not only longer, the prophecy of Professors E. Metchnikoff and I. Fisher may be right, that in this way the useful period of human life might be extended, and there will thus be a greater utilization of the accumulated experience and wisdom of older people for the community.

The detailed paper on the subject will be published elsewhere.

Dr. Muriel Robertson (*Lister Institute of Preventive Medicine*): In English law I believe you cannot be indicted for murder unless the corpse can be produced. I am in much the same case in the matter of the span of life in the Protozoa. If the span of life is concluded, there should remain a corpse, however small. But the Protozoa do not behave like that.

Take for example the flagellate *Heteromita*. It divides by fission with no corpse left. When A becomes A_1 and A_2, there is no end to the span of life. It may be said that these are low simple creatures. In another more developed organism called *Polytoma* there is a process of conjugation: two flagellates fuse and become one. They are haploid organisms and require no reduction divisions to be ready to conjugate. Only the conjugation cyst has the diploid number of chromosomes. At

In birds the length of life varies considerably in different species but the more usual duration of life is from 15 to 20 years. With mammals the length of life in general is longer in the larger species than in the smaller. In domestic mammals large numbers of individual cases of long life have been reported by letters to various papers: horses, in rare cases, have reached over 40 years, cattle somewhat over 30 and sheep over 20 years. Few domestic animals, however, die of old age: Hunter-Smith (1933) found, for example, that in a dairy herd only 5% of the cows survived up to an age of 13 to 16 years, while Wright (1933) and others have shown that old age accounts for only about 4·5% of the wastage of cows from dairy herds. Cannon and Hansen (1939) in U.S.A. found too that only 0·26% of dairy cows reach an age of 15 years or over. The average life of the dairy cow is only about 5 years, although the maximum milk yield is not reached until about the 7th year. Kelly (1939) from the records of a large Merino flock found that 60% survived up to 6 years, 30% to 10 years and 10% to 12 years old.

By retarding growth by nutritional control, that is, by prolonging the upward growth period of the curve of life, McCay *et al.* (1939) were able to increase the mean age of death in rats: members of groups retarded in growth for periods of 100–1,000 days were still alive when the last of the control groups had died at the age of 965 days. Thus physiological and anatomical age can be partially divorced from chronological age. In mammals in general the span of life is prolonged when the length of the growth period is increased, as in the larger animals, and in man who is distinguished from the other animals by the relatively long prepubertal period.

In man a few cases of very long life, such as that of Thomas Parr who lived for 152 years (Harvey, 1700), have been reported but the limit is normally about 112 years. Women, on the average, live to be somewhat older than men. Under modern civilization the chances of life have been increased, but this has been brought about largely by decrease in mortality in early life rather than by increasing the total span of life. For example, Pearl (1938) has shown that in U.S.A., whereas in 1890 56% of males born lived to 40 years of age, in the 1930s 81·6% reached that age; the duration of life after 40 years was, however, but slightly longer than it was in 1890. Similar statistics concerning the numbers per 1,000 births which survive to different ages are very much needed for our domestic animals in order that we can see clearly when, and through which causes, the losses are occurring. These, if taken after definite intervals of time, or under different circumstances of management, would show the effect of these on the life span. For example, Pearl and Raenkham (1932) have estimated that while in ancient Rome the average life expectancy at birth was 25 years, in Rome of the 1930s it was 55 years, while in U.S.A. at that time it was 64 years. The decline in the death-rate in early life, however, is unevenly distributed and the mortality is still high during the first two months, a fact which Waller (1939) attributes largely to defects in the mother's milk supply. This is also true in farm animals and Wallace (1948) has shown that in sheep both the vigour and weight of the lamb at birth and the mother's milk supply can be increased by good nutrition of the mother for eight weeks before parturition.

The steps taken in recent years to control infectious diseases which were formerly the major causes of death in man have now shifted the major causes to those from the insidiously developing degenerative diseases (Brody, 1945). This focuses attention on the order of development and senescence in the different tissues mentioned earlier. This control of infectious diseases and reduction of death-rate from these causes has influenced the age distribution of the population in U.S.A.; thus, while in 1850 some 83% of the population were under 40 years of age, by 1980 only 52% will be under this age. Such comparisons may also be made in space between Eastern and Western peoples. In domestic animals the control of infectious diseases would also do much to prolong the average life-span.

Let us now consider the conditions which affect the normal life-span rather than those affecting the chances of life at birth. Experimental studies on life duration and comparisons between species, as well as analyses of human statistics (much needed in domestic animals), suggest the generalization that the length of life is usually in inverse proportion to the rate of living (Pearl, 1938). In man investigations point to the fact that the main consideration which determines long life is a genetic one. Oliver Wendell Holmes' advice on this point was to select long-lived parents, and particularly long-lived mothers. The average physical characteristics of long-lived and short-lived groups of men show that the former are less of the short thickset type than the latter. These two types can be produced in pigs by control of the nutritional plane during the phase of growth (McMeekan, 1940), high nutrition in the early stages followed by rationing later giving a long, lean animal, while poor nutrition in the early stages (leading to a poorly developed skeleton) followed by high nutrition later giving a short animal with a large accumulation of fat. The accumulation of storage substances and products of metabolism in the body may lead to speedy senescence. Short-lived individuals display a relatively deficient early growth but rapid and unstable accretions of connective tissue elements in late life. Such accumulations are characteristic of old age and their presence throws a strain on the metabolism of the living cellular elements which support these accretions, and consequently tend to shorten life.

DISCUSSION ON TREATMENT OF NON-TUBERCULOUS EMPYEMA

Mr. R. C. Brock: *The treatment of acute empyema.*—This is such a big subject that it is not possible in a short introductory talk to do more than discuss briefly a few features. I have therefore chosen for consideration what I think are fundamentals.

(1) *What is an empyema?*—The very wide ignorance of what constitutes an empyema and the looseness of thought and definition that result are the chief cause of many of the differences of opinion expressed about treatment.

An empyema should be defined as a localized collection of pus in the pleura; it is a mature abscess, the end-result of an acute suppurative process. In the early stages there is an acute pleurisy that proceeds to sero-purulent effusion; this sero-purulent effusion matures, the pus thickens, thickened pleural exudate and limiting adhesions develop (unless the empyema is total) until finally an abscess is formed. In the earlier formative stages the sero-purulent fluid is thin and if left in a container will sediment out to give a layer of clear supernatant serous fluid above a deposit of pus. As the process matures the proportion of purulent deposit increases until finally there is little or no supernatant clear fluid. To describe the earlier formative stages of the acute suppurative pleurisy as an empyema is just as wrong as to describe the early stages of an acute septic cellulitis as an abscess before a localized collection of pus has formed. No one would question the fundamental importance of paying attention to the stages of development of an acute septic cellulitis in discussing treatment. It is no less fundamental to consider the stage of development of the suppurative pleurisy in discussing the treatment of "empyema." In discussing the treatment of a mature empyema, we must also discuss the treatment of the earlier acutely infected pleura. The term empyema should cease to be used as synonymous with the whole process of septic pleural infection and should be reserved for the mature condition or residual abscess which results.

This failure to understand the pathology of pleural infection is responsible for much of the confused thought and advice that has reappeared with the introduction of chemotherapy, and notably of penicillin. The effect, and indeed the success or the first division within the cyst, the reduction takes place and when, after a second division, the four new flagellates emerge, they are haploid organisms. But there is nothing left over and no death of the organism.

There is a large group of Protozoa—the ciliates, which are relatively speaking highly organized. They have all the essentials: a sensitive and elaborate system of co-ordinated movement—an excretory system and a simple but adequate digestive mechanism composed of acid-secreting vacuoles. The ciliates conjugate by the exchange of nuclei and then each proceeds upon its way after some rather complicated internal nuclear rearrangements. The complete individual is in each case preserved.

Some excellent workers in America, belonging to the school of Calkins, Woodruff and Jennings, in their determination to find the end of the span of life in these organisms, spent literally years of their lives observing the rate of division under conditions in which conjugation did not take place, in the hope that the strain as a whole might show old age and die. The ciliates however, so long as the food supply was adequate, wore out the observers and would not themselves show senescence.

It must be admitted that the ciliates have, in addition to conjugation, an individual nuclear reorganization, a sort of spring cleaning called endomixis but this does not do away with the fact that only starvation or violence puts an end to the ciliate itself.

Now, can it be claimed that although the corpse cannot be produced, the span of life is the number of hours intervening between two divisions? That is to say that, when A has produced A_1 and A_2—A is dead. I think that is fantastic as the *whole* actual substance of A is still growing and functioning alive in A_1 and A_2.

So the choice must be made, either the Paramœcia in my watch glass, for example, are never more than twenty-four hours old, or the individual I am now looking at has itself existed for millions of years since it first gradually developed out of the original slime.

It would seem, therefore, that as long as there is no differentiation which sets apart the reproductive from the non-reproductive cells, there is no end to the span of life except through starvation or violence. The surviving organisms are the original creatures.

It must be admitted that even the rather highly organized ciliates have what some people would consider a low standard of living. Therefore it would appear that if you want but little here below, you can get that little, long.

Dr. R. E. Rewell: In this discussion attention has been directed entirely to those individuals of any species which survive the longest, even those living to what may be called the "average span" have been neglected. We have been reminded of the high mortality among human infants and its well-known decrease with improving external conditions with a resulting rise in the average expectation of life at an early age. It has been held usually that very long-lived individuals are no less common in savage than in civilized communities, though he appears to have shown that this may not be the case.

A distinction has been drawn between those causes of death which may be ascribed to accident and those to more fundamental causes. However, in many cases this distinction is not clear. Thus in the case of a human infant dying of bronchopneumonia it may be that the infant is unduly susceptible, that particularly virulent micro-organisms are present in its environment or it may have been chilled. With young organisms, moreover, it is impossible to deduce longevity in the stock from the length of survival of the offspring.

It is noteworthy that in different species degenerative changes in different organs limit the length of life. Thus in man vascular catastrophes from degenerative changes in the arteries are a frequent cause of death in middle life, but in other mammals such changes are far more rare, though I have seen lesions resembling Mönckeberg's sclerosis in a Mitchell's Wombat aged over 20 years. (Sections of liver and kidney of an aged Pine Marten were demonstrated to show the absence of degenerative changes in the arterioles.)

(iii) An illness complicating measles or whooping-cough.

(iv) A streptococcal or staphylococcal infection.

(v) The duration of the pleuro-pulmonary process; it is rare for maturation to occur in less than two to three weeks.

(vi) The gravity of the illness; a patient who is profoundly ill or has recently been profoundly ill needs very careful assessment.

(vii) When the temperature chart is of the remittent or sustained type indicating an invasive infection rather than the swinging septic type of mature suppuration.

(viii) The character of the aspirated fluid. The proportions of sediment and supernatant fluid are often a good guide to the stage of the pleural illness.

Finally it must be stressed that drainage of an empyema is never an emergency unless there is a bronchial fistula big enough to produce a risk of flooding the lungs. It is, of course, always desirable to drain pus as soon as its presence is recognized, but it is not a true emergency. If there is any doubt as to maturation of the process it is always safer to delay for a few days and to relieve symptoms by aspiration or by intercostal drainage. Thorough and repeated aspiration is an essential part of the management of the formative phase for even if it does not achieve cure of the pleural suppuration it should at any rate result in a smaller residual empyema that will heal correspondingly more quickly.

(*B*) *The provision of adequate drainage:* Once more it must be stressed that much of the difference of opinion about the success of simple aspiration or of intercostal drainage as opposed to rib-resection arises from failure to appreciate the importance of the stage of the illness in which each method is used. Many of the cures of "empyema" by aspiration are really cures of early pleural infection. It is much less likely that a mature or nearly mature empyema can be cured by aspiration alone, simply because of the adverse mechanical factors present in the thick exudate, rigid or partly rigid walls and massive fibrin clots. Conversely, drainage by rib-resection in the early stages is not only unwise but dangerous. It is the failure of recognition of this that still leads to statements that rib-resection is very dangerous in infants and should not be done. The margin for error in them is small and a too early rib-resection will often kill. On the other hand my experience is that a mature empyema in an infant demands drainage by rib-resection just as much as in an adult.

Aspiration and intercostal drainage, so valuable as temporary measures, can never function satisfactorily when fibrin masses are present, and to persist in their use not only prolongs the patient's illness unnecessarily but also exposes him to the grave risk of a chronic empyema. We are always seeing new suggestions or reading descriptions of complicated apparatus, the object of which is to suck pus out through a small hole rather than let it come out freely through a larger hole. The advocates of these hole-in-the-corner methods should remember that rib-resection is needed for proper pleural toilet as well as for the insertion of an adequate drainage tube. The exposure that rib-resection alone can give is essential for certain and rapid healing in almost all cases of mature empyema.

Not only must the drainage hole be big enough but it must be in the right place if drainage is to be sufficient and the siting of the hole must always be carefully considered. It is a sound plan to introduce lipiodol and air at the time of aspiration of pus and then to take radiographs in postero-anterior and lateral planes in order to delineate the upper and lower extent and the shape of the cavity. In a typical posterior basal empyema drainage should be (*a*) in the paravertebral gutter just lateral to the angle of the rib, (*b*) not lower than the 9th rib as otherwise the drainage track may be shut off as the diaphragm rises during healing.

failure, of penicillin will be greatly influenced by the stage of evolution of the pleural suppuration. Its exhibition in the early "cellulitic" phase is more likely to be followed by successful control of the process than in the later stages when there is an abscess with thick pus, walls covered with tough exudate and often fibrin clots or purulent masses lying in the cavity. This should be self-evident and yet from many published accounts it is clear that the authors have not realized it.

The great benefits of penicillin therapy are so obvious that they need no emphasis, though it must not be forgotten that penicillin does one thing and one thing only—it kills certain bacteria provided always it can get to them. It can control or sterilize a bacterial battlefield in the body. On the other hand it is not a scavenger, it cannot clear up the battlefield. The body resources must serve this function, but there are times when the correction of the secondary mechanical effects of infection is too much for the bodily resources. That is why surgeons are still needed; that is why penicillin, although a great friend and a strong weapon, will never replace the surgeon. When mechanical derangements remain his help is needed. To delay or to withhold surgical help to clear up the battlefield is to harm the patient; at the least increasing the morbidity of his illness and often causing his death.

(2) *The fundamentals of treatment of pleural infection.*—(*A*) Assessment of the correct time for drainage; (*B*) provision of adequate drainage; (*C*) institution of proper physical treatment; (*D*) decision as to the correct time to stop drainage.

(*A*) *The correct time for drainage:* A great deal follows logically from what has already been said about pathology. In the early formative stages of pleural suppuration drainage is both unnecessary and dangerous: unnecessary because with proper management by aspiration and chemotherapy (i.e. penicillin) it may be possible to achieve resolution without abscess formation. It is in this phase that the methods of penicillin therapy described by Fatti and Florey (1946) are most likely to be successful. It may be dangerous because, as was so ably pointed out by Graham as a result of study of the high mortality of pleural suppuration in the influenza epidemic of 1917 and 1918, the patient is often suffering not only from pleural infection but from one or several other serious infective processes as well. He may be almost overwhelmed by a severe invasive infection with pneumonia, septicæmia, pericarditis, &c. If this pleural effusion, by virtue of its gross mechanical presence, is allowed to dominate the clinical and therapeutic picture and it is drained too early, then the patient may be unable to withstand the extra mechanical strain thrown upon him and he may die. It is true that the dangers of draining a diffuse suppurative pleurisy in which no limiting adhesions have formed may be minimized or even avoided by some form of closed intercostal drainage. The method still remains a dangerous one, for in these very patients in whom the danger is greatest and the margin of safety is very small, the powers of tissue reaction are so low and enfeebled that the tissues seem to melt away around the tube and in a short time an open sucking wound is caused. Even if the patient survives premature drainage he is often left with a total empyema which, if not treated skilfully, will lead to long or even permanent invalidism and great physical deformity.

Space does not allow full discussion of the criteria of assessment of the correct time for drainage, but it must suffice to say that it is essential to consider carefully the stage of evolution of the pleural process. Features which must be especially considered are:

(i) The age of the patient; children under 5 and more particularly infants and toddlers with a pleural infection are often suffering from a severe invasive infection and great caution must be exercised.

(ii) The occurrence in an epidemic of influenzal type.

of the lung, and if the expansion of the lung is maintained by continuous pleural suction, these patients get well and can be completely healed in two to three weeks and are left with a virtually normal chest. The operation is a severe one but is well tolerated if performed with simultaneous blood transfusion.

It is necessary to consider whether this method could, with advantage, be applied to acute empyema in civil life. I think we have much to learn about this but at present I would say that if a case of pleural suppuration is conducted correctly in the formative stage and a relatively small residual empyema results, it is best treated on the orthodox lines described above. Open thoracotomy and decortication would seem to be unnecessarily severe and to introduce too big a risk, especially as many empyema patients have only just recovered from a severe and often debilitating illness. On the other hand cases occur in which a large, possibly multilocular, and perhaps neglected empyema is present. Simple drainage by rib-resection may mean many weeks or even months of drainage and great care must be expended in the manipulations of the tube, &c. I am sure that open thoracotomy and decortication in these patients offers much. It can give healing almost by primary intention, or at the worst will leave a small simple pocket to be drained.

I have been unable to do more than refer briefly to the big question of chronic empyema. It has been truly said that the best treatment of chronic empyema is not to let it occur. We should remember that if an uncomplicated acute empyema is treated carefully upon the simple and fundamental lines laid down above healing should be steady and progressive to complete cure. This complete cure can only be attained when the lung has been completely expanded to fill the whole of the cavity, and the visceral and parietal pleuræ are firmly fused together. At any moment in the course of healing it is possible for some quite simple fault to slow up or stop this natural and steady process. The fault may occur only too easily; it may be, for instance, that the drainage tube is incorrectly placed or incorrectly or unwisely adjusted or not adjusted at all. As a result the patient is placed in danger of developing or actually develops a chronic empyema. Simple and constant care and attention will prevent this, and if we appreciate that this is so we shall spare ourselves a great deal of anxiety and our patients much unnecessary suffering.

FATTI, L., FLOREY, M. E., *et al.* (1946) *Lancet* (i), 257 and 295.

Mr. T. Holmes Sellors: The term "empyema" should only be used with the clear distinction of the actual pathology of the pleural condition.

It is realized that chemotherapy, in particular penicillin, can achieve good results in diffuse and early infection, but that its use in a local pleural abscess is open to definite limitations. Penicillin can certainly sterilize many of these abscesses, but it cannot obliterate the actual cavity, and persistence with it beyond a certain stage increases the liability to formation of a chronic thick-walled dead space.

To continue the story of treatment of the localized empyema after drainage, it is necessary to consider a method of closure of this cavity. In ordinary circumstances abscesses with soft walls, once they have been drained, close in steadily, but in the case of an empyema the outer wall is rigid, and in any case should not be allowed to collapse inwards. The underlying lung must be encouraged to expand outwards and make contact with the chest wall—but in such a way that the closure is complete and occurs without pocketing. When the fibrin-coated parietal and visceral pleural layers are in apposition, the empyema space may be regarded as healed, not before.

The deposit of fibrin on the cavity walls plays also a great role in the healing process. If there is any delay in correct handling, this fibrin organizes into firm

(C) *Physical treatment:* An empyema is but an abscess in a special site and like an abscess anywhere else in the body depends for its healing, once adequate drainage has been provided, on approximation of its walls. One object of *adequate* drainage is, of course, to allow this approximation to proceed unchecked. Delay in instituting adequate drainage by persisting in aspiration too long, results in greater thickening of the walls and the process of approximation is either greatly prolonged or completely prevented. In an abscess elsewhere the walls usually fall together concentrically but this must be avoided at all costs in empyema. The obliteration of the empyema should be achieved by *expansion* of the lung and not by falling in of the chest wall and displacement of the mediastinum and diaphragm. Indeed the rapidity of expansion of the lung is directly influenced by preventing the chest wall and diaphragm from becoming rigid and contracted and by promoting their movement and thus their expansile action. To this end, therefore, early and meticulous physical treatment is fundamental.

Physical treatment consists of four parts:

(*a*) General exercises to improve general muscular and bodily tone.

(*b*) Arm and shoulder movements to prevent stiffness.

(*c*) Postural supervision to prevent scoliosis.

(*d*) Breathing exercises to prevent fixation of the ribs and diaphragm and to ensure early and rapid expansion of the lung. A patient, far from suffering diminution of respiratory function after an empyema, should actually improve it if proper physical exercises are given.

The modern breathing exercises are simple, and are directed towards maximum concentration on the affected zone without great and unnecessary expenditure of energy as in the older exercises. Properly taught and graded they are no strain even to a very ill patient immediately after operation. All the attendants must see that the patient practises them regularly throughout the day and not just when the masseuse comes. Five minutes every hour should be the slogan.

It follows, also, that the treatment of an empyema should be ambulatory. Many patients are kept in bed as long as the drainage tube is retained. This is quite wrong; unless there is some contra-indication on medical grounds the patient should be got up within a few days of operation.

(D) *When to stop drainage:* Fortunately it is now far less common to see the drainage tube removed in an empiric or arbitrary time, such as two weeks. There is only one safe time to remove the drainage tube and that is *when a cavity can no longer be demonstrated to exist in the pleura.* If the tube is removed before this, then there is great risk of a chronic empyema following. Too early removal of the tube is indeed the commonest cause of chronicity of an empyema. There are many important practical details in connexion with the management of the tube. The interest of the surgeon inexperienced in empyema will be greatest immediately after operation and become less and less as the days or weeks pass by; very often after a few weeks his interest is nil and he leaves the management of the important phase of removal of the drainage tube to someone else. The surgeon experienced in empyema knows that his personal interest in the case must *increase* as the days pass by.

Decortication in the treatment of acute empyema.—Perhaps the most important thing we have learnt in chest surgery from the war is the great success that can follow early evacuation of clot and decortication of the lung in an infected hæmothorax. A patient gravely ill with a chest full of breaking-down infected clot, often with a heavy mixed and foul anaerobic infection, if treated by aspiration or by drainage alone either dies or drifts into chronicity. If treated by open thoracotomy and decortication

The old teaching of removing a tube each day for boiling, and then replacing it was one of the most productive causes of chronic empyema. Sooner or later the original tube could not be replaced, and a smaller one was inserted, and so on, until a pin-point sinus was left to drain large spaces.

If the sinus becomes unduly small a laminaria or sea-tangle tent can be used, and the swelling of this may in twenty-four hours enlarge a narrow opening to an appreciable extent.

It has already been mentioned that, if the tube is kept too short, the thickening parietal pleura may grow over the internal opening. Similarly, too long a tube may impinge on the lung and lead to ulceration. The maintaining of a tube of adequate bore is, of course, essential, and the standard method of using a safety-pin and narrow length of strapping for holding the tube in position on the chest wall should be adopted as a routine. A simple corset dressing over one or two thicknesses of gauze is all that should be needed to cover the tube. Elaborate dressings or many-tailed bandages should never be employed.

The decision as to the time of tube removal is actually simple. No empyema cavity must remain, and the only opening should be a narrow track through the chest wall. It is possible when closure is obviously nearly complete to replace the wide tube by one of smaller bore just before the final removal.

The *bacteriology* of the discharges should be examined at intervals. It is realized that extensive drainage leads to secondary infection in spite of all precautions that may be taken with dressings, and the most common organisms encountered in this respect are *Ps. pyocyaneus* and *B. proteus*. On culture these act as "spreaders" and may mask a more harmful pathogenic organism. If selective cultures can be obtained, an organism responsive to chemotherapy may be encountered. We have not found that antiseptic or antibiotic substances in paste or cream form have had any direct local benefit, though their systemic use has been valuable.

Irrigation was at one time in considerable favour, but when a careful pleural toilet has been made its value is limited, and it is moreover dangerous in the presence of a bronchopleural fistula, when the irrigating fluid might easily enter the lung.

The presence of a bronchopleural fistula is easily recognized on a pleurogram, and is a common occurrence during the course of empyema treatment. It is, however, of little importance unless of considerable size, or dependent for its origin on some additional pathological factor such as new growth or tuberculosis. These fistulæ may delay healing to a small extent, but ultimately heal spontaneously under the ordinary process of drainage and gradual closure of the empyema cavity.

Chronic empyema is too large a subject to be discussed in any detail, though its most common cause, namely poor handling of the acute phase, has been mentioned.

The treatment is basically the same: active inspiratory exercises for lung re-expansion plus adequate and controlled drainage.

I have not done a thoracoplasty or extensive operation on any chronic empyema for the past eight years, though some patients have taken a year or eighteen months to heal. A limited small operation in the form of local muscle graft may hasten the final closure, but in the non-tuberculous cases I have not found major surgery necessary, so long as enough time is given to adequate conservative treatment.

During the period of healing the general condition of the patient should not be ignored. A secondary anæmia is a very common finding and may require blood transfusion. The estimate of blood proteins may also show a low figure, which should be countered by a high protein intake, possibly with some of the more palatable cicatrizing tissue, which is laid down in greater thickness on the chest wall side than on the lung, but in both cases it is a powerful deterrent to obliteration of the cavity, and is an important factor in the formation of the chronic empyema dead space.

Parietal fibrosis results in pulling down of the ribs and their approximation with resultant scoliosis. The actual shape also alters, becoming triangular instead of flat, and it can be understood that full functional restoration is only possible if there have been no structural or skeletal changes.

The prevention of the chronic empyema lies therefore in two main factors: (1) The maintenance of adequate drainage until the cavity is obliterated, and (2) breathing exercises and physical treatment to encourage the lung to re-expand and restore respiratory function.

Breathing exercises are absolutely essential. They are based on active, powerful and concentrated inspiratory efforts. The movement of the chest wall itself is a very good index to lung function, and if the chest wall can be made to move freely it can be assumed that underlying lung expansion is good. These inspiratory exercises require a voluntary control of an area of the chest wall. This is operated by working against pressure of the physiotherapist's hand, and later the pressure is given by the patient himself. The exercises can be started from the very onset of the condition and carried out with increasing vigour day by day. They must be done regularly for five or ten minutes every hour, and with the utmost concentration.

At the same time there is no need to maintain patients in bed once their general condition permits movement. More general physical exercises become possible, and can be worked up in classes. The use of webbing belts to help the breathing exercises has been found valuable, and, as an adjunct, regular measurement of the vital capacity and a general competitive spirit are a considerable stimulus. The patient by the time of closure of the cavity should not only have as good a respiratory function as the normal individual—it should be better.

The other factor is the handling of the tube and *closure of the cavity*. Obliteration may take place uniformly and speedily, but uneven expansion may lead to "bottle necks" and a number of unusual shapes. The correctly placed tube lies so that discavity drainage is always possible, and after the first day or two the amount of discharge from that tube should be minimal. Free drainage suggests that a dependent or unrecognized pocket will have to be dealt with. It is not possible to visualize actually what is happening through the chest wall, so we have to depend upon other methods to gauge the healing process of the empyema. A gloved finger or soft bougie is sometimes useful, but we have come to depend on radiography and the use of contrast media—in other words, the pleurogram. Two-plane radiographs are taken after the cavity has been filled with a radio-opaque oil (incidentally barium emulsion is permissible if there is no bronchial fistula). Pleurograms should be made when the outline of the cavity cannot be visualized on the ordinary radiograph, and should then be repeated at regular intervals, say ten or fourteen days, until complete closure is obtained, and after each pleurogram has been made the tube adjustment can be safely considered. A "bottle neck" easily forms if the tube is not through the full thickness of the chest wall, or if the basal expansion occurs more readily than that of the apex. In such a case the tube would have to be lengthened, so that its open end lies within a short distance of that of the apex of the pocket. In other cases a dependent arm or limb may require secondary drainage to ensure its healing, and a rapid axillary expansion may leave a "horse-shoe" or "circular" form of track whose closure has to be carefully watched.

The actual *handling of the tube* must be regarded as an important technical exercise. Any alteration in the position, length or size of the tube must be most carefully studied.

The old teaching of removing a tube each day for boiling, and then replacing it was one of the most productive causes of chronic empyema. Sooner or later the original tube could not be replaced, and a smaller one was inserted, and so on, until a pin-point sinus was left to drain large spaces.

If the sinus becomes unduly small a laminaria or sea-tangle tent can be used, and the swelling of this may in twenty-four hours enlarge a narrow opening to an appreciable extent.

It has already been mentioned that, if the tube is kept too short, the thickening parietal pleura may grow over the internal opening. Similarly, too long a tube may impinge on the lung and lead to ulceration. The maintaining of a tube of adequate bore is, of course, essential, and the standard method of using a safety-pin and narrow length of strapping for holding the tube in position on the chest wall should be adopted as a routine. A simple corset dressing over one or two thicknesses of gauze is all that should be needed to cover the tube. Elaborate dressings or many-tailed bandages should never be employed.

The decision as to the time of tube removal is actually simple. No empyema cavity must remain, and the only opening should be a narrow track through the chest wall. It is possible when closure is obviously nearly complete to replace the wide tube by one of smaller bore just before the final removal.

The *bacteriology* of the discharges should be examined at intervals. It is realized that extensive drainage leads to secondary infection in spite of all precautions that may be taken with dressings, and the most common organisms encountered in this respect are *Ps. pyocyaneus* and *B. proteus*. On culture these act as "spreaders" and may mask a more harmful pathogenic organism. If selective cultures can be obtained, an organism responsive to chemotherapy may be encountered. We have not found that antiseptic or antibiotic substances in paste or cream form have had any direct local benefit, though their systemic use has been valuable.

Irrigation was at one time in considerable favour, but when a careful pleural toilet has been made its value is limited, and it is moreover dangerous in the presence of a bronchopleural fistula, when the irrigating fluid might easily enter the lung.

The presence of a bronchopleural fistula is easily recognized on a pleurogram, and is a common occurrence during the course of empyema treatment. It is, however, of little importance unless of considerable size, or dependent for its origin on some additional pathological factor such as new growth or tuberculosis. These fistulæ may delay healing to a small extent, but ultimately heal spontaneously under the ordinary process of drainage and gradual closure of the empyema cavity.

Chronic empyema is too large a subject to be discussed in any detail, though its most common cause, namely poor handling of the acute phase, has been mentioned.

The treatment is basically the same: active inspiratory exercises for lung re-expansion plus adequate and controlled drainage.

I have not done a thoracoplasty or extensive operation on any chronic empyema for the past eight years, though some patients have taken a year or eighteen months to heal. A limited small operation in the form of local muscle graft may hasten the final closure, but in the non-tuberculous cases I have not found major surgery necessary, so long as enough time is given to adequate conservative treatment.

During the period of healing the general condition of the patient should not be ignored. A secondary anæmia is a very common finding and may require blood transfusion. The estimate of blood proteins may also show a low figure, which should be countered by a high protein intake, possibly with some of the more palatable casein hydrolysates, and at regular intervals a complete assessment of the patient's general condition as well as the local lesion should be made.

A tragic complication is the occurrence in a small proportion of cases of cerebral abscess. This does not occur in the acute stages, but in the more chronic ones. If there is any secondary hæmorrhage, the patient should be put at complete rest, and if there are any complaints of headache or dizziness these should be investigated immediately.

In conclusion, it should be realized that chronic empyema is a severe and distressing disability which in the majority of cases is occasioned by mishandling of the acute phase.

[*March 5, 1947*]

The Packing of Abdominal Incisions in Peritonitis

By IVOR LEWIS, M.S.

ONE night five years ago I was operating on a bad perforated appendix and was just closing the peritoneum when the patient collapsed. Fearing a death on the table I packed the wound with gauze, stuck some strapping over it and got the patient back to bed. To my surprise he recovered and was discharged four weeks later with his wound neatly healed. This incident prompted me to try the method again in cases of foul peritonitis. I had, from time to time, seen claims made for packing the abdominal wall in peritonitis—but had dismissed them as cranky and dangerous. In 1929 Garlock advocated leaving the wound wide open, occasionally putting a few sutures in the peritoneum, and in 264 cases reported only 6% incisional hernias compared with 15% by Bartlett, who sutured such wounds in the same hospital. Gamble and later Coller have also commended the practice. Gradually I came to use the method quite often as the cases healed well and smoothly.

Description of procedure.—Where there is offensive or thick pus the abdomen is drained and the abdominal incision packed. My incision of choice for appendicitis is McBurney's. For drainage a suprapubic stab wound is made and a ribbed rubber drain used. The peritoneum, together with available extraperitoneal tissue and transversalis fibres, is firmly sutured with a continuous catgut, in such a way that the suture line is watertight. Vaseline gauze is then laid in the wound lightly and three strips of strapping placed firmly across it. A separate dressing is placed over the drain, and the operation is over. Silk or cotton is to be avoided, but I have used *fine* nylon in many of the cases—with trouble from a sinus only once. Lately I have also used silkworm gut—the ends threaded over buttons on each side of the wound. The suture can then be removed at the end of a fortnight. The wound is not touched for five days. It is then re-dressed on alternate days. At the end of a week it is a deep gutter lined by clean granulation tissue, exuding a little pus. At the end of a fortnight it is a narrow chink, and in three weeks it is a linear wound flush with the skin and largely healed over.

After-treatment.—Normal "clean stitch" appendicitis cases I like to get up on the first day. These septic cases, however, have been kept in bed for three weeks, mainly because they are ill, not because of the abdominal wound. (Mere getting up does not, of course, put any particular strain on the abdominal incision.) Recently I have allowed some patients up at the end of a fortnight. The wound is throughout kept firmly strapped and the abdomen firmly bandaged. The drain is left in for three days, or longer if the pus is thick.

The patient is usually fit for discharge with a simple dry dressing during the fourth week.

Indications.—In the nature of things most of the cases will be appendix peritonitis, where the pus is foul or thick. Particularly dangerous is suturing the muscles where the appendix is a bluish-black slough suggesting heavy anaerobic infection. Incidentally a number of cases of fatal gas-gangrene of the abdominal wall have been reported in such patients. Offensive peritonitis from any other origin may with advantage be treated thus, provided the incision is suitable. I have treated gangrenous strangulated hernias with contamination, perforated stercoral ulcer, and a late perforated duodenal ulcer.

The incision.—The disruptive strain on a vertical incision is several times as great as that on a transverse. Moreover the sutures, as they take the fibres of the aponeurosis lengthwise rather than across, cut out more easily. I have, therefore, used the method only a few times in vertical incisions, although the results have been satisfactory, except for one disruption. I consider that packing a vertical wound is not a reasonable proposition where much post-operative distension is likely. The gridiron incision is ideal for natural strength. Any transverse incision is, however, suitable and oblique incisions for hernia can also be treated thus with safety, though the hernia may be expected to recur later, as it will anyhow with sepsis.

Results.—We have used the method at the North Middlesex Hospital in 64 cases in the last five years. Of the appendix cases, three died post-operatively: two of peritonitis on the second day and one of peritonitis, obstruction, and burst belly on the tenth day. This last patient should not have been selected as she had a vertical mid-line incision and was distended from peritonitic obstruction.

We have used it five times in gangrenous strangulated hernia with contamination. One died and a hernia recurred in two patients. Three hernias have occurred in the appendix cases, 20 of which have been done less than a year. The rarity of scar hernias has, so far, been the most surprising fact. The cases have run a very smooth course, the pain, distension and temperature steadily subside within a few days; so striking has this been that it makes one wonder how far the critical post-operative worsening so often seen in peritonitis cases is due to abdominal wall cellulitis and inadequate drainage. The packed wound is painless and free from œdema. There is no undermining or pocketing. The scars are strong and linear—far superior in strength and appearance to those *sutured* under septic conditions.

Comments.—(*a*) The method differs from that used by Garlock in making a special point of firm suture of the peritoneum plus any convenient fibres of transversalis fascia. A watertight continuous suture prevents further pus oozing into the wound from the peritoneum.

(*b*) To suture an infected abdominal incision seems to be bad procedure because: It dams up the pus causing it to spread along the intermuscular and extraperitoneal planes. It strangles the swollen tissues, causing sloughing of fascial strands. Often an intramural abscess forms which may burst externally or even inwards into the peritoneum laying the foundation for a hernia. The appearance of the wound is only too well known—œdematous, angry, painful, with pus oozing from every pore. Surgeons are no longer in any doubt of the desirability of leaving open heavily contaminated wounds in other parts of the body. In the abdominal wall they have felt that the strain on the healing wound overrides all other principles of good surgery. In my experience such wounds can, with advantage, be left open provided they are properly directed.

(*c*) On what does the strength of an abdominal scar depend? The answer is "on the integrity of the serotransversalis". Studies of disruption of abdominal wounds and of the evolution of scar hernia show this conclusively. Scar hernias are not due to stretching of a scar; they are due to a concealed disruption of the wound in the early post-operative period. The surgeons who have the post-operative hernias are those who have the burst abdomens.

(*d*) It is widely believed that healing by second intention is necessarily inferior, weaker or untidier, than healing *per primam.* But the choice in a case of peritonitis is really between healing by granulation under good conditions (open treatment) and under bad conditions (closure and with devitalized tissues).

The Concentration of Penicillin in Bile

By E. G. TUCKWELL, F.R.C.S.

PENICILLIN is antibiotic to typhoid bacilli in high concentration varying with the strain of the organism. As attempts to cure typhoid carriers by administration of the drug have not been successful in spite of adequate concentration being demonstrated in the duodenal bile, my medical colleagues asked me to get samples of common duct bile after administration of a single large dose of penicillin.

That penicillin is concentrated in the bile duct much above serum levels was demonstrated by Florey (Abraham *et al.*, 1941) and his co-workers, using cats and rabbits after subcutaneous or intraduodenal administration.

Rammenkamp and Helm (1943) collected human bile by means of a duodenal tube to show that after intravenous injection of 20,000 units of penicillin the bile contained concentrations higher than serum. To one patient who had a cannula in the common bile duct they gave 20,000 units of penicillin intravenously and found 1·25 units/c.c. in the bile fifteen minutes later, the level falling to zero in 150 minutes.

Struble and Bellows (1944) found a concentration of 6·65 units/c.c. in the bile collected by a duodenal tube after "a single massive intravenous dose of penicillin". The bile retained its concentration for three hours. In order to get bile concentrations up to the antityphoid level we decided to give a single intramuscular injection of 250,000 units in 1 c.c. of water. Four patients, who had undergone cholecystectomy and choledocholithotomy with insertion of a T-tube into the common duct, were given this dose and the bile collected continuously as it drained down the tube. At the end of each period of one hour the test-tube containing bile was replaced by a new one. The experiment was continued for six to eight hours. Assay of the penicillin in bile was carried out by Dr. R. Shooter, to whom I am very grateful for helpful advice, using the cylinder plate method and comparison with known strengths of Oxford staphylococci.

The results of three such excretion experiments are shown on the graph (fig. 1). It will be noticed that they vary in height, but that the rapid rise is to a peak period with a rapid fall again. The concentration in all three cases is above serum levels, but not maintained—their peak period is between the second and third hour in two cases, and this seems to be the general impression formed by other observers. In one patient the peak occurred after seven hours; he had had severe and repeated attacks of jaundice for many months and the excretion was observed five days after removal of common duct stones.

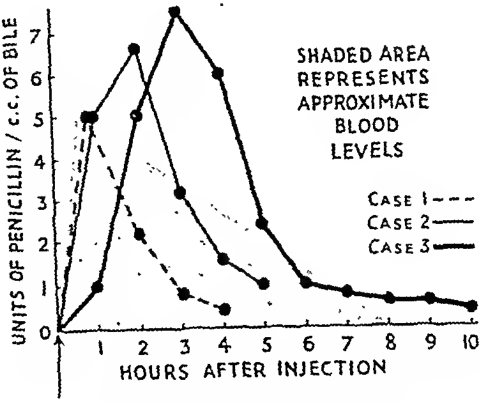

FIG. 1.—250,000 units of penicillin injected intramuscularly. Specimens of bile collected continuously over each period of one hour.

On the chart, Case 1 (- - -) had fever and jaundice for ten weeks with operation two days before; Case 2 (—) had ten weeks' fever and jaundice and operation six days before; Case 3 (—) had only been jaundiced very recently and the estimation made five days after operation.

Concentration of penicillin is greatly reduced by any liver damage and Zaslow and others (1947) have shown that if the concentration in the common bile duct is low, or if no penicillin can be demonstrated, then liver function tests show liver damage not suspected by clinical examination.

Zaslow gave 15,000 units of penicillin intravenously to patients immediately before operation or cholecystectomy. The gall-bladders were removed entire and the contained bile assayed for penicillin. His results show that the penicillin concentration in the gall-bladder was equal to, or lower than, that in the common duct, but that if the cystic duct was obstructed by stone or inflammation then the penicillin did not appear in the gall-bladder at all and was unlikely to be effective in the treatment of empyema. These gall-bladders were all pathological and my very small experience has led me to believe that a normal healthy gall-bladder will concentrate the penicillin to a greater level than that in the common duct.

I selected two patients, with apparently normal liver function, who were to undergo partial gastrectomy for peptic ulceration. 250,000 units of penicillin in 1 c.c. water were given intramuscularly two and a half hours before the estimated time of operation. Immediately the abdomen was opened samples of bile were aspirated from the gall-bladder and in one case from the common duct also; in the other case the local adhesions from a duodenal ulcer made the common duct difficult of access and I abandoned the attempt. In the first patient gall-bladder bile showed a concentration of 25 units penicillin/c.c. bile at the same time that common duct bile showed 10 units penicillin/c.c. bile—two and a half hours after the intramuscular injection. In the second patient gall-bladder bile showed a concentration of 8 units penicillin/c.c. bile two and three-quarter hours after injection.

These figures suggest that a healthy gall-bladder can concentrate penicillin to a strength which may be lethal to the typhoid bacillus, but that any liver impairment, or damage to the gall-bladder, will make these concentrations unlikely. In any event the administration must be repeated frequently to maintain a high concentration in the bile (a continuous drip of 1,000,000/three hours).

Streptomycin apparently behaves just like penicillin; we have only given it to one patient with common duct drainage but she had a good concentration at three hours and some still present at six hours. Zaslow got the same results from streptomycin as he got from penicillin, namely, that none appeared in the gall-bladder if the cystic duct was obstructed, and that levels in pathological gall-bladders were equal to, or slightly lower than, those in the common duct.

De Bakey and Pulaski (1946) have attempted to treat two typhoid carriers with streptomycin without success.

In conclusion I may say that high concentrations of penicillin in the common bile duct, above 6 units/c.c., depend on large dosage and good liver function, this high concentration is very transient and probably appears between the second and third hours. High concentration of penicillin in the gall-bladder depends both on liver function and the patency of the cystic duct; if these factors are satisfactory very high concentration may be obtained, but how long it is maintained I do not know.

DISCUSSION: THE LABORATORY DIAGNOSIS OF VIRUS INFECTIONS

Professor A. W. Downie, Liverpool: *Laboratory diagnosis of smallpox.*—Although smallpox in its typical form may be relatively easy to diagnose clinically, recent experience in this country has served to emphasize the difficulties which face the clinician when the disease occurs in vaccinated persons. In such instances the infection may run a mild and atypical course and it is in these cases that the laboratory can offer valuable aid. The methods available to the laboratory worker and the precautions to be taken in the collection of specimens have already been set out (Downie, 1946), and it is proposed here to discuss the merits and disadvantages of the various methods in the light of extended experience.

Examination of stained smears from skin lesions.—The value of this method in the early stage of smallpox infection has been stressed by van Rooyen and Illingworth (1944). The usefulness of the test depends on the careful preparation of smears and the instructions of van Rooyen and Illingworth should be followed. When pustulation has occurred the results are not so reliable, as elementary bodies in these smears appear to be much less numerous and their presence tends to be obscured by other particulate debris in the exudate. Smears should be allowed to dry and sent to the laboratory without fixation or other treatment, and as such smears from smallpox cases contain living virus (Downie and Dumbell, 1947*a*), care should be taken in packing and despatching the slides. At least two slides should be sent from each suspected case so that the material on one may be used for the inoculation of the chorio-allantois of developing chick embryos as described below. If the preparations have been properly made and stained by Paschen's or Gutstein's method, the finding of numerous typical elementary bodies may be valuable evidence in support of a diagnosis of variola. Some experience is necessary for the correct evaluation of the microscopic findings and it should be emphasized that one cannot, by microscopical examination alone, identify the elementary bodies of a particular virus; as always in such laboratory tests, the results of the examination of smears must be considered together with the clinical picture and the epidemiological data available. It should, however, be added that in smears made from the lesions of virus infections such as herpes simplex, herpes zoster and chicken-pox, elementary bodies are usually scanty and do not stain as readily as those of variola. The elementary bodies of vaccinia are indistinguishable from those of variola and consequently the examination of smears will not help to distinguish a case of atypical variola from secondary vaccinial lesions occurring in a recently vaccinated person. During the past two years I have examined smears from 24 cases of smallpox (*see* Table I) in addition to numerous

Table I.—The Results of Laboratory Tests on Specimens from 61 Cases of Smallpox.

	Microscopical examination of smears	Inoculation on chorio-allantois	Serological test for antigen	Test of serum for antibody
No. of patients	24	29	31	34
No. of specimens	25	37	41	39
Specimens positive	13	35	40	37

Material was not available for all these tests in each of the 61 cases, but, with one exception, one or more of the tests was positive in every case.

These figures suggest that a healthy gall-bladder can concentrate penicillin to a strength which may be lethal to the typhoid bacillus, but that any liver impairment, or damage to the gall-bladder, will make these concentrations unlikely. In any event the administration must be repeated frequently to maintain a high concentration in the bile (a continuous drip of 1,000,000/three hours).

Streptomycin apparently behaves just like penicillin; we have only given it to one patient with common duct drainage but she had a good concentration at three hours and some still present at six hours. Zaslow got the same results from streptomycin as he got from penicillin, namely, that none appeared in the gall-bladder if the cystic duct was obstructed, and that levels in pathological gall-bladders were equal to, or slightly lower than, those in the common duct.

De Bakey and Pulaski (1946) have attempted to treat two typhoid carriers with streptomycin without success.

In conclusion I may say that high concentrations of penicillin in the common bile duct, above 6 units/c.c., depend on large dosage and good liver function, this high concentration is very transient and probably appears between the second and third hours. High concentration of penicillin in the gall-bladder depends both on liver function and the patency of the cystic duct; if these factors are satisfactory very high concentration may be obtained, but how long it is maintained I do not know.

examination. Of specimens from infections other than smallpox only three produced typical virus infections of the chorio-allantois. One yielded the strain of herpes simplex referred to above and the other two produced characteristic vaccinial lesions. These latter two specimens came from secondary vaccinial vesicles in smallpox contacts who had been vaccinated some days previously.

Serological test for variola antigen.—The test which we have used as a routine is the complement-fixation test based on the technique recommended by Craigie and Wishart (1936). This test is more sensitive than the precipitation test and gives highly satisfactory results if suitable material is submitted for examination. As recommended by Craigie and Wishart the contents of at least six vesicles or pustules or the crusts from at least six lesions should be submitted to the laboratory. Extracts of these materials are tested against a hyperimmune antivaccinial serum prepared in the rabbit and this serum should have a satisfactory titre of antibody to the stable as well as to the labile component of the variola-vaccinia antigen. The test can be completed within twenty-four hours of receipt of the specimen but is obviously not of value during the papular stage of the disease; nor will the test serve to distinguish the antigen in vaccinial from that in variolar lesions. With these limitations the test is specific and reliable, although rather more material is necessary for examination than for the detection of virus by the chorio-allantoic inoculation test. The one negative result recorded in the table was due to the inadequate amount of material submitted and in this instance ''cultivation'' of the virus on the chorio-allantois was successful. Of many specimens submitted for test from patients suffering from diseases other than smallpox only one gave a positive reaction for variola-vaccinia antigen. This specimen came from a secondary vaccinial lesion and was one of the two mentioned above which produced typical vaccinial infection of the chorio-allantois.

Examination of the patient's serum for antibody to variola virus.—This test, like most examinations for antibody in the serum of patients convalescing from specific infections, is not so satisfactory as the previous tests which have as their object the identification of the infecting virus. Like all such tests it does not give a positive result in the early stage of the disease—within the first week after the onset of symptoms. Various tests for antibody are available but perhaps the most convenient utilizes the complement-fixation technique, the patient's serum being tested against either a vaccinial antigen prepared from skin lesions produced in rabbits or a variola antigen extracted from smallpox crusts. Of thirty-nine specimens of serum tested from 34 cases of smallpox, all except two gave a positive complement-fixation test for antibody (*see* table), the titres of the sera varying from 1 : 5 to 1 : 320. These samples were obtained from the eighth day of disease onwards. The two sera which gave a negative result were collected on the sixth and ninth days respectively after the onset of symptoms. Antibody may be detectable by this test in persons who have been vaccinated within the previous few months and, in tests on over 100 sera from such individuals, approximately 30% gave positive reactions with titres ranging from 1 : 5 to 1 : 80. The interpretation of a positive result will therefore be difficult in smallpox contacts who have recently been vaccinated. As antibody detectable by this technique seems to disappear from the blood within six months after vaccination, the test may be of diagnostic value after the first week of illness in persons who have not been vaccinated within the previous six months.

Summary.—Each of the laboratory tests described is of diagnostic value in individual cases depending on the stage of the disease. The examination of smears is particularly useful in the papular and vesicular stage if specimens are properly collected. The isolation of virus by the inoculation of material on the chorio-allantois of developing hens' eggs is an extremely delicate and reliable method but smears from various other conditions associated with skin lesions. In the majority of smears from smallpox cases elementary bodies were to be found and, when the smears had been properly collected from cases in the papular or vesicular stage, the microscopic appearances were characteristic; but in some which had obviously been made from the contents of pustules, the appearances were not as a rule sufficiently typical to be diagnostically helpful. In 9 of the 24 cases smears were made from vesicle fluid submitted for serological examination, and in three of these elementary bodies could not be found, although the fluid subsequently produced typical variola infection on the chorio-allantois of developing chick embryos. A negative result from the microscopic examination of such specimens can obviously be of no value in excluding a diagnosis of smallpox. The chief merits of this test are that it can be carried through within one hour, no elaborate apparatus is required and it is likely to be most helpful in the early stages of the disease.

Isolation and identification of the virus from smallpox cases.—The virus may be obtained from variola lesions by the inoculation of animals although the monkey is the only animal which is highly susceptible and the use of this animal is impracticable for routine diagnostic tests. Paul's test, which depends on the production of typical lesions on the cornea of rabbits after scarification and inoculation of infective material, has, in the hands of many workers, given rather irregular results. Within the last few years the chorio-allantois of developing chick embryos has been found to be highly susceptible to infection with variola virus from human sources (Irons *et al.*, 1941). Our own experience has convinced us that the technique of inoculation on the chorio-allantois is a very delicate test for the presence of variola virus (Downie and Dumbell, 1947*b*). When infective material from the scrapings of papules, from vesicle or pustule fluid or from crusts is inoculated on the chorio-allantois of ten- to thirteen-day chick embryos there appear, within two to three days' further incubation, characteristic lesions which differ in appearance from those produced either by vaccinia or by any other virus which multiplies in the chorio-allantois. The nature of the virus in the lesions can be confirmed by histological and serological tests. This method has as its chief disadvantages, (*a*) two or three days are required before a result is obtained, and (*b*) a supply of incubated fertile hens' eggs has to be available for a regular diagnostic service. The advantages of the technique are, (*a*) it is the most sensitive test at present available for the detection of variola virus, and (*b*) it offers the readiest means of distinguishing vaccinial from variolar infection. The viruses of chicken-pox and herpes zoster will not produce visible lesions on the chorio-allantois; the virus of herpes simplex, which we encountered once during these observations, produces smaller lesions on the chorio-allantois which histologically do not show in infected ectodermal cells the cytoplasmic inclusions which are present in the lesions due to the variola virus. Of 37 specimens from 29 cases of smallpox inoculated on the chorio-allantois, only two failed to produce typical variola lesions. One of these specimens gave a positive serological test for variola antigen and was examined before we had adopted the routine technique of mixing penicillin with the inoculum. The extract of the crusts in this case was found to be heavily infected with *Staphylococcus pyogenes* and consequently was treated with ether at room temperature for several days in order to destroy the bacteria before inoculation on the chorio-allantois. Subsequent tests showed that such treatment destroyed vaccinia virus and it seems likely that the failure to isolate virus was due to the ether treatment of the variola specimen. The other specimen which failed to infect the chorio-allantois was a single crust from a smallpox contact who had recently been vaccinated and in this case there was some doubt as to the diagnosis; insufficient material was available for serological test but a diagnosis of atypical variola was made on clinical grounds. Ten of the thirty-five specimens from which the virus was isolated on the chorio-allantois were insufficient for serological test and in five of these the material used for inoculation of eggs was obtained from dried smears sent for microscopic fluid, tracheal fluid and embryonic lungs. This method has opened up a new line of approach to the problem of influenza for this new medium, in which the virus will multiply, is not only economical and easy to handle, but devoid of latent viruses. Great progress has been made in the last few years in the development of this method until now it has become an extremely sensitive method of virus isolation.

The method adopted at the National Institute for Medical Research is that suggested by Beveridge and Burnet (1946). By the addition of antibacterial substances to the throat washing, filtration through a gradocol membrane is not necessary, the subsequent loss of virus is avoided and the maximum amount of virus allowed to come into contact with the respiratory epithelium. Throat washings containing 25% serum broth in saline are lightly centrifuged and are then inoculated direct into the amniotic cavity of 13-day chick embryos. Each egg receives 0·25 ml. throat washing and penicillin (100 units per ml.) and in addition 0·1 ml. of 5% sodium sulphamerazine. At least five eggs are inoculated with each washing as only a percentage become infected on primary, passage. After a further four days' incubation all surviving eggs are chilled in the ice-box and are then tested for the presence of virus. For this purpose, use is made of the phenomenon described by Hirst (1941) and independently by McClelland and Hare (1941) who showed that the influenza virus would cause agglutination of fowl red cells, thus providing a useful laboratory test for the presence of the virus. Burnet and Bull (1943) showed that the influenza A virus on primary isolation would agglutinate guinea-pig (or other mammalian) red cells to a higher titre than it would fowl cells; this they called the O-phase ("Original"). After passage, however, the ratio changed and fowl red cells were agglutinated to a higher titre; this was named the D-phase ("Derivative"). This change in ratio is referred to as the O-D variation. It is therefore necessary to test primary amniotic fluids with both species of red cells. This phenomenon of the O-D variation is not shown by the B virus.

This method is an extremely sensitive one for virus isolation and virus typing and is comparatively easy to carry out once the technical details have been mastered.

Indirect method: Titration of serum antibody.—(*a*) *Neutralizing antibody:* The result of infection with influenza is a rise in both neutralizing and complement-fixing antibodies in the serum. This can best be determined by measuring the rise in serum antibody between an acute and convalescent sample of serum. The determination of the antibody level of a single specimen of serum is of little value in the test for neutralizing antibodies as it does not take into account past clinical and subclinical infections. The most convenient method of measuring the neutralizing antibody in serum is that described by Hirst (1941). The test is based on the fact that the agglutination of fowl red cells by the influenza virus can be inhibited by serum and the agglutinin-inhibition level of the serum determined. The modification of Hirst's original method described by Salk (1944) has many practical advantages. A fourfold rise in antibody between an acute and convalescent sample of serum has until recently been regarded as indicative of infection, but in carrying out a large series of these tests during two epidemics, one is impressed by the large number of sera from typical cases of influenza which only show a twofold rise, or, in a few cases, no rise in antibody. There are several technical difficulties associated with these red cell agglutination tests but on the whole they do provide a valuable guide to the diagnosis of influenza and also reflect the incidence of infection in a community.

(*b*) *Complement fixation:* There is an increase also in the complement-fixing antibody as a result of infection. Hoyle and Fairbrother (1937) have described a method of carrying out this test using the soluble antigen of influenza prepared from mouse lung, which gives a result in many cases comparable to the neutralization method (Hoyle, 1945). The advances made in recent years in the study of influenza are essentially practical and the methods described can be carried out in most laboratories with advantage to our knowledge of epidemic influenza.

requires three days before a report can be made. The detection of virus antigen in vesicle fluid or crusts by the complement-fixation technique is a highly specific test for variola-vaccinia antigen and gives reliable results if sufficient material is submitted for examination. The test for antibody is likely to be useful after the first week of illness and only if the patient has not recently been vaccinated.

Dr. J. A. Dudgeon: *The laboratory diagnosis of influenza.*—Influenza is an infection of the respiratory epithelium caused by a virus which is essentially pneumotropic and which is characterized by the recurrence of epidemics at frequent intervals throughout the world. During one such epidemic in this country in 1933, Wilson Smith, Andrewes and Laidlaw (1933) were able to show that a transmissible infection could be produced in ferrets following the intranasal inoculation of a filtrate from an early case of influenza. This was the first evidence that the causative organism of influenza was a virus and since that time strains have been isolated in many different parts of the world. So far, two antigenically distinct strains have been isolated from typical epidemics of influenza: influenza virus A, forming one large group (similar antigenically to the original strain isolated in 1933) and influenza virus B, the other distinct group first isolated seven years ago in the U.S.A. by Francis (1940) and independently by Magill (1940). These two viruses produce very much the same clinical picture of influenza, though they are distinct in their antigenic structure. As a rule virus B infections tend to be less virulent than those caused by the A virus.

The clinical diagnosis of influenza during an epidemic presents little difficulty, but the laboratory can provide useful information as to the type of infection, whether A or B, and in the case of sporadic influenza may be the only means of reaching a diagnosis from the other causes of upper respiratory infection.

There are two main methods of investigating influenza in the laboratory: (1) The direct method, which depends upon the isolation of the virus from throat washings of typical cases. (2) The indirect method, which depends upon the fact that infection is followed by a rise in serum antibody, which can be measured in several ways.

Direct method: Isolation of virus.—(*a*) *Ferret inoculation:* This is the classical method by which the virus was first isolated. The typical response to inoculation in a ferret is an acute upper respiratory infection accompanied by a varying degree of pyrexia, usually biphasic in type but often showing only a single peak, and followed by complete recovery of the ferret with the development of an immunity to further inoculation with the same virus. In recent years this typical picture of influenza in the ferret has not always been produced in the laboratory and the response in the ferret has been extremely variable. There may be a complete lack of symptoms, with practically no pyrexia, yet the serum antibody of the ferret may be markedly raised. More often there is a monophasic type of pyrexia with rapid recovery. This response in the ferret tends to vary with the pathogenicity of the virus for man. On the whole, virus B strains produce very few symptoms in the ferret and are not enhanced by passage, as is the case with A strains (Dudgeon *et al.*, 1946). Ferret inoculation thus has its limitations as a means of virus isolation and has to be carried out in specially equipped laboratories to exclude the risk of accidentally infecting the ferrets, which are to be used for virus isolation, with influenza and other viruses.

(*b*) *Developing chick embryo. Amniotic inoculation:* Burnet (1940) showed that the influenza virus could be adapted to growth in the amniotic sac of the developing chick embryo and that the virus could subsequently be recovered from the amniotic fluid, tracheal fluid and embryonic lungs. This method has opened up a new line of approach to the problem of influenza for this new medium, in which the virus will multiply, is not only economical and easy to handle, but devoid of latent viruses. Great progress has been made in the last few years in the development of this method until now it has become an extremely sensitive method of virus isolation.

The method adopted at the National Institute for Medical Research is that suggested by Beveridge and Burnet (1946). By the addition of antibacterial substances to the throat washing, filtration through a gradocol membrane is not necessary, the subsequent loss of virus is avoided and the maximum amount of virus allowed to come into contact with the respiratory epithelium. Throat washings containing 25% serum broth in saline are lightly centrifuged and are then inoculated direct into the amniotic cavity of 13-day chick embryos. Each egg receives 0·25 ml. throat washing and penicillin (100 units per ml.) and in addition 0·1 ml. of 5% sodium sulphamerazine. At least five eggs are inoculated with each washing as only a percentage become infected on primary passage. After a further four days' incubation all surviving eggs are chilled in the ice-box and are then tested for the presence of virus. For this purpose, use is made of the phenomenon described by Hirst (1941) and independently by McClelland and Hare (1941) who showed that the influenza virus would cause agglutination of fowl red cells, thus providing a useful laboratory test for the presence of the virus. Burnet and Bull (1943) showed that the influenza A virus on primary isolation would agglutinate guinea-pig (or other mammalian) red cells to a higher titre than it would fowl cells; this they called the O-phase ("Original"). After passage, however, the ratio changed and fowl red cells were agglutinated to a higher titre; this was named the D-phase ("Derivative"). This change in ratio is referred to as the O-D variation. It is therefore necessary to test primary amniotic fluids with both species of red cells. This phenomenon of the O-D variation is not shown by the B virus.

This method is an extremely sensitive one for virus isolation and virus typing and is comparatively easy to carry out once the technical details have been mastered.

Indirect method: Titration of serum antibody.—(*a*) *Neutralizing antibody:* The result of infection with influenza is a rise in both neutralizing and complement-fixing antibodies in the serum. This can best be determined by measuring the rise in serum antibody between an acute and convalescent sample of serum. The determination of the antibody level of a single specimen of serum is of little value in the test for neutralizing antibodies as it does not take into account past clinical and subclinical infections. The most convenient method of measuring the neutralizing antibody in serum is that described by Hirst (1941). The test is based on the fact that the agglutination of fowl red cells by the influenza virus can be inhibited by serum and the agglutinin-inhibition level of the serum determined. Dr. J. A. Dudgeon: *The laboratory diagnosis of influenza.*—Influenza is an infection of the respiratory epithelium caused by a virus which is essentially pneumotropic and which is characterized by the recurrence of epidemics at frequent intervals throughout the world. During one such epidemic in this country in 1933, Wilson Smith, Andrewes and Laidlaw (1933) were able to show that a transmissible infection could be produced in ferrets following the intranasal inoculation of a filtrate from an early case of influenza. This was the first evidence that the causative organism of influenza was a virus and since that time strains have been isolated in many different parts of the world. So far, two antigenically distinct strains have been isolated from typical epidemics of influenza: influenza virus A, forming one large group (similar antigenically to the original strain isolated in 1933) and influenza virus B, the other distinct group first isolated seven years ago in the U.S.A. by Francis (1940) and independently by Magill (1940). These two viruses produce very much the same clinical picture of influenza, though they are distinct in their antigenic structure. As a rule virus B infections tend to be less virulent than those caused by the A virus.

The clinical diagnosis of influenza during an epidemic presents little difficulty, but the laboratory can provide useful information as to the type of infection, whether A or B, and in the case of sporadic influenza may be the only means of reaching a diagnosis from the other causes of upper respiratory infection.

There are two main methods of investigating influenza in the laboratory: (1) The direct method, which depends upon the isolation of the virus from throat washings of typical cases. (2) The indirect method, which depends upon the fact that infection is followed by a rise in serum antibody, which can be measured in several ways.

Direct method: Isolation of virus.—(*a*) *Ferret inoculation:* This is the classical method by which the virus was first isolated. The typical response to inoculation in a ferret is an acute upper respiratory infection accompanied by a varying degree of pyrexia, usually biphasic in type but often showing only a single peak, and followed by complete recovery of the ferret with the development of an immunity to further inoculation with the same virus. In recent years this typical picture of influenza in the ferret has not always been produced in the laboratory and the response in the ferret has been extremely variable. There may be a complete lack of symptoms, with practically no pyrexia, yet the serum antibody of the ferret may be markedly raised. More often there is a monophasic type of pyrexia with rapid recovery. This response in the ferret tends to vary with the pathogenicity of the virus for man. On the whole, virus B strains produce very few symptoms in the ferret and are not enhanced by passage, as is the case with A strains (Dudgeon *et al.*, 1946). Ferret inoculation thus has its limitations as a means of virus isolation and has to be carried out in specially equipped laboratories to exclude the risk of accidentally infecting the ferrets, which are to be used for virus isolation, with influenza and other viruses.

(*b*) *Developing chick embryo. Amniotic inoculation:* Burnet (1940) showed that the influenza virus could be adapted to growth in the amniotic sac of the developing chick embryo and that the virus could subsequently be recovered from the amniotic

the urethra in the male or on the mucosa of the vulva, vagina or cervix in the female; it can occur more rarely about the anus or in the rectal mucosa, on the finger or in the mouth. Infection spreads by lymphatics to the nearest lymph glands and those most commonly involved are the inguinal. These may soften and break down and in the pus the virus can, at times, be demonstrated microscopically.

ISOLATION OF VIRUS BY ANIMAL OR EGG INOCULATION

Although microscopy is of value in the diagnosis of these infections its usefulness has definite limitations and it should never replace the attempt to isolate and identify the virus.

Psittacosis: In human cases of psittacosis the virus may be sought in the blood during the first few days of disease or later, in those cases where the lungs are involved, in the sputum or in material obtained by lung puncture. Both the incubated egg and the mouse are suitable for the isolation of psittacosis virus. If blood is the material to be examined it should be injected into mice intraperitoneally using as large an inoculum as possible. Sputum or lung puncture material, suspended in the least quantity of diluent (broth; saline; phosphate buffer) to provide an inoculum which can be injected through a reasonably fine needle, is used for the inoculation of mice by the peritoneal and nasal routes. It is important to employ the latter route since pigeon strains of psittacosis virus usually produce an inapparent infection in mice when injected intraperitoneally. Where bacteria are present in the material—and this applies particularly to sputum—filtration should be avoided if possible since it reduces the amount of virus, and the mice should be protected against the bacteria by the simultaneous injection of sulphathiazole to which psittacosis virus is usually insusceptible. I say "usually insusceptible" since contrary to the opinion of most workers, I have seen two cases of human psittacosis which appeared to respond to sulphapyridine and one to sulphathiazole. The inoculated mice should be observed for a month and any showing signs of illness killed, examined for signs of infection such as pneumonic consolidation in the nasally inoculated mice or enlargement of the spleen and peritonitis in those receiving the material by the peritoneal route. Should the lesions observed not appear to be of bacterial origin passage should be made to further mice with suspensions of lung or spleen respectively. Even in the absence of any signs of illness some of the mice should be killed after ten or twelve days and passage made in order to unmask a possible subclinical infection. This virus takes in the incubated hen's egg by practically any route, though for primary inoculation with material possibly containing some bacteria inoculation of the chorio-allantois would be the method of choice since this membrane is better able to deal with these bacteria than is the yolk sac. Some ten- to twelve-day eggs might, therefore, be inoculated in parallel with the mice.

Lymphogranuloma venereum: Pus from a bubo, preferably an unopened one, should be used for the inoculation of mice intracerebrally and four- to five-day eggs into the yolk sac. Should the pus contain bacterial secondary invaders it is sometimes possible to select the virus by injecting a suspension of the pus intradermally in the thigh of a guinea-pig and removing the inguinal glands on the same side two to three days later. A suspension of these glands, if culturally sterile, is then used for the inoculation of mice and eggs. One gets the impression from the literature that the isolation of this virus is a relatively easy matter, but my own experience does not confirm this. Material from three cases during the last year was inoculated into mice with a completely negative result in two, whilst from the third the strain obtained was lost after the third mouse passage. I understand that others in this country have had no better success than I.

The identification of strains of virus isolated from suspected cases of psittacosis or lymphogranuloma is made on the size and staining properties (Castaneda positive) of the virus and the infectivity for the mouse by the nasal, peritoneal and cerebral routes, these facts being considered in relation to the type of material examined and

Professor S. P. Bedson: *Psittacosis-lymphogranuloma group.*—The viruses of the psittacosis-lymphogranuloma group belong to a larger group which includes, in addition, the viruses of trachoma, inclusion conjunctivitis or inclusion blennorrhœa, mouse pneumonitis of Nigg and Eaton and cat pneumonia of Baker. They are distinguished from other viruses by the possession in common of certain characters:

(1) Large size; their smallest forms are from 150 to 250 mμ in diameter.

(2) They stain more readily than other viruses and they can also be stained differentially by the method of Castaneda or Macchiavello, enabling them to be distinguished readily from particulate matter of a non-virus nature and from other viruses which do not stain by these methods.

(3) When multiplying they undergo a regular sequence of morphological change.

(4) Their cytoplasmic colonies or inclusions contain little inclusion material which is basophilic and its scantiness makes it possible readily to discern the structure of the inclusion.

(5) They contain thymonucleic acid unlike other viruses (Lépine and Sautter, 1946).

MICROSCOPY

It follows from this that microscopy should be of some service in the laboratory investigation of disease due to the psittacosis-lymphogranuloma group of viruses. Not that the microscope enables one to differentiate between these viruses because, of course, they look much the same, but it often makes it possible to say whether or not a virus of this group is present, and this information, coupled with the clinical data and knowledge of the source of the material, permits, if not the identification of the virus, at least a shrewd guess as to its identity.

Psittacosis infections.—Psittacosis is primarily a disease of birds. At one time it was thought that only psittacine birds were naturally affected, but we now know that the disease may occur in other species of birds. It has been observed in various species of finch, in fulmar petrels, in pigeons and in the domestic fowl and all these have been shown to be the source of human infections. Some authorities would distinguish between the strains of psittacosis virus occurring in these different bird species. Pigeon and fowl strains are sometimes referred to as ornithosis virus and though it is true that pigeon strains do differ in some respects from psittacine strains, it is too early yet to say whether these differences are sufficiently great to warrant different specific status. Man contracts infection usually by inhaling infective particles provided by dried droppings, and when clinically obvious the disease may take the form of a pyrexia without any signs of localization or accompanied by varying degrees of lung involvement. Although it may at times be possible to demonstrate the virus microscopically in sputum and lung puncture material this can hardly be recommended as a fruitful diagnostic procedure. In the case of infection of birds—and evidence of this may often be sought in connexion with the investigation of human cases of psittacosis—direct microscopy of smears made from the enlarged spleens or infected air sacs may often enable a rapid diagnosis.

Lymphogranuloma venereum.—Infection with this virus appears to be peculiar to man. Infection is spread by contact which in the main is venereal. The inconspicuous primary lesion usually occurs on the glans penis or in the anterior part of

the urethra in the male or on the mucosa of the vulva, vagina or cervix in the female; it can occur more rarely about the anus or in the rectal mucosa, on the finger or in the mouth. Infection spreads by lymphatics to the nearest lymph glands and those most commonly involved are the inguinal. These may soften and break down and in the pus the virus can, at times, be demonstrated microscopically.

Lymphogranuloma venereum.—Infection with this virus appears to be peculiar to man. Infection is spread by contact which in the main is venereal. The inconspicuous primary lesion usually occurs on the glans penis or in the anterior part of

essential in a clinically equivocal case. The work of Rake and Eaton and their colleagues during the last few years is even more upsetting to our preconceptions. Rake, Eaton and Shaffer (1941) have shown that sera from cases of psittacosis, lymphogranuloma and atypical pneumonia fix complement equally well with psittacosis, meningopneumonitis (ornithosis) and lymphogranuloma antigens and what is of equal importance, that cases of atypical pneumonia due to psittacosis virus may give a positive Frei test. This evidence of antigenic sharing between these viruses has been further supported by cross-immunity experiments in animals (Eaton, Martin and Beck, 1942; Beck, Eaton and O'Donnell, 1944). My own experience confirms this. Sera from cases diagnosed clinically as lymphogranuloma and giving a positive Frei test have fixed complement just as well with a psittacosis antigen as with one prepared from lymphogranuloma virus, though in the few cases in which I have made an intradermal test with the psittacosis antigen in addition to the Frei test with lygranum, the skin tests have not always shown the concordance of the serological tests. The implications of this work are obvious. These serological tests in disease due to viruses of the psittacosis-lymphogranuloma group are not virus-specific but only group-specific and their interpretation must invariably be made in the light of the clinical and epidemiological evidence. There is even a suggestion that this sharing of antigens extends to other Castaneda-positive viruses and that antibody-fixing complement with psittacosis and L.G.V. antigens may occur in trachoma and infections with the related virus of inclusion conjunctivitis (Rake, Shaffer and Thygeson, 1942). The few observations I have made have not confirmed this. The Frei test, too, loses its specificity and must be read in conjunction with the clinical and serological findings. The whole position is a little confused and in my opinion it will remain so until we have a more exact understanding of the antigenic relationship of these viruses.

Dr. F. O. MacCallum: *Neurotropic viruses.*—Our present knowledge indicates that infection by the known neurotropic viruses occurs comparatively rarely in this country, but interest in them has greatly increased in recent years. There are, in addition, a considerable number of cases of benign meningitis, meningo-encephalitis, encephalitis and myelitis, which are presumably of virus origin. Thus, there are two interesting problems: on the one hand to determine the possible reasons for the limitation of spread in epidemic form of recognized diseases such as acute anterior poliomyelitis and, on the other, to identify the causative agents of the group of presumed neurotropic virus infections.

The first of these problems does not concern us here; as to the second, since the clinical picture does not serve to differentiate virus infections of the C.N.S., the differential diagnosis within each group depends on the aid of the laboratory. The exceptions are rabies, and poliomyelitis, where, usually, the laboratory is only the clinical history of the case supplying it. There are other tests that can be applied, such as infectivity for the pigeon and cross-immunity tests in mice or hamsters, but these are the concern of the expert.

SEROLOGICAL DIAGNOSIS

The isolation and identification of these viruses naturally take time, and valuable and necessary though this type of laboratory investigation may be, its findings are only of retrospective interest as far as the clinician is concerned. It is for this reason that the indirect method of laboratory diagnosis of this disease has been developed despite the fact that the answer provided by the demonstration of antibody in the patient's serum is of less value than isolation and identification of the virus. Specific antibodies are developed with considerable regularity in these infections and their presence can be detected most satisfactorily by the complement-fixation test. It is true that the agglutination reaction, even slide agglutination, can be used for this purpose but as Merril has shown (1936), the complement-fixation test is the more delicate and therefore of greater value where, as is the case with viruses, an antigen of high concentration is difficult to obtain. Some twelve years ago (Bedson, 1935) we started using the complement-fixation test at the London Hospital for the diagnosis of psittacosis. At first the antigen used was a crude suspension of virulent mouse spleen, but when it was found that a partially purified suspension of virus heated to 100° C. was even more satisfactory (Bedson, 1936) this safer antigen was employed. The results obtained with this test appeared to accord well with the clinical, epidemiological and other laboratory findings (Bedson, 1937) and confirmation of this has been forthcoming from America (Meyer, Eddie and Yanamura, 1939). More recently the complement-fixation test has been used in the diagnosis of lymphogranuloma venereum and found to be of service (Hecht, 1935; Coutts and Ponce, 1935; Shaffer, Rake and Grace, 1942; Landau, 1946). Much of the earlier work in this field was based on the assumption that these reactions were specific and that a single observation showing a reasonably high titre of antibody was diagnostic, but a more extended use of these tests and a study of the relationship of the viruses of the psittacosis-lymphogranuloma group have shown these assumptions to be unwarranted. One has always held that for serological evidence of active infection to be acceptable there should be a material excursion in the titre of the antibodies in question, either a rising titre in the active stage of the disease or a falling one in the convalescence, preferably the former. Extended use of the psittacosis complement-fixation test has shown that it is no exception to the rule. This has emerged clearly from the serological investigations of the virus syndrome, primary atypical pneumonia, made during the war. A proportion, roughly about 10%, of these cases are caused by viruses of the psittacosis group. In a series of 45 sporadic cases investigated by Smadel (1943) in eastern urban populations of the United States, 9 showed serological evidence of being due to psittacosis virus and this virus was isolated from the sputum in one; in another case in which the C.F.T. was not done the virus was isolated from the lungs post mortem. In this country (Bedson unpublished) 9 of 120 cases had either a very high or a rising titre of antibody for psittacosis virus. Other workers in America (Eaton, Beck and Pearson, 1941; Meyer, Eddie and Yanamura, 1942; Eaton, 1943; Favour, 1943) have produced evidence that viruses of the psittacosis group are concerned in the causation of atypical pneumonia. Smadel (1943) commenting on the use of the complement-fixation test in the investigation of this condition gives it as his opinion that a rise of not less than fourfold in the antibody titre is necessary if one is to conclude that the presence of antibody denotes active infection, and with this view I would certainly concur. My more limited experience of the complement-fixation test in lymphogranuloma leads me to a similar conclusion; though a single observation showing a high titre in a clinically acceptable case is good confirmatory evidence, a rising titre of antibody is better and is quite found in the Americas have not been seen in this country in animals or man, but as equine encephalomyelitis has occurred in all the States of the eastern coast of U.S.A. in recent years, one cannot ignore the possibility of such an infection. Infection with the viruses of Japanese B. encephalitis and Russian spring-summer (tick-borne) encephalitis can probably be disregarded, though the latter appears to be closely related immunologically to louping-ill, which is found in sheep in Scotland and is said to have been isolated in Russia.

Louping-ill is the only one of the known virus encephalitides under suspicion at the moment. This virus infection of sheep, transmitted by the tick *Ixodes ricinus*, is, as far as is known, confined to Scotland and northern England. Infection in man is only known to have occurred in laboratory workers or in veterinarians who have done post-mortem examinations on infected sheep. A serological survey is now in progress to determine whether unrecognized infection is more widespread than is realized, as was found to be the case with Rift-Valley fever.

Though poliomyelitis has never become the serious disease that it is in Australia, Canada, and U.S.A., it is an endemic infection in this country and provides a very interesting problem for study. As can be seen from the table, the virus of poliomyelitis can be isolated from the nasopharyngeal secretions and intestinal contents during life and from the central nervous system as well as some other tissues, of fatal cases. The virus has *not* been isolated from the cerebrospinal fluid and has been detected in the blood only very rarely. Unfortunately, small laboratory animals are not susceptible to most strains of the virus, and it is necessary to use monkeys for the original isolation. This makes routine laboratory diagnosis of this disease impracticable in England at the present time. The immunological relationship of different strains is not yet clear, but certain strains which have been adapted to mice can be used for serological surveys of immunity. We are using such a strain for these tests now and are attempting to adapt to rodents a strain isolated by inoculation of rhesus monkeys from a fatal human case in London in June 1946.

The largest group of cases which needs investigation is that of benign lymphocytic or aseptic meningitis, of which a certain proportion are caused by the known virus of lymphocytic choriomeningitis (L.C.M.), but the majority are of undetermined origin. L.C.M. virus has been isolated on a number of occasions in the U.S.A., and neutralizing antibodies were found in the sera of about 10% of 1,000 individuals giving no history of disease of the central nervous system. The virus of L.C.M. has been found to exist as a latent infection in some mouse colonies, and has been isolated from mice trapped in houses where human cases of L.C.M. have occurred. In England, the position seems to be somewhat different. The virus has been isolated from man on only about 12 occasions. In several instances, where there appears to have been undoubted isolation of the virus from man by inoculation into clean stocks of mice and guinea-pigs, neither neutralizing nor complement-fixing antibodies could be detected in the patients' serum in the convalescent stage. It is hoped that further study will reveal more exactly the part that L.C.M. virus plays in benign aseptic meningitis in this country.

The virus of L.C.M. may be isolated from the blood in the febrile, influenza-like, pre-meningeal phase, but the disease will not be recognized in this stage, except where a number of cases occur in one focus within a short period. The virus is present in the cerebrospinal fluid for a comparatively short space of time during the acute stage of the meningitis. Whole blood (2·0 to 10·0 c.c.) and C.S.F. (5·0 to 10·0 c.c.) should be collected in the febrile and meningeal stages, for isolation of virus and clotted blood (3·0 to 10·0 c.c.) in the acute stage and four to six weeks later for antibody estimations. The amount of blood and C.S.F. collected will, of course, depend on the circumstances, but it is obvious that the larger the sample for study, the greater the chance of carrying out satisfactory tests.

needed to verify the clinical diagnosis, although sporadic cases of poliomyelitis may be simulated by other virus infections, e.g. lymphocytic choriomeningitis.

The laboratory diagnosis of infections with neurotropic viruses entails the application of methods similar to those used in the diagnosis of any other infectious disease. In the acute stage, attempts are made to isolate the causative agent by growth in appropriate culture media, e.g. the developing hen's egg, and experimental animals ranging from mouse to chimpanzee. In the convalescent period, various serological tests are used to detect the presence of specific antibodies, e.g. neutralizing and complement-fixing antibodies, agglutinins and precipitins. No attempt will be made here to describe in detail the methods and constituents of the tests used in each case, but rather to make a general statement indicating the type of test used and the necessary materials to be collected from the patient for laboratory diagnosis.

In the detection of virus in the acute stage, the most important point is the proper collection, storage and transport of material to be examined. If in doubt, it will always be most helpful for all concerned if the laboratory which is to carry out the investigations is consulted beforehand. Many of these viruses are comparatively heat labile as soon as they are removed from their natural host, and it is essential that all such material should be kept at temperatures below +4° C. immediately they are obtained from the patient and until received at the laboratory for diagnosis.

Many laboratories now possess refrigerators maintained at a temperature of −20° C. which is most satisfactory; otherwise small specimens may be frozen in the coil of the refrigerator. Specimens should be packed in ice for transport and dispatched to the diagnostic laboratory by the most rapid method of delivery. The exception to this is blood serum for serological tests, which may be sent by post. For complement-fixation tests in particular, it is essential to have clean sterile, non-hæmolysed serum, so that when possible, the serum should be removed from the clot before dispatching it.

* Not tested so far. ‡ No test.

In the table are listed the sites from which virus has been isolated, or the appropriate serological tests in the more common neurotropic virus diseases of man, and some neurotropic virus diseases of animals, which are known to have affected workers experimenting with them, e.g. louping-ill. As far as we know, we are concerned with comparatively few of these recognized infections in Great Britain.

Rabies is no longer a problem, though occasionally cases occur in individuals who have been bitten by a rabid animal abroad and who develop the disease after returning to England. Two such cases from Greece and India have recently occurred in London and confirmation of the clinical diagnosis was obtained by infecting mice, guinea-pigs and rabbits with suspension of the brain which had been placed in 50% glycerol-saline at post-mortem.

St. Louis encephalitis and the various types of equine encephalomyelitis which are found in the Americas have not been seen in this country in animals or man, but as equine encephalomyelitis has occurred in all the States of the eastern coast of U.S.A. in recent years, one cannot ignore the possibility of such an infection. Infection with the viruses of Japanese B. encephalitis and Russian spring-summer (tick-borne) encephalitis can probably be disregarded, though the latter appears to be closely related immunologically to louping-ill, which is found in sheep in Scotland and is said to have been isolated in Russia.

Carcinoma of the Thyroid

By J. M. Graham, P.R.C.S.Ed., and R. McWhirter, F.R.C.S.Ed.

The object of this communication is to discuss some of the facts associated with malignant disease of the thyroid gland with special reference to the results of treatment. Our observations are based upon a series of 144 unselected cases which have been drawn mainly from the south-east of Scotland and have been admitted to the Royal Infirmary, Edinburgh. The cases are representative of an area in which simple goitre is not endemic but occurs only sporadically.

Sex incidence.—Of the total number of patients 31 were males and 113 were females. These figures, which show a ratio of 1 male to 3·6 females, may be compared with those of a corresponding series of cases of simple goitre, which were operated on, in which the incidence was 1 male to 9 females.

Age.—The average age of the cases was 59·75 years. The youngest patient was 18 and the oldest was 93.

Histological Classification

The diagnosis of malignant disease was confirmed by histological examination in 97 of the cases. In the remaining 47 cases it was made on clinical grounds alone.

As the histological reports were made originally by several pathologists, we considered it would be advantageous to have the slides reviewed by one experienced authority. We are indebted to Professor Drennan, Professor of Pathology at Edinburgh University, for undertaking this work and for classifying the cases on a uniform basis. His opinion has enabled us to eliminate a few cases in which the original diagnosis of malignant disease was not confirmed, and a review of the subsequent history of these rejected cases has supported the correctness of the final histological report. Some of the slides of the early cases were not available for inspection, and in all 79 of the 97 cases have been classified by Professor Drennan.

In 34 (23%) of the present series there was a history of a previous goitre. In most classifications it is usual to include these cases in a separate group referred to under the descriptive term "malignant adenoma". This arrangement has not been retained as the degree of malignancy and the histological appearances in such cases vary within wide limits. Some of the tumours, commencing in a fœtal adenoma, are relatively slow-growing and well-differentiated, while in other cases the tumours are rapidly growing, highly malignant and composed of undifferentiated cells. For the purpose of this investigation, therefore, the cases of malignant adenoma have been grouped according to the histological type.

All cases, whether beginning in an adenoma or not, have been subdivided into three histological groups:

Recent studies in various centres have suggested that in an epidemic of mumps there may be a number of cases which never show any signs or symptoms of parotitis, but have meningitic symptoms and an increase of cells in the C.S.F. It is obvious that such cases may occur apart from an epidemic and so provide a proportion of cases of benign aseptic meningitis. The virus of mumps has been isolated from the C.S.F. as well as the saliva by inoculation into the parotid gland of rhesus monkeys, and into the developing hen's egg. However, the simplest method of diagnosis is the examination of acute and convalescent sera for antibody using either the complement-fixation or fowl red cell agglutination tests.

The virus of herpes simplex has been isolated from the C.S.F. of a suspected case of lymphocytic choriomeningitis and from the central nervous system of four cases of fatal encephalitis in the U.S.A. We isolated this virus at the Wellcome Institute in 1940 from tissues of a fatal case of encephalitis sent us by Major C. H. Stuart-Harris, R.A.M.C. The patient was a soldier who died in France before Dunkirk and though the tissues for virus isolation survived the journey, the tissues prepared for histological examination were destroyed. Thus, proof of origin of the virus was lacking. The part that herpes simplex virus plays in non-fatal infections of the central nervous system will be difficult to determine by serological tests because of the large number of individuals who carry the virus and have antibodies to it in their blood, but changes in antibody titre during the acute and convalescent stages of a suspected case would be significant.

Involvement of the central nervous system in cases of infection with the virus of lymphogranuloma venereum (L.G.V.) has been reported. Virus has been isolated from the C.S.F. by inoculation of animals. The apparently small number of infections with this virus reported in this country suggest, however, that this complication will seldom be seen.

It is probable that there are numerous other viruses still to be isolated from the large group of cases of benign meningitis, encephalitis and encephalomyelitis. In all these cases, the method of attack is essentially the same; collection of whole blood and C.S.F. in the acute stage of the illness and acute and convalescent sera if the case is not fatal.

In fatal cases, pieces of the central nervous system and any other organ which appears to be affected are collected with aseptic precautions and placed in sterile containers. These tissues may be preserved in this manner at 4° C. or lower, but if 50% glycerol-saline is available, it is advisable to add this to the specimens in order to prevent growth of any bacteria that may be present, and also support survival of the virus if it is not possible to store at temperatures below +4° C. At the same time, similar pieces of tissues are placed in fixative for histological examination.

Summary.—The isolation and identification of a neurotropic virus require close co-operation between the clinician and laboratory in the collection of specimens.

All specimens for examination, e.g. nasopharyngeal washings, whole blood, C.S.F., intestinal contents, and post-mortem tissues should be kept at temperatures below 4° C. after collection from the patient. Whole blood and cerebrospinal fluid should be collected in the acute stages of the illness for virus isolation and blood serum in the acute and convalescent stages for antibody studies.

Infection with the known neurotropic viruses appears to be uncommon in England, with the exception of poliomyelitis virus. It is hoped that a more intensive investigation of suspected cases will reveal previously unidentified viruses and further information concerning known infections, such as those of the viruses of lymphocytic choriomeningitis, poliomyelitis and mumps.

Carcinoma of the Thyroid

By J. M. Graham, P.R.C.S.Ed., and R. McWhirter, F.R.C.S.Ed.

The object of this communication is to discuss some of the facts associated with malignant disease of the thyroid gland with special reference to the results of treatment. Our observations are based upon a series of 144 unselected cases which have been drawn mainly from the south-east of Scotland and have been admitted to the Royal Infirmary, Edinburgh. The cases are representative of an area in which simple goitre is not endemic but occurs only sporadically.

Sex incidence.—Of the total number of patients 31 were males and 113 were females. These figures, which show a ratio of 1 male to 3·6 females, may be compared with those of a corresponding series of cases of simple goitre, which were operated on, in which the incidence was 1 male to 9 females.

Age.—The average age of the cases was 59·75 years. The youngest patient was 18 and the oldest was 93.

Histological Classification

The diagnosis of malignant disease was confirmed by histological examination in 97 of the cases. In the remaining 47 cases it was made on clinical grounds alone.

As the histological reports were made originally by several pathologists, we considered it would be advantageous to have the slides reviewed by one experienced authority. We are indebted to Professor Drennan, Professor of Pathology at Edinburgh University, for undertaking this work and for classifying the cases on a uniform basis. His opinion has enabled us to eliminate a few cases in which the original diagnosis of malignant disease was not confirmed, and a review of the subsequent history of these rejected cases has supported the correctness of the final histological report. Some of the slides of the early cases were not available for inspection, and in all 79 of the 97 cases have been classified by Professor Drennan.

In 34 (23%) of the present series there was a history of a previous goitre. In most classifications it is usual to include these cases in a separate group referred to under the descriptive term "malignant adenoma". This arrangement has not been retained as the degree of malignancy and the histological appearances in such cases vary within wide limits. Some of the tumours, commencing in a fœtal adenoma, are relatively slow-growing and well-differentiated, while in other cases the tumours are rapidly growing, highly malignant and composed of undifferentiated cells. For the purpose of this investigation, therefore, the cases of malignant adenoma have been grouped according to the histological type.

All cases, whether beginning in an adenoma or not, have been subdivided into three histological groups:

(1) Adenocarcinoma	18 cases	23%
(2) Papillary Adenocarcinoma ..	13 cases	16%
(3) Undifferentiated Carcinoma	48 cases	61%

Squamous metaplasia may occasionally occur but as a rule this involves only a portion of the tumour which can therefore still be classified into one or other of the above types.

The same rule was adopted where portions of the tumour had a sarcomatous appearance due to the cells having a spindle shape. We agree with Ewing that sarcoma of the thyroid must be exceedingly rare for when large sections are examined it is often possible to trace continuity between the spindle cells and areas which are typically carcinomatous.

A scirrhous reaction is rare in thyroid carcinoma and in this connexion it may be of interest to draw attention to the fact that bony metastases in thyroid cancer are nearly always osteolytic, i.e. as in the soft tissues so in bone the tumour cells fail to excite a reaction to their presence.

(1) *Adenocarcinoma.*—The cases in this group are those in which the cells retain a definite acinous formation which varies in the individual case in the degree of deviation from the normal. In some cases areas of undifferentiated carcinoma are present, but these cases are included within this group when the acinous structure is obvious throughout most of the sections. Variations therefore in the degree of malignancy and the rapidity of growth are observed. The average duration of the malignant disease when the patient first came to hospital was eleven months, and it is characteristic of this group that the tumour grows relatively slowly. The signs of malignancy are obvious when the capsule is invaded and the growth is attached to the adjacent structures. Secondary involvement of the lymph glands was present in 3 of the 18 cases; it was only observed after the tumour had become fixed. Invasion of the vascular spaces is comparatively frequent, and distant metastases were present in 2 of the cases when first seen, and developed later in a considerable number. It was observed that the secondary growths tended to show a greater degree of differentiation than the primary tumours.

(2) *Papillary Adenocarcinoma.*—The history of the cases before and after treatment indicates that this is the most slowly growing and least malignant type of thyroid tumour. The average duration of the disease in the cases in this group before coming to hospital was thirty-eight months, and we have records of cases in which the growth has persisted or recurred over a period of twenty years.

The tumour may be comparatively cystic or apparently solid, depending on the extent to which the cystic spaces are filled with papilliferous tissue. It may reach to a large size before the clinical picture of a fixed, malignant goitre is presented. The signs of malignancy remain localized in the neck as a rule, and there is little tendency to spread by the blood-stream; distant metastases were observed only in one case. The cervical lymph glands were already invaded in 3 of the cases when first seen, and further evidence of the tendency to spread by the lymph stream in this type of carcinoma appeared subsequently, after operation or radiotherapy, in a considerable proportion of the cases.

The histological picture shows a greater degree of differentiation than in other types of carcinoma of the thyroid. The papillary processes are lined by a single layer of cuboidal or columnar epithelium, or in some cases by more than one layer. Compared with the simple type of papilloma the papillary processes have less connective tissue and proportionately more epithelium. Occasionally syncytial masses may be seen or local areas where the epithelial cells are escaping into the stroma or invading the capsule. In the absence of these signs it may be difficult to decide whether a papillary type of tumour is benign or malignant.

The following case may be quoted as an example of this type of carcinoma:—

Doris W., aged 18. Several enlarged glands were noticed on the left side of the neck. They were regarded as tuberculous by her medical man, but no improvement followed sunlight treatment. When she was admitted to hospital eleven months later the left lobe of the thyroid was enlarged to approximately twice its normal size, and was nodular in outline, firm and almost hard in consistence. Five or six enlarged glands were felt beneath the sternomastoid and in the posterior triangle of the neck on the same side. At operation on 9.10.42 the left lobe was found to be adherent to the trachea, but there was no sign of infiltration. The entire left lobe of the thyroid and the isthmus were removed, together with the internal jugular vein to which the glands were adherent, from the level of the tonsillar gland to a short distance above the clavicle. Several glands were also cleared from the posterior triangle. Subsequently the patient received a course of X-ray therapy. She has so far remained free of recurrence.

The entire left lobe was found to be replaced by a greyish-white fleshy tissue, and the cut surface of the lymph glands had a similar appearance. Microscopically the sections from the thyroid lobe showed a highly differentiated papillary adenocarcinoma with more cellular areas in which the papillary structure was absent. The glands were almost entirely replaced by a similar type of carcinoma, but here and there the structure of a lymph gland could be recognized at the periphery.

There seemed no doubt in this case that the tumour was a papillary adenocarcinoma of the thyroid with secondary widespread involvement of the cervical glands on the same side. It could not therefore be confused with the type of case referred to by Crile in which he describes the occurrence of multiple papillary adenomata arising in lateral aberrant thyroid rests, with or without a similar type of papillary tumour in the thyroid gland, which he attributes to multicentric primary growths in aberrant thyroid tissue.

(3) *Undifferentiated Carcinoma.*—This is the most malignant form of goitre. It was the commonest type in our series, occurring in 48 cases (61 %). It usually presents the typical clinical features of malignant disease at an early stage. With few exceptions the tumour grows rapidly and is inoperable within a few months or even weeks of its first appearance. Tumours of this type soon become fixed to the trachea, œsophagus and adjacent structures, and pressure symptoms are common. Secondary involvement of the lymph glands was present in 12 of the 48 cases. Distant metastases were found in 8 of the cases at the time of their first examination. Frequently death occurs before metastases, due to blood-spread, have time to become clinically obvious.

The microscopic picture usually found is that of masses or sheets of uniform spheroidal or polygonal cells with little or no stroma. However this uniformity of cell type is not always present and a varying degree of pleomorphism may occur. In the more extreme examples typical multinucleated giant cells may be observed in extensive portions of the tumour.

The following is an example of an exceptional case of undifferentiated carcinoma in which the rate of growth was extremely slow:

Robert A., aged 57 years. A swelling in the left lobe of the thyroid had been present for several years. During a period of six months it had slowly increased in size. The tumour was recognized as a solitary adenoma, firm in consistence and about 6 cm. in diameter. It appeared to be partly fixed to the deeper structures. The tumour was removed by enucleation-resection on 10.3.31. Both macroscopically and microscopically it showed the characteristics of a fœtal adenoma of long standing. There was evidence, however, of more active growth towards the surface, where the cells were spheroidal in type without acinous formation.

Five years later a local recurrence in the neck was removed, and this showed the structure of an undifferentiated carcinoma with little evidence of active mitosis.

In 1939 metastases appeared in the lungs. The patient remained in comparatively good health, although subsequent X-ray photographs showed considerable extension of the metastatic deposits in the chest, until shortly before his death in 1946.

CARCINOMA OF ABERRANT THYROID TISSUE

Three of the tumours in our series had their origin in aberrant thyroid tissue. Most aberrant thyroid tumours show a papillary structure, whether benign or malignant. The cases now referred to illustrate the three main histological types which carcinoma of the thyroid may assume.

(1) *Adenocarcinoma of lateral aberrant thyroid.*—William C., aged 33. The tumour was situated in the right side of the neck opposite the angle of the mandible. It had slowly increased in size and even at the end of three years was only 4×3 cm. Histologically it had the structure of an adeno-

carcinoma which was well encapsulated, and was obviously of a low grade of malignancy. It was removed in 1944, and the patient subsequently received X-ray treatment. There has been no recurrence.

(2) *Papillary adenocarcinoma of lateral aberrant thyroid.*—Job B., aged 56. A tumour on the right side of the neck was first noticed in 1923. When removed in 1924 it formed a large, encapsuled and partly cystic growth which lay beneath the sternomastoid and in the supraclavicular fossa. It was adherent to the internal jugular and subclavian veins. It was not connected with the thyroid gland. A recurrence appeared two years later, but the patient was not seen until 1936. The tumour then formed a large fixed mass in the lower part of the neck on the right side, extending into the superior mediastinum and into both axillæ. No improvement followed X-ray therapy.

The original tumour had the structure of a papillary adenoma. Sections made from the growth thirteen years after it had first been noticed showed the typical appearance of a papillary adenocarcinoma. The papillæ had more evidence of epithelial activity than formerly, and there were areas also of undifferentiated carcinoma.

In spite of the extent of the growth, the patient's general condition was good, and he was successfully operated on in two stages for simple hypertrophy of the prostate. He died five months later without signs of metastases elsewhere.

The case illustrates the slow rate of growth and the local nature of this type of malignant disease.

(3) *Undifferentiated carcinoma in a lingual thyroid.*—Mrs. I., aged 47. In childhood a thyroglossal cyst had been removed from the mid-line of the neck. A lingual thyroid was noted at the level of the hyoid in 1931. As the patient suffered no inconvenience operation was not considered. When she reported to hospital five years later the swelling at the back of the tongue was much increased in size and caused considerable discomfort in swallowing. A firm, enlarged gland was present in the right tonsillar region. The growth in the tongue was firm in consistence and was more extensive on the right side. Although not ulcerated its malignant nature was apparent. On X-ray examination of the neck the tumour could be seen projecting backwards in the lateral view, and the usual shadow of the thyroid gland was absent from its normal position.

A course of X-ray treatment was given. The enlarged gland disappeared, and the tumour in the tongue was reduced in size. Ten months later the patient returned in poor condition. Several indurated masses could be felt in the lateral walls of the pharynx and in the anterior pillar of the fauces. An X-ray examination of the chest showed gross metastases in the lungs. The patient died in hospital, and at the post-mortem a shrunken carcinoma with considerable fibrosis was found in the back of the tongue. Sections from the tongue and from the metastases showed an undifferentiated form of carcinoma similar to that commonly seen in the thyroid.

DIFFERENTIAL DIAGNOSIS

In many cases the nature of the condition is only too obvious. The chief problems of diagnosis are related to the early stages. We have had no case in our series in which the diagnosis was made purely on histological grounds. The diagnosis was obvious or at least suspected clinically in all but one case in which, however, the specimen after operation showed macroscopically the characteristics of a carcinoma. In this respect the series differs materially from many recorded, especially in American literature, in which a high proportion of the cases are examples of early malignant adenoma showing only microscopically the evidence of malignancy. Few, if any, cases of such a nature can have been missed in our series, as we have no record of a case, in which the histological diagnosis of simple adenoma was originally made, returning later with metastases or local recurrence.

The appearance of a nodular goitre in a patient approaching middle age, recent increase in the size of a goitre, or alteration in its consistence or outline should be regarded with suspicion. Fixation of the swelling to the trachea while the thyroid still moves freely on swallowing is one of the earliest signs to appear. X-ray examination of the neck will show the position of the trachea. Forward displacement of the trachea with antero-posterior narrowing of the lumen is much more suggestive of carcinoma than of simple goitre. A barium swallow in cases with dysphagia frequently shows narrowing of the œsophagus such as is rarely seen in simple goitre.

A calcified adenoma or nodular goitre may be very hard, but the presence of even extensive calcification does not exclude carcinoma. Evidence of calcification has been present in several of our cases.

An old nodular goitre which has undergone degenerative changes with varying amounts of fibrosis and lymphocytic infiltration may closely simulate malignant disease. Such cases merge into true Riedel's or ligneous thyroiditis, which in our experience is much rarer than malignant disease.

Riedel's thyroiditis.—The chief characteristic feature of ligneous thyroiditis is the densely hard consistence. The swelling may be limited to one lobe or may involve the whole of the thyroid gland. It is usually of limited size, smooth or only slightly nodular in outline and, although it may be fixed, of slower growth than the type of carcinoma with which it is likely to be confused. The swelling, which may be tender, is not associated with enlargement of the lymph glands.

Hashimoto's thyroiditis or lymphogenous goitre has in the past frequently been mistaken for malignant disease, but a careful consideration of the facts of the case will usually enable it to be distinguished. It occurs in women and the whole gland is obviously enlarged to a moderate extent. It is smooth in outline and firm rather than hard in consistence. The gland outline is exceptionally well-defined and mobilization of the lobes, should operation be undertaken, is unusually easy. Although with increasing experience most cases of Hashimoto's thyroiditis can be recognized, there are exceptions in which the gland is firmer or more fixed than usual, but the nature of the goitre should be apparent at operation or if a biopsy is done.

Syphilitic thyroiditis.—We have seen two cases of gummatous disease and one of interstitial fibrosis due to syphilis in which malignant disease was simulated. In two of the cases the history and other signs suggested the diagnosis, and the condition was relieved by antisyphilitic treatment. In the remaining case an emergency operation was required. The patient, a male, aged 17, was admitted suffering from dysphagia and severe dyspnœa associated with a swelling in the region of the thyroid which had first been noticed ten weeks previously. The thyroid was irregularly enlarged and firm, with a fixed, tumour-like mass in the region of the isthmus. A pre-operative diagnosis of carcinoma of the thyroid was made, and appeared to be confirmed at the time of operation by the fact that the tissue had infiltrated as well as compressed the trachea. The tumour and a portion of the anterior wall of the trachea were removed, and the patient was left with a tracheotomy. Sections of the tissue on examination showed the typical changes of a gumma, and the Wassermann was strongly positive. The patient showed none of the ordinary signs of congenital syphilis from which he was suffering.

Hæmorrhage into a thyroid cyst.—We have seen several cases of rapid enlargement of a thyroid cyst due to hæmorrhage which were readily recognized as such. In one case, however—that of an elderly woman with a large cyst—the hæmorrhage had evidently been recurrent and gradual. When admitted as an emergency case she was suffering from dyspnœa which had prevented her from lying down for three weeks and which had become extreme. The swelling and tension in the neck were such that there seemed little doubt that the symptoms were due to a rapidly growing carcinoma. Operation, reluctantly undertaken, led to the happiest result.

Secondary carcinoma of the thyroid.—The fact that malignant goitre may be due to direct spread from an epithelioma of the pharynx or cervical œsophagus requires emphasis. The dysphagia present may be regarded as due to the thyroid enlargement. Direct examination, therefore, may be necessary to exclude a primary growth in the gullet.

TREATMENT OF CARCINOMA OF THE THYROID

Factors affecting the survival rate.—Before discussing the results obtained attention must be drawn to two points which have an important bearing on the survival rate.

(1) The review differs from most publications in that it is not confined to cases actually treated but includes all cases referred to a large general hospital. In 53% of the cases either no treatment at all was given or such treatment as was possible was purely palliative. It will be clear, therefore, that the survey is not limited to early operable cases.

(2) The series contains a high proportion of undifferentiated carcinomata. These cases constituted 61% of the total classified cases. Undifferentiated carcinomata are rapidly growing and are often inoperable by the time they are first seen. Actually it was found that 25% of them died within one month and 50% were dead within four months of the time when they first came to hospital.

The survival rate of cases not histologically proven.—33% of the cases were not histologically proven but as already noted many cases were advanced and in some of the rapidly growing tumours the patient's distress was so great and the necessity for treatment so urgent that it was considered inadvisable to subject the patient even to such a minor procedure as a biopsy. In a few such cases where a biopsy was attempted the trauma of exposing the tumour and the few days' delay in commencing treatment led to the death of the patient. As will be shown later many of these tumours respond rapidly to X-ray therapy and in a very short time there is no tumour tissue available for removal. The following table shows that, of the cases in which the diagnosis was established on clinical grounds alone, the survival rate was not higher than where the diagnosis was confirmed histologically.

TABLE I
HISTOLOGICALLY PROVEN

No. of Cases = 97 (67% of Total)

Years after treatment	Exposed to risk	q_x*	Survival rate
0	83·5	·5868	100%
1	31·5	·2540	41·32%
2	19	·0526	30·82%
3	16	·0625	29·20%
4	12	·0833	27·38%
5			25·10%

TABLE II
NOT HISTOLOGICALLY PROVEN
No. of Cases = 47 (33% of Total)

Years after treatment	Exposed to risk	q_x*	Survival rate
0	45	·6667	100%
1	14	·1428	33·33%
2	12	·0000	28·57%
3	11	·0909	28·57%
4	8·5	·1176	25·97%
5			22·92%

*The "q_x" value is the probability or chance of any one patient dying in any particular year. The figures are obtained by the method of calculation suggested by Dr. Lewis-Fáning and they provide a more reliable indication of the results than those obtainable by more ordinary methods. It will be noted that the survival rate for each year is given in the last column.

The method of investigating the results.—In determining the best method of treatment the ideal approach to the problem would be to compare a series of cases treated by surgery alone with a comparable series treated by X-rays alone. Unfortunately this was not possible because surgical removal was confined to operable cases and only inoperable cases were treated by X-rays alone.

The problem of determining the most appropriate method of treatment had therefore to be approached in a more indirect manner. Two methods of investigation appeared to be worth considering:

(*a*) To ascertain the results according to the clinical extent of the disease.
(*b*) To ascertain the results according to the histological nature of the tumour.

(*a*) *The results according to the clinical extent of the disease.*—For the purposes of this paper the following clinical classification was adopted.

Operable: The primary tumour was either mobile or only slightly fixed to the adjacent tissues. If glands were present they must be mobile and confined to one side of the neck.

Inoperable: No distant metastases. All cases in which the primary tumour was extensively fixed to the adjacent tissues. Bilateral glands or fixed glands confined to the neck.

Inoperable: Distant metastases present. All cases with clinical or radiographic evidence of distant metastases.

Recurrent: All cases originally treated elsewhere and only referred when local recurrences or distant metastases had taken place.

TABLE III

TREATMENT METHODS USED

	Total	Radical Surgery with or without X-rays	Radical X-rays	Palliative treatment	No treatment
Operable	29	29	—	0	0
Inoperable: no distant metastases	84	0	39	37	8
Inoperable: distant metastases	24	0	0	16	8
Recurrent	7	0	0	6	1
Total	144	29	39	59	17
%	100%	20%	27%	41%	12%

All cases with distant metastases and all the recurrent cases are dead and need not be considered further.

Of the 29 operable cases all were fully treated and so far as could be ascertained at the time of the operation the tumour was apparently completely removed. Seven cases were treated by complete thyroidectomy and the remainder by subtotal thyroidectomy. There were no post-operative deaths. In 18 cases post-operative X-ray therapy was given. The five-year survival rate was 73% as is shown in Table IV.

TABLE IV

29 OPERABLE CASES (20% OF THE TOTAL)

Years after treatment	Exposed to risk	q_x	Survival rate
0	26	·2692	100
1	17·5	·0000	73·08%
2	14	·0000	73·08%
3	13	·0000	73·08%
4	11	·0000	73·08%
5			73·08%

Of the 11 cases alive at the end of five years, 4 had immediate post-operative X-ray therapy, and of the remaining 7 which were treated by surgery alone in the first place 4 recurred within five years and were then treated by X-rays. After five years a further 2 had recurrences treated by X-rays leaving only one symptom-free case treated by surgery alone.

Of the 84 inoperable cases without clinical or radiographic evidence of distant metastases it will be seen from Table III that 8 had no treatment at all and that 37 had only palliative treatment. In a number of cases surgical removal was attempted but had to be abandoned because of the extent of the disease. In spite of what has been said it will be seen from Table V that 16% of the cases were alive at the end of five years.

TABLE V

INOPERABLE. NO DISTANT METASTASES
No. of Cases = 84 (58% of Total)

Years after treatment	Exposed to risk	q_x	Survival rate
0	76	·6842	100%
1	22	·2727	31·58%
2	16	·1250	22·97%
3	12	·0000	20·10%
4	9·5	·2105	20·10%
5			15·87%

In only 39 of the 84 cases could the X-ray treatment be considered adequate, and of this more limited series 29% were alive at the end of five years.

TABLE VI

INOPERABLE. NO DISTANT METASTASES
RADICAL X-RAYS
No. of Cases = 39

Years after treatment	Exposed to risk	q_x	Survival rate
0	38	·5526	100%
1	16	·1250	44·74%
2	14	·1428	39·15%
3	10	·0000	33·56%
4	7·5	·1333	33·56%
5			29·09%

(*b*) *Results according to the histological type of tumour.*—In the following tables all cases whether treated or not are included. The numbers are small and the results must be accepted with caution until larger numbers have been treated.

Of the 18 cases of adenocarcinoma 46% were alive at the end of five years.

TABLE VII

ADENOCARCINOMA. ALL CASES HISTOLOGICALLY PROVEN
No. of Cases = 18

Years after treatment	Exposed to risk	q_x	Survival rate
0	15·5	·3871	100%
1	8	·2500	61·3%
2	4	·0000	46·0%
3	4	·0000	46·0%
4	2	·0000	46·0%
5			46·0%

Of the 13 cases of papillary adenocarcinoma 40% were alive at the end of five years.

TABLE VIII

PAPILLARY ADENOCARCINOMA. ALL CASES HISTOLOGICALLY PROVEN
No. of Cases = 13

Years after treatment	Exposed to risk	q_x	Survival rate
0	10·5	·1905	100%
1	8	·1250	80·95%
2	7	·1429	70·83%
3	6	·1667	60·71%
4	5	·2000	50·59%
5			40·47%

Both the adenocarcinomata and the papillary adenocarcinomata are as a rule slowly-growing tumours and untreated cases or incompletely treated cases may survive for more than five years. The efficacy of treatment could be ascertained more clearly in these cases by a study of the ten-year survival rate. In both groups of cases surgery and X-rays were employed in their treatment but surgery appeared to play the more important rôle.

In the undifferentiated tumours on the other hand, the five-year survival rate is a good guide to the value of treatment for they are nearly always very rapidly growing and hence rapidly fatal unless successfully treated. In spite of the fact that many are highly radiosensitive high five-year survival rates are not to be expected for these tumours disseminate early and widely and 80% were inoperable by the time they were first seen. The five-year survival rate of all cases was 14% and as no case treated by surgery alone survived for five years the results must be attributed to X-ray treatment.

TABLE IX

UNDIFFERENTIATED CARCINOMA. ALL CASES HISTOLOGICALLY PROVEN

No. of Cases = 48

Years after treatment	Exposed to risk	q	Survival rate
0	43·5	·7586	100%
1	10	·4000	24·14%
2	5	·0000	14·48%
3	4	·0000	14·48%
4	3	·0000	14·48%
5			14·48%

Mention has been made of the fact that many undifferentiated carcinomata are highly radiosensitive and indeed they are amongst the most radiosensitive tumours of the whole body. Their radiosensitivity may be compared with the medulloblastomata, the seminomata and with certain types of reticulum-cell sarcomata. The sensitive types respond far more rapidly to treatment than lymphogenous goitre and absolute proof that these sensitive cases were, in fact, malignant tumours has been ascertained beyond any doubt by the observance of metastases as well as by histological examination.

The undifferentiated carcinomata are often admitted to hospital as emergencies and must be treated forthwith or the patient will die. It is doubtful if the urgency of these cases and the value of X-rays in their treatment is fully appreciated by members of hospital staffs. Too often they are given morphia or an attempt is made to perform a tracheotomy. When treated by X-rays dramatic relief may be obtained in as short a time as twenty-four hours.

Conclusions from the Two Investigations.—From the foregoing analysis the following points emerge:

As might be expected the best results are obtained in the early (i.e. the operable) cases where surgical removal with or without post-operative X-ray therapy gives a satisfactory five-year survival rate. Unfortunately only 20% of the total cases were in this early category. The value of post-operative X-rays is difficult to assess in this group as the numbers are too small to permit of a more detailed analysis.

In the inoperable cases such surgical intervention as was undertaken was limited and amounted as a rule only to biopsy. In no case was all the tumour tissue removed. The five-year survival rate obtained must be credited to X-rays alone and the figures especially in the cases treated by X-rays show that X-rays have a definite and useful part to play in the treatment of thyroid carcinoma even when the tumour is completely inoperable.

Examination of the results according to the histological type of the tumour shows that the histological type is an important guide to the five-year survival rate and that better results are to be expected in the tumours showing some degree of differentiation.

The analysis, while of some value, does not clearly indicate the best method of treatment to be adopted, but in view of the obvious importance of the histological type of the tumour it was decided to carry this aspect of the investigation further.

THE RADIOSENSITIVITY OF THE DIFFERENT HISTOLOGICAL TYPES

In determining the radiosensitivity of the three histological subdivisions account was taken, in this analysis, only of the rate of response of the tumour tissue treated irrespective of whether the primary tumour itself or only a gland or metastatic deposit was being treated. If the tumour diminished rapidly in size it was regarded as radiosensitive and all other cases were placed in the radioresistant category. The survival rate was ignored because clearly a case might respond well in the treated area and yet die in a short time from some other known or unknown deposit.

In 19 cases where the X-ray treatment followed surgery it appeared possible that all the tumour tissue had been removed and these cases were, of course, excluded from the analysis. In a further 61 cases either no X-ray treatment was given or else the dosage was so low that no useful assessment could be made. In the remaining 64 cases sufficient dosage was given to the clinically obvious tumour to determine its sensitivity. The results are shown in Table X.

TABLE X

RADIOSENSITIVITY

Radiosensitivity Determined	64
? No Tissue to test Radiosensitivity	19
No treatment or palliative treatment	61
Total ..	144

	Adeno-carcinoma	Pap.adeno-carcinoma	Undiff. carcinoma	Type unknown	Total
Radiosensitive	0	0	11	17	28
Not radiosensitive	7	3	9	17	36
Total	7	3	20	34	64
%Radiosensitive	0%	0%	55%	50%	44%

Somewhat surprisingly it was found that all the tumours proving to be radiosensitive were in the completely undifferentiated category. The numbers of differentiated tumours are too small for the conclusion to be drawn that all differentiated tumours are radioresistant and clearly further observations require to be made.

The other interesting point is that all the undifferentiated tumours were not radiosensitive—in fact only 55% were radiosensitive. So far it has not been possible to distinguish these two types from one another by histological examination, thus recalling an observation made in a previous communication to this Society where it was shown that the radiosensitive and the radioresistant meningiomata cannot be distinguished from one another by means of histological examination. (*Proc. R. Soc. Med.*, 1946, 39, 673.)

However, other findings are of some help in distinguishing the radiosensitive group. The average duration of symptoms in the radiosensitive cases was 6·3 months and of the radioresistant cases sixteen months. Of the 28 radiosensitive cases only three had pre-existing adenomata and the tumour as a rule involved the gland diffusely, producing a smooth uniform enlargement of the whole gland.

It will be noted that of the 64 cases 44% were radiosensitive and therefore suitable for treatment by radiotherapy. The five year survival rate however is poor in these cases because of the early spread of cells to distant sites. Where death took place in a short period of time it was found that most of the patients died from metastases in the lungs. Because of the already high tendency of these tumours to spread to the lungs the greatest care must be taken not to carry out any procedure which may possibly increase this tendency to metastasize. It follows therefore if a tumour is possibly of the radiosensitive type that any attempt at surgical removal should not be made, for incomplete removal will almost certainly bring about dissemination of cells. Similarly, resort to tracheotomy in cases of severe dyspnœa is inadvisable, not only because this will only prolong life by a few days or weeks, but also because a tracheotomy under these conditions will so disturb the tumour that dissemination of cells is highly probable and because tracheotomy will interfere with the application of X-rays. These observations are further supported by the findings in other tumours, and the work done on breast carcinoma in Edinburgh suggests that spread of tumour cells by operation is not uncommon. In making this statement it will be appreciated that the remarks apply only to possibly radiosensitive tumours. Where tumours are likely to be insensitive considerable palliative relief may be obtained by the removal of as much of the tumour as possible and if the tumour is slowly growing this relief may last for a considerable time.

The table also shows clearly the value of the method of histological classification adopted and suggests that the older classifications which recognized the malignant adenoma as a subdivision might well be abandoned. As already indicated the malignant adenoma may consist of any of the three above types. It is a clinical term and gives no guide to the radiosensitivity of a tumour and therefore to the best method or combination of methods to be used.

INDICATIONS FOR OPERATION

Operation is indicated when there is a reasonable prospect of removing the tumour completely. If the growth is limited to part of a lobe the entire lobe should be removed with the isthmus. Limited fixation of the tumour does not exclude an operation on the same lines. When the nature of the goitre is uncertain at the operation it is better to remove the lobe rather than to do a partial resection. Extensive involvement of both lobes usually means that complete excision of the growth is impossible. A varying amount of the second lobe may, however, be removed. A complete thyroidectomy is rarely indicated.

If enlarged glands are present the case is usually inoperable. The presence of enlarged glands and of a slow-growing tumour of the thyroid suggesting a papillary adenocarcinoma is an indication for a radical operation including the removal of the affected thyroid lobe, even if it is adherent, and of the glands by a wide and thorough dissection.

In operable cases any signs of invasion of the superficial veins require a more extensive operation, including removal of the internal jugular vein together with the affected lobe with its veins intact, as suggested by Joll.

When the tumour is fixed and complete removal is regarded as impossible, a biopsy only is done. As already noted the incomplete removal of an undifferentiated and therefore usually highly malignant goitre is likely to be followed by extensive local recurrence and rapid dissemination to distant sites, but in tumours likely to be resistant considerable palliative relief may be provided by such a procedure.

The relation between simple goitre and carcinoma of the thyroid is proved by the high incidence of malignant disease of the thyroid in endemic centres and by the frequent history of a pre-existing goitre. The probability that most cases of carcinoma commencing in a pre-existing goitre begin in a fœtal adenoma is a sound reason for recommending the removal of all solitary adenomata without delay. Adenomata should be removed by enucleation-resection rather than by enucleation alone. The advisability of operation should also be considered in other forms of nodular goitre.

The analysis, while of some value, does not clearly indicate the best method of treatment to be adopted, but in view of the obvious importance of the histological type of the tumour it was decided to carry this aspect of the investigation further.

THE RADIOSENSITIVITY OF THE DIFFERENT HISTOLOGICAL TYPES

In determining the radiosensitivity of the three histological subdivisions account was taken, in this analysis, only of the rate of response of the tumour tissue treated irrespective of whether the primary tumour itself or only a gland or metastatic deposit was being treated. If the tumour diminished rapidly in size it was regarded as radiosensitive and all other cases were placed in the radioresistant category. The survival rate was ignored because clearly a case might respond well in the treated area and yet die in a short time from some other known or unknown deposit.

In 19 cases where the X-ray treatment followed surgery it appeared possible that all the tumour tissue had been removed and these cases were, of course, excluded from the analysis. In a further 61 cases either no X-ray treatment was given or else the dosage was so low that no useful assessment could be made. In the remaining 64 cases sufficient dosage was given to the clinically obvious tumour to determine its sensitivity. The results are shown in Table X.

TABLE X

RADIOSENSITIVITY

Radiosensitivity Determined	64
? No Tissue to test Radiosensitivity	19
No treatment or palliative treatment	61
Total ..	144

	Adeno-carcinoma	Pap.adeno-carcinoma	Undiff. carcinoma	Type unknown	Total
Radiosensitive	0	0	11	17	28
Not radiosensitive	7	3	9	17	36
Total	7	3	20	34	64
%Radiosensitive	0%	0%	55%	50%	44%

Somewhat surprisingly it was found that all the tumours proving to be radiosensitive were in the completely undifferentiated category. The numbers of differentiated tumours are too small for the conclusion to be drawn that all differentiated tumours are radioresistant and clearly further observations require to be made.

The other interesting point is that all the undifferentiated tumours were not radiosensitive—in fact only 55% were radiosensitive. So far it has not been possible to distinguish these two types from one another by histological examination, thus recalling an observation made in a previous communication to this Society where it was shown that the radiosensitive and the radioresistant meningiomata cannot be distinguished from one another by means of histological examination. (*Proc. R. Soc. Med.*, 1946, 39, 673.)

However, other findings are of some help in distinguishing the radiosensitive group. The average duration of symptoms in the radiosensitive cases was 6·3 months and of the radioresistant cases sixteen months. Of the 28 radiosensitive cases only three had pre-existing adenomata and the tumour as a rule involved the gland diffusely, producing a smooth uniform enlargement of the whole gland.

It will be noted that of the 64 cases 44% were radiosensitive and therefore suitable for treatment by radiotherapy. The five year survival rate however is poor in these cases because of the early spread of cells to distant sites. Where death took place in a short period of time it was found that most of the patients died from metastases

JOINT MEETING WITH THE SOCIÉTÉ DE NEUROLOGIE DE PARIS HELD ON APRIL 15 AND 17, 1947

[*April* 15, 1947]

DISCUSSION ON PENICILLIN IN NEUROLOGY

Sir Hugh Cairns: *Penicillin in suppurative conditions of the brain and meninges* [Abstract].—This paper summarizes four years' experience in the use of penicillin in pyogenic infections of the brain and meninges.

THEORY OF PENICILLIN TREATMENT

(1) *General theory.*—Penicillin must be given access to all infecting organisms; the limited powers of penicillin to penetrate any large non-vascular area of infection have not always been fully appreciated. The application of this principle in treatment of brain wounds, brain abscess, and pyogenic meningitis was discussed.

(2) *Intrathecal penicillin.*—Dosage and routes were discussed. Increasing the dose does not increase the persistence of penicillin in the C.S.F. or the survival rate in meningitis, and it may do harm.

(3) *Subdural penicillin* passes rapidly into the blood-stream. Consequently, for purulent pachymeningitis, subdural injections should be given every four to six hours. Exceptionally penicillin disappears rapidly from the subarachnoid space by leakage into the subdural space.

(4) *Systemic penicillin* does not pass into the C.S.F. in adequate amounts, but is of subsidiary value in most intracranial infections for a variety of reasons.

Results of treatment.—The immediate treatment of a bacteriologically unidentified meningitis should be by systemic sulphonamides and systemic penicillin. Intrathecal penicillin should usually not be given until the organism in the C.S.F. has been identified and aseptic precautions can be exercised in its use; but in fulminating meningitis it may occasionally be necessary to use penicillin intrathecally immediately.

Leptomeningitis will be discussed by my colleague Dr. Honor Smith.

Purulent pachymeningitis.—This condition is most commonly produced by a non-B. hæmolytic streptococcus, spreading from osteomyelitis of the skull secondary to infection of the paranasal sinuses. Pus spreads in the subdural space, paralysing the underlying brain cortex. Formerly this condition was almost invariably fatal but since penicillin has been freely available, we have saved 6 of 11 patients.

Brain abscess.—With the help of penicillin it has been possible to extirpate successfully cerebellar abscess and, following the work of Le Beau, bronchogenic abscess. Thus, complete extirpation of brain abscess, which we owe to the classic work of Clovis Vincent, has now become the standard method of treatment for almost all varieties of brain abscess. Though penicillin has greatly improved the prospects in the more difficult types of brain abscess, it has in no way diminished the need for unremitting expert care in each individual case.

Prevention of infection of operative wounds.—For over two years a powder of calcium penicillin mixed with sulpha-mezathine (5,000 units per gramme) has been insufflated into all clean operation wounds. This gives a level of over 0·02 u./c.c. penicillin in the wound juices for twelve to eighteen hours, sufficient to inhibit the growth of the common pyogenic contaminants of the wound during that period. With this powder the incidence of post-operative infection, as compared with its incidence in the previous six and a half years, has been significantly reduced.

Dr. Honor V. Smith (*Nuffield Department of Surgery, Oxford*): *The treatment of leptomeningitis with penicillin.*—Most of our work on the treatment of meningitis with penicillin has been done on pneumococcal meningitis (Smith, Duthie and Cairns, 1946), but we have found

METHOD OF X-RAY TREATMENT

Until recently the method of X-ray treatment used consisted of two opposed lateral fields to the thyroid gland and treatment was regarded as complete if a minimum dose of 3,500 r was delivered to the tumour in three weeks or less. A single anterior field was used to treat retrosternal carcinomata and to treat retrosternal extensions of a carcinoma in the neck.

When the local response to X-ray treatment was good local recurrences did not take place subsequently but the results were poor on account of the high tendency of these tumours to metastasize to the lungs. In an attempt to overcome this difficulty, and because the tumours worth treating by radiotherapy are generally highly radiosensitive, it was decided to treat all undifferentiated tumours by wide-field X-ray therapy. The field extends from the chin above to the lower limits of the thorax below. Anterior and posterior fields are used and a surface dose of 2,500 r is given in daily fractions over approximately five weeks. If during the course of treatment it is seen that the primary tumour is not responding the wide-field treatment is stopped and the patient is given localized treatment to the thyroid gland only. It is hoped by including the thorax it will be possible to raise the survival rate of the radiosensitive tumours and the immediate results can be regarded as promising.

Care must be taken in all cases treated by wide-field X-ray treatment to avoid producing at a later date a serious or even fatal anæmia. Observations in thyroid and in other tumours indicate that this difficulty can be overcome by carefully noting the blood platelet level and by terminating treatment if the platelet count should fall below 100,000 cells per c.mm. Further details of this work will shortly be published by Dr. W. Court Brown to whom we are indebted for the examinations made.

CONCLUSIONS

While the direct comparison of treatment methods proved impossible the other observations indicate reasonably clearly that the following points can meanwhile be accepted as a useful working basis until they are modified by further observations.

(1) If the patient has a localized nodule of some standing and the case is operable (as defined) every effort should be made to remove the tumour radically by surgery. The value of subsequent X-ray therapy is doubtful if the tumour proves to be an adenocarcinoma or a papillary adenocarcinoma, but as the observations were made on a limited number of cases it would be wise to continue its use until a more definite statement can be made. If the case proves to be an undifferentiated carcinoma post-operative X-ray treatment should be given.

(2) If the patient has diffuse uniform enlargement of the whole or greater part of the thyroid gland and if the duration of the swelling is short the tumour is probably an undifferentiated carcinoma and X-ray treatment is indicated. If present methods prove successful wide-field X-ray treatment should be given so as to include the thorax.

(3) A biopsy should be obtained in all cases where this is possible so that further evidence may be obtained regarding the value of the histological type of the tumour as a guide to the best method of treatment. If, however, dyspnœa is very marked X-ray treatment should be commenced immediately because any delay in these cases may lead to the death of the patient.

(4) Surgical removal of as much tumour tissue as possible in an advanced carcinoma which clinically is possibly an undifferentiated carcinoma should not be attempted because the surgical interference must increase the risk of dissemination of tumour cells outwith the area to be irradiated.

cranial abscess is present it is imperative to give the intrathecal penicillin by ventricular injections as in such cases lumbar and cisternal injections are not only useless but highly dangerous. Further, the abscess itself demands surgical treatment on the lines already described by Sir Hugh Cairns (1947).

Meningococcal meningitis.—Intrathecal penicillin is rarely required in the treatment of meningococcal meningitis since the results obtained by sulphonamides alone are excellent. It is, however, indicated if the patient shows signs of sulphonamide intolerance or when he is vomiting persistently or is so severely dehydrated that sulphonamide therapy carries a grave risk of renal block. It is also indicated in the rare cases when the response to sulphonamides is disappointing.

CONCLUSION

Finally, the penicillin therapy of meningitis must be supplemented by the closest observation of the patient and the best of nursing care. No two cases are ever quite alike and each must be treated on its own merits. If these conditions are fulfilled recovery should be expected. Comparison of the results obtained in our first 38 cases with those of a series of cases treated in the same hospital on sulphonamides alone, illustrates the change in prognosis brought about by the introduction of penicillin (Smith, Duthie and Cairns, 1946, fig. 8).

Dr. C. Worster-Drought: *Penicillin in neurosyphilis* [Abstract[1]].—Penicillin has a definite and established place in the treatment of neurosyphilis.

Most of the present-day experiences of penicillin treatment in neurosyphilis are based on the "standard" course established in 1944 for the treatment of early syphilis in the British Services and in the U.S. Army in Europe, viz.: a total dosage of 2,400,000 international units given by parenteral injection every three hours, day and night, for seven and a half days.

In view of the percentage of relapses even in early syphilis (7-15%) it is doubtful if this course is sufficient for neurosyphilis. It is suggested that a total dosage of at least 3,000,000 units be given to all cases of neurosyphilis and that in parenchymatous neurosyphilis the total dosage should reach 4,000,000 to 5,000,000 units.

It may eventually prove unnecessary to keep penicillin in the blood at as high a continuous level as possible throughout the period of treatment. If so, equally good therapeutic effects might be obtainable with larger doses of penicillin given at longer intervals (300,000 units given every twelve hours or 500,000 units every twenty-four hours for eight to fifteen days). Such a method would enable cases of chronic neurosyphilis to be treated as out-patients.

Intramuscular injection is the best method of administering penicillin. For various reasons, the intravenous route—either by continuous drip or by repeated single injection—has little to commend it.

If it is eventually shown that a continuous and fairly constant level of penicillin in the blood is really necessary for full therapeutic effects, the preparations of penicillin in oil and beeswax may prove useful. It has been shown that following a deep subcutaneous injection of 300,000 units in oil-wax, penicillin can be found in the blood serum for sixteen to twenty hours but not at the end of twenty-four hours. Thus, cases of neurosyphilis could be treated as out-patients with one injection of 300,000 units daily for ten to fourteen days. A disadvantage is that persistence of the oily preparation in the tissues has been reported and that occasionally a localized and tender induration appears three days after injection of the oil-wax penicillin. Further trials are necessary.

There is no evidence that the intrathecal administration of penicillin is of greater therapeutic value in neurosyphilis than when the remedy is given by intramuscular injection. Owing to the resulting reactions and the various additional risks, intrathecal injection of penicillin is best avoided in most cases of neurosyphilis.

Owing to the risk of possible Herxheimer-Jarisch reactions following the first doses of penicillin, all cases of neurosyphilis should receive an initial series of bismuth injections before starting the full course of penicillin.

In view of the percentage of relapses reported in cases even of early syphilis treated with penicillin alone and in spite of the initial beneficial effects following penicillin treatment, the author has at no time abandoned the use of arsenicals and bismuth—used in conjunction our methods applicable to any variety of meningitis in which the infecting organism is sensitive to penicillin. These methods will therefore be briefly described together with the principal difficulties we have encountered.

---

[1] Published in full: *Brit. med. J.*, 1947 (ii), 559.

Our routine treatment in an uncomplicated case is as follows (Smith, Duthie and Cairns, 1946, fig. 1): penicillin is given once or twice daily for a minimum of five days by intrathecal injection in doses of 8,000 to 16,000 units, made up in solutions of 2,000 units per c.c. We have found that larger doses than this, especially when given in concentrated solution, are no more effective and may actually be harmful. Intrathecal injections are essential because penicillin will not pass from the blood to the C.S.F. in anything except minute amounts (Kinsman and d'Alonzo, 1946; Smith, Duthie and Cairns, 1946). Intrathecal penicillin may be given by the lumbar, cisternal or ventricular injection; occasionally it is necessary to use all three routes, but in uncomplicated cases we have found the lumbar route safe, convenient and effective. In addition to intrathecal penicillin, sulphonamides are given in full doses and up to the present time we have found sulphadiazine the preparation of choice. This is given to supplement the intrathecal penicillin. The latter can only be fully effective when it can circulate freely in the C.S.F. and thus reach all parts of the cerebrospinal pathways. To achieve this, it is essential that these pathways are patent and we have evidence that sulphonamides are able to prevent or delay the deposition of fibrino-pus which, in the untreated case, is so apt to block these pathways. Sulphonamides should be given as soon as meningitis is diagnosed as they will often tide the patient over the interval which may elapse before treatment with penicillin can be begun. They are also useful for covering the period in which intrathecal penicillin is withheld.

Penicillin is also given systemically in the usual doses because in the majority of cases pneumococcal meningitis is secondary to an overt primary focus of infection (Smith, Duthie and Cairns, 1946, fig. 2). While we do not depend on the systemic penicillin to influence the course of the meningitis itself, we have found it valuable in controlling the primary focus of infection. For example, in otogenic meningitis, the commonest variety of both pneumococcal and streptococcal meningitis, we consider that operation on the ear is no longer indicated during the acute stage of the illness (Smith, Schiller and Cairns, 1946). Further, pneumococcal meningitis may either be caused, or complicated by septicæmia and for this also systemic penicillin is invaluable.

COMPLICATIONS

Spinal block.—Unfortunately complications are common and the two that we have met with most frequently are spinal block and relapse of the meningitis. Spinal block is seen in the acute stage of the illness, when it is presumably caused by the deposition of fibrino-pus, and may also develop after some days when chemotherapy has been delayed or inadequate. We have also seen it following lumbar injections of 50,000 units or more of penicillin, especially when concentrated solutions have been used. The first sign of impending block is difficulty in obtaining fluid at lumbar puncture. Whenever this occurs penicillin should be given by cisternal or, preferably, by ventricular injection, as lumbar injections are rendered useless.

Relapse.—Relapses are also common; 16 of our 50 patients relapsed one or more times before finally recovering. In one case the patient relapsed eight times and in each relapse was as ill as in the original attack of meningitis (Smith, Duthie and Cairns, 1946, fig. 3). The treatment of relapse does not differ from that of the initial attack and the prognosis is good provided that each relapse is promptly recognized and energetically treated.

RESULTS

We have now treated 50 unselected cases of pneumococcal meningitis with 39 recoveries. In 11 fatal cases, 2 patients died of causes other than meningitis; of the remaining 9, 4 patients were virtually moribund when admitted to hospital and died within a few hours of receiving their first injection of penicillin. Delay in the institution of treatment was thus the commonest cause of failure in our series and was most often due to delay in diagnosis. In the fulminating case, pneumococcal meningitis develops with extreme rapidity and the differential diagnosis is from subarachnoid hæmorrhage. Such cases are among the most acute of all medical emergencies and a few hours delay in instituting penicillin therapy may make the difference between death and complete recovery.

Streptococcal meningitis.—Penicillin therapy carried out on the lines just described is indicated also in streptococcal and staphylococcal meningitis. In our experience, which is admittedly limited, we have found that streptococcal meningitis is relatively frequently complicated by intracranial abscess (Smith, Schiller and Cairns, 1946, fig. 2). If an intramalaria. It is hoped that in future these different methods of treatment will be more evenly balanced and that one will be in a position to evaluate the relative merits of such courses, if any such distinction can be discovered. Penicillin has been administered intramuscularly in every case—the dosage employed has been 300,000 units daily in one injection for fourteen days, giving a total of 4·2 mega units. The penicillin used has been sodium penicillin dissolved in sterile distilled water.

In the first place patients given penicillin only were carefully selected. They were all of poor physical condition, their malaria risks were high and in many of them the prognosis was regarded as relatively hopeless. This probably explains why 6 out of 14 cases have died. The remaining 51 cases treated by different combinations of malaria and penicillin are still alive. Of the 6 cases who died, 2 died of intercurrent disease, coronary thrombosis and acute purulent bronchopneumonia ; a third died of aortic disease; the remaining three died of G.P.I. Two cases were very advanced and the third case can be described as a fulminating type.

While it is not possible to give any percentages, owing to the small number of cases under review, we have been impressed by certain features of the clinical results. One of the most striking was the improvement noticed in many patients during the actual course of penicillin, which is a phenomenon rarely, if ever, seen during malaria therapy. This improvement was both physical and mental in character. Patients showing improvement with penicillin who were unfit for malaria on admission became well enough to receive a course of fever, though a certain proportion of them were only fit for a modified course, e.g. 3-5 peaks of 103° F. or over. The most dramatic results were seen in patients who were confused and in poor physical condition. Penicillin was administered to 8 patients with cardiovascular lesions, 4 with cardiovascular degeneration, 2 with aortic regurgitation and 2 with syphilitic aortitis. No Herxheimer reactions were encountered and no preparatory course of a heavy metal and potassium iodide was given.

Case 1189.—Male, aged 40. Admitted 12.12.45. Grandiose, elated, very excited and violent; physically emaciated and in very poor general condition. History of mental symptoms for about eight weeks.

Physical signs—A.R. pupils. Tremors of tongue and fingers. C.S.F.: W.R. $+30^{+}$, Cells 5 per c.mm., Protein 80 mg.%, Lange 5555432100.

In view of his very poor physical condition he was considered unfit for malaria and so was given penicillin 300,000 units intramuscularly for fourteen days. His condition deteriorated steadily, both mentally and physically, and this fulminating case of G.P.I. died 26.2.46, six months from the date of onset of symptoms.

Case 1249 (Maudsley Hospital).—Male, age 46. Admitted 21.5.46. This patient's symptoms dated from August 1944, following a bad flying-bomb raid. After exhibiting emotional instability for several months, he developed a confusional attack and in December 1945 got lost in a street. His mental condition considerably deteriorated and it was not until May 1946 that he was admitted into hospital. His physical condition then revealed ocular signs—unequal pupils, left A.R.; speech slurred; poor co-ordination with an unsteady gait and a positive Romberg. He received treatment by penicillin 300,000 units daily for fourteen days, to a total of 4·2 mega units. During the course of penicillin his speech became more distinct, his replies to simple questions were less rambling and his physical condition improved. He continued to improve and was discharged home on 20.7.46.

Six months later he attended the follow-up clinic. He appeared simple and childish, but was at work doing internal house repairs. His clinical condition was paralleled by a serological one.

Before treatment—Blood: W.R. $+30^{+}$, Kahn ++++. C.S.F.: W.R. $+30^{+}$, Cells 15 per c.mm., Protein 50 mg.%, Lange 5555432100.

Six months after treatment. Blood: W.R. +10, Kahn ++++. C.S.F.: W.R. +6, Cells 3 per c.mm., Protein 90 mg.%. Lange 5554321000.

We are satisfied that penicillin will prove a useful adjunct to malaria; whether penicillin will supersede malaria is doubtful; only the lapse of time will enable us to come to definite conclusions. We know that malaria alone for the established case of G.P.I. should be supplemented by some additional form of therapy. It may well be that penicillin will prove the optimum choice. Moreover, the combination of penicillin and malaria may make possible the reduction of the number of peaks of fever generally aimed at. The optimum dosage of penicillin and the length of treatment have yet to be settled, and it is only by trial and error and the continued follow-up of cases treated by different regimens that we can arrive at the proper answer.

To summarize our clinical observations:

The majority of patients who improved began to do so during the actual course of penicillin.

Patients showing improvement with penicillin, who were unfit for malaria on admission, became well enough to receive a course of fever, though a certain proportion of them were only fit for a modified course, i.e. 3-5 peaks of 103° F. or over.

The most striking clinical results were seen in patients who were confused and in poor physical condition.

with penicillin—in the treatment of neurosyphilis. It is even possible that a "synergistic" action exists between the two types of treatment as indicated by the animal experiments of Eagle and his co-workers and the observations of Levaditi and Vaisman (1946).

Three injections of arsenical and bismuth can be given during the week of penicillin treatment and then follow 12 injections each of arsenical (neoarsphenamine, mapharsen or acetylarsan) and bismuth at weekly intervals. It is necessary to repeat the courses of arsenical and bismuth according to the type of case.

Penicillin in adequate dosage and administered by whatever route has a striking initial beneficial effect on all forms of meningovascular neurosyphilis and especially acute forms. The pleocytosis and the increased protein of the cerebrospinal fluid will often show a noteworthy decrease within a few days of starting treatment and will frequently reach a normal level within two to four weeks. The intensity of the Wassermann reaction in the cerebrospinal fluid gradually decreases and may become negative within two to four months. There is no parallel action on the blood Wassermann reaction which may continue positive for many months and even indefinitely in cases limited to penicillin treatment.

General paresis is best treated with an initial course of penicillin of total dosage 4,000,000 to 5,000,000 units followed by full malarial or fever therapy (10 to 12 malarial rigors). Finally, the usual courses of arsenical and bismuth are advisable until the serological reactions become negative.

In cases of general paresis (and taboparesis) in which malarial or fever therapy is contra-indicated by reason of cardiovascular disease, one must rely on penicillin alone. Some improvement—but not cure—can be expected.

In tabes dorsalis no dramatic change follows penicillin treatment. Cases are best treated with an initial course of penicillin and then with the usual courses of arsenical and bismuth for two to four years, until apparently quiescent and the serological reactions have become negative.

Special symptoms such as "lightning pains" and "gastric crises" benefit from penicillin in some cases, including those in which the serological reactions are already negative.

Primary optic atrophy of syphilitic origin can be arrested in a fair proportion of cases by malarial therapy. Penicillin alone is not likely to arrest the optic atrophy but may prove useful in hastening arrest or in bringing about arrest in an even larger proportion of cases. Treatment should consist of an initial course of penicillin of total dosage 4,000,000 units to 5,000,000 units, followed by full malarial therapy (10 to 12 rigors) and afterwards arsenical and bismuth. Observation of any case of syphilitic optic atrophy must extend to five years or longer before any form of treatment can claim success.

A distinction must be drawn between "Early asymptomatic neurosyphilis" and "Late asymptomatic neurosyphilis". The latter condition, being of serious import, must be treated with penicillin and malarial or fever therapy on the same lines as "general paresis".

It will not be possible fully to assess the final results of penicillin treatment in neurosyphilis—even when combined with the older methods—for several years. The necessity for the careful and prolonged "follow up" of cases is imperative. We can only wait and ascertain what proportion of the thousands of cases of early syphilis treated with penicillin alone in the British and United States Forces will eventually relapse or develop some form of neurosyphilis. Consequently, as a result of further observations, it may be necessary to amplify, extend, or otherwise alter the schemes of treatment advocated.

Dr. W. D. Nicol and Dr. M. Whelen (*Malaria Therapy Centre, Horton Emergency Hospital*): *Penicillin and neurosyphilis.*—In this very brief communication we would at once stress the fact that at this time our knowledge of the use of penicillin in the treatment of G.P.I. and neurosyphilis is both inadequate and incomplete. Moreover, the number of cases treated is small, 57, all of whom, with the exception of 2 cases treated at the Maudsley Hospital, were admissions to the Malaria Therapy Centre at Horton. The majority of cases, 42, were general paretics; in addition there were 6 tabetics, 4 taboparetics, 2 congenital neurosyphilitics, 1 cerebral syphilitic, 1 psychopath with neurosyphilis and 1 late asymptomatic neurosyphilitic. To assess the value of any therapeutic measures one should examine the clinical condition and the cerebrospinal fluid at regular intervals. We are not in a position to assess serological results owing to the short time that has elapsed since treatment, and are, therefore, compelled to confine our observations to clinical results.

Of 57 cases treated, 14 were given penicillin only, 7 received a subsequent course of malaria, 6 received penicillin and malaria concurrently and 30 were given a course of penicillin after with the classical symptoms that reveal disturbance of functions of the heart, the kidney or the brain.

(2) *The permanent form* of cerebral œdema due to arterial hypertension is perhaps the more frequent; the clinical picture is one of intracranial pressure, which resembles that seen in a case of brain tumour: headache more or less permanent, vomiting, slow cerebration and drowsiness. Transient loss of sight or progressive diminution of vision is an early important feature, caused by neuroretinitis of the fundi with hæmorrhages and with spots, especially in the macular region. But this is an advanced state of the lesion. At the beginning the fundus may present the appearance of a choked disc and the question of a tumour of the brain may arise, the high blood-pressure, the increase of arterial retinal pressure, the signs of retinal arteriosclerosis with associated cardiac or nephritic symptoms will be important arguments in favour of the diagnosis of cerebral œdema with neuro-retinitis; but, in certain cases, the diagnosis may be difficult, especially at the early stage of the affection, since a tumour of the brain may occur in a patient with high arterial pressure.

The evolution in this form is often variable; there can be improvement occurring spontaneously or as a result of therapy. The condition tends to be progressive and the prognosis is serious, the cerebral œdema progressing invariably, and to the blindness caused by the retinal œdema, are added intense headache, progressive drowsiness and death in some months in a state of cachexia, if it is not accelerated by other vascular cerebral complications or by nephrocardiac deficiency.

The *diagnosis* of the *acute form* of meningo-cerebral œdema is, as a rule, easy, the other vascular accidents due to arterial hypertension (cerebral hæmorrhage and softening of the brain) having a different symptomatology and evolution. The only difficulty in diagnosis would be with a subarachnoid hæmorrhage. Lumbar puncture makes easy the recognition of the latter condition by the appearance of the fluid; however, one can see the association of both syndromes.

In the case of the *permanent form* of cerebral œdema, the question of a tumour of the brain, in a patient having a permanent high arterial pressure, may arise. Ventriculography may be necessary, but it must be realized that dilatation of the ventricles can exist in the brain of patients with cerebral œdema and this finding must not be taken as a sign of tumour or circumscribed meningitis of the posterior fossa.

Pathological study of meningo-cerebral œdema must be done on the fresh brain. After opening the dura, one sees the pericerebral subarachnoidal space filled with an increased quantity of fluid; the brain itself is swollen by œdema, especially in the occipital lobes, and is the seat of intense vascular congestion, the smallest branches of the pial nest being visible.

Histological study (made after slow and progressive inclusion by celloidin, which must avoid artificial retractions) shows infiltration of the brain tissue by œdema, with distension of the perivascular and even pericellular spaces, areolar aspect of the cerebral tissue, especially around the vessels, distension and swelling of oligodendroglia, and even reactional cellular alterations. The maximal alterations are in the pia mater, the grey matter of the paraventricular regions and the hypothalamus. Hæmorrhages can be only microscopic in the perivascular spaces, but there may be more important hæmorrhages, especially in basal ganglia and their arterial origin can be demonstrated.

The lesions of the retina in the permanent form are identical: mechanical distension of the tissue by œdema and in places enormous bubbles of œdema corresponding with the white spots seen by ophthalmoscopy; retinal hæmorrhages whose arterial origin can be demonstrated, and lesions of the walls of the small arteries of the retina.

These clinical and pathological data are related to different *pathogenic* problems.

The increase in the local circulation in the brain and retina is obvious; it has an effect, in the permanent form, on the anatomical state of the walls of the vessels, especially on the smallest vessels, consequently the physiology of these vessels must be altered.

It is these structural changes which make possible hæmorrhages whose arterial origin is pathologically demonstrated. But it seems possible, before such anatomical alteration, that water and plasma proteins can pass through the arterial walls in certain conditions.

The increase in local circulation may be the result of an active vasodilatation which opens the bed of many capillaries to the blood flow, or it can be the result of increase of pressure of the cerebral or retinal circulation due to sudden increase of general arterial pressure. Hypertonic hormones have different actions on the cerebral and retinal vessels and on vessels of the general circulation, so that it is the cerebral vessels which will be dilated concurrently with vasoconstriction in the general circulation. Clinical and pathological data are in favour of this interpretation. There is also a place for discussion about the direct mechanism of œdema, first, the conditions influencing the permeability of the small vessels and secondly the reactions of the brain centres to circulatory changes.

Penicillin was administered to 8 patients with cardiac lesions, 4 with cardiovascular degeneration, 2 with aortic regurgitation and 2 with syphilitic aortitis. No Herxheimer reactions were encountered and no preparatory course of a heavy metal and potassium iodide was given.

Penicillin failed to save the lives of one general paralytic of a fulminating type and two very advanced cases, so in this respect it is apparently no more successful than older forms of treatment.

[*April* 17, 1947]

DISCUSSION ON CEREBRAL ŒDEMA

Professor Th. Alajouanine: *Meningo-cerebral œdema caused by arterial hypertension.*—Cerebral œdema must be defined as a special mode of vascular disturbance of the brain. This form of pathological alteration together with other cerebral vascular conditions ranks next to hæmorrhage and softening of the brain, as we have already emphasized in our report on "Morbid Cerebral Circulation" read (with Thurel) at the Annual International Neurological Meeting in Paris in 1936.

By "cerebral œdema" we do not mean the simple œdematous reaction encountered in the neighbourhood of focal vascular lesions of the brain (hæmorrhage or softening); we have in view a generalized and diffuse œdema of the brain and the meninges, directly produced by arterial hypertension and related to a mechanism quite different from that which produces softening of the brain, and cerebral hæmorrhage.

This vascular process can be observed (and in fact has been observed) in various cases of arterial hypertension resulting from different ætiological factors. But the most characteristic and perhaps the most frequent causes of cerebral œdema are: malignant hypertension of young adults and paroxysmal hypertension due to neuro-endocrine disturbances. It may, however, be seen in all forms of arterial hypertension.

The clinical manifestations of meningo-cerebral œdema due to arterial hypertension will be described under two principal headings: (1) In the first group of cases, there are paroxysmal clinical events co-existing with paroxysmal increase of blood-pressure, giving a transient symptomatology that recalls in certain points the clinical picture of a subarachnoid hæmorrhage. The vascular origin of such accidents cannot be mistaken; it is the *acute form* of meningo-cerebral hypertensive œdema;

(2) In a second group of cases, we deal with a permanent morbid state. The clinical picture resembles that of a brain tumour, so prominent are the headache, the drowsiness and the visual disturbances due to a neuro-retinitis (choked disc with retinal œdema). This sort of case constitutes the *permanent form* of cerebral hypertensive œdema.

(1) *The acute form* is not the most frequent, but has the most typical features, though the intensity of the manifestations may vary.

The patient suffers suddenly from an intense headache often with a pulsatile character. Vomiting soon occurs followed by visual disturbances (mist over the eyes or complete loss of sight). Quickly there develops a progressive mental dulling which makes the patient fall into a torpid state, though true coma is rare.

Different kinds of accidents can happen during this stage; periods of restlessness with mental confusion, epileptiform seizures, sometimes of Jacksonian type, sometimes generalized; objective signs of a localized lesion of the brain (monoplegia, hemiplegia and aphasia) ordinarily of short duration. (Pathological observations show that they are due to small arterial hæmorrhages in the basal ganglia.)

Ophthalmoscopic examination may show a hyperæmia of the fundi, exceptionally a choked disc or a small retinal hæmorrhage. Arterial retinal pressure is usually higher than the diastolic arterial pressure.

These various manifestations appearing suddenly, in association with a paroxysm of arterial hypertension, leave no doubt as to the nature of the symptoms.

Lumbar puncture shows an increase of pressure of the cerebrospinal fluid, with oscillations synchronous with the pulse. The examination of the fluid reveals an increase of protein up to 0·01 gramme % with an absence of cellular reaction (albumin-cytologic dissociation).

This form of meningo-cerebral œdema often resolves spontaneously, or after lumbar puncture. The increase of arterial pressure is transient so that in a few days symptoms have disappeared. Headache clears up first, then the mental state improves, finally the sight returns completely or incompletely leaving a permanent hemianopia, sometimes with alexia due to occipital œdema. Ordinarily no permanent sign of paresis remains, at least after the first attack: the latter may reappear with a new paroxysmal rise in arterial hypertension.

The same patient can subsequently have other vascular manifestations, subarachnoid hæmorrhage, cerebral hæmorrhage, or the arterial hypertension may become permanent with the classical symptoms that reveal disturbance of functions of the heart, the kidney or the brain.

(2) *The permanent form* of cerebral œdema due to arterial hypertension is perhaps the more frequent; the clinical picture is one of intracranial pressure, which resembles that seen in a case of brain tumour: headache more or less permanent, vomiting, slow cerebration and drowsiness. Transient loss of sight or progressive diminution of vision is an early important feature, caused by neuroretinitis of the fundi with hæmorrhages and with spots, especially in the macular region. But this is an advanced state of the lesion. At the beginning the fundus may present the appearance of a choked disc and the question of a tumour of the brain may arise, the high blood-pressure, the increase of arterial retinal pressure, the signs of retinal arteriosclerosis with associated cardiac or nephritic symptoms will be important arguments in favour of the diagnosis of cerebral œdema with neuro-retinitis; but, in certain cases, the diagnosis may be difficult, especially at the early stage of the affection, since a tumour of the brain may occur in a patient with high arterial pressure.

The evolution in this form is often variable; there can be improvement occurring spontaneously or as a result of therapy. The condition tends to be progressive and the prognosis is serious, the cerebral œdema progressing invariably, and to the blindness caused by the retinal œdema, are added intense headache, progressive drowsiness and death in some months in a state of cachexia, if it is not accelerated by other vascular cerebral complications or by nephrocardiac deficiency.

The *diagnosis* of the *acute form* of meningo-cerebral œdema is, as a rule, easy, the other vascular accidents due to arterial hypertension (cerebral hæmorrhage and softening of the brain) having a different symptomatology and evolution. The only difficulty in diagnosis would be with a subarachnoid hæmorrhage. Lumbar puncture makes easy the recognition of the latter condition by the appearance of the fluid; however, one can see the association of both syndromes.

In the case of the *permanent form* of cerebral œdema, the question of a tumour of the brain, in a patient having a permanent high arterial pressure, may arise. Ventriculography may be necessary, but it must be realized that dilatation of the ventricles can exist in the brain of patients with cerebral œdema and this finding must not be taken as a sign of tumour or circumscribed meningitis of the posterior fossa.

Pathological study of meningo-cerebral œdema must be done on the fresh brain. After opening the dura, one sees the pericerebral subarachnoidal space filled with an increased quantity of fluid; the brain itself is swollen by œdema, especially in the occipital lobes, and is the seat of intense vascular congestion, the smallest branches of the pial nest being visible.

Histological study (made after slow and progressive inclusion by celloidin, which must avoid artificial retractions) shows infiltration of the brain tissue by œdema, with distension of the perivascular and even pericellular spaces, areolar aspect of the cerebral tissue, especially around the vessels, distension and swelling of oligodendroglia, and even reactional cellular alterations. The maximal alterations are in the pia mater, the grey matter of the paraventricular regions and the hypothalamus. Hæmorrhages can be only microscopic in the perivascular spaces, but there may be more important hæmorrhages, especially in basal ganglia and their arterial origin can be demonstrated.

The lesions of the retina in the permanent form are identical: mechanical distension of the tissue by œdema and in places enormous bubbles of œdema corresponding with the white spots seen by ophthalmoscopy; retinal hæmorrhages whose arterial origin can be demonstrated, and lesions of the walls of the small arteries of the retina.

These clinical and pathological data are related to different *pathogenic* problems.

The increase in the local circulation in the brain and retina is obvious; it has an effect, in the permanent form, on the anatomical state of the walls of the vessels, especially on the smallest vessels, consequently the physiology of these vessels must be altered.

It is these structural changes which make possible hæmorrhages whose arterial origin is pathologically demonstrated. But it seems possible, before such anatomical alteration, that water and plasma proteins can pass through the arterial walls in certain conditions.

The increase in local circulation may be the result of an active vasodilatation which opens the bed of many capillaries to the blood flow, or it can be the result of increase of pressure of the cerebral or retinal circulation due to sudden increase of general arterial pressure. Hypertonic hormones have different actions on the cerebral and retinal vessels and on vessels of the general circulation, so that it is the cerebral vessels which will be dilated concurrently with vasoconstriction in the general circulation. Clinical and pathological data are in favour of this interpretation. There is also a place for discussion about the direct mechanism of œdema, first, the conditions influencing the permeability of the small vessels and secondly the reactions of the brain centres to circulatory changes.

The Treatment is different in both forms of meningo-cerebral œdema, and this is the practical interest of this study.

The acute form suggests the opportunity for an active and immediate therapy; one must fight quickly against the increasing of blood-pressure by removal of a large quantity of venous blood and by vasodilators whose action on the peripheral circulation will help to decrease the cerebral blood flow. One must also try to reduce intracranial pressure and its consequences by withdrawal of cerebrospinal fluid. After the acute period, surgical treatment of the arterial hypertension must be considered in order to avoid the return of other accidents.

The prognosis of the permanent form is less favourable, because of the vascular alterations due to permanent hypertension. Treatment by restriction of salt, hypertonic injections or lumbar punctures has very little result. Surgical treatment is usually contra-indicated because of the state of the vessels, of the kidneys, or of the heart. For the neuro-retinitis, subtemporal decompression has often very little effect.

Dr. Douglas McAlpine said that Professor Alajouanine had introduced a subject which had been rather neglected in this country by neurologists because these cases were usually admitted under a general physician except when the clinical picture was mistaken for that of a cerebral tumour. With regard to the first group of cases, namely those showing acute cerebral symptoms, it was also his experience that they occurred mainly in hypertensive patients over the age of 50. In a series of 15 cases which had been under the care of his medical colleagues at the Middlesex Hospital, the average age was 58. It was difficult to fit in the clinical picture seen in this group, namely the abrupt onset of headache, the disturbance of consciousness, the occasional fit and the rapid clearing up of symptoms, with the conception of a generalized cerebral œdema. Furthermore, papillœdema was usually absent in these cases and the C.S.F. pressure was seldom raised. But, as Professor Alajouanine had pointed out, there might be all grades of cerebral œdema varying from a generalized to a local process. However, his own view, based on the work of Volhard (1931), had been that in this form of hypertensive cerebral attack œdema was not such an important factor as anoxia. The precipitating factor was a sudden additional rise in blood-pressure accompanied by a generalized vasoconstriction. Some years ago he had published a case of hypertension in which during the course of four hours the systolic pressure rose from 210 to 300 at which figure a series of epileptiform attacks occurred. Three hours later the blood-pressure had fallen to its previous level and the patient was free from cerebral symptoms (McAlpine, 1933).

In the second group of cases a rapid rise in blood-pressure was also responsible for the cerebral symptoms. In this group there was no doubt about the existence of cerebral œdema since papillœdema and a raised C.S.F. pressure were characteristic features. In a group of 32 cases collected from the records of the Middlesex Hospital, in which, as far as possible, chronic nephritic cases had been excluded mainly by post-mortem examination, the average age at the onset of cerebral symptoms was 42. Headache and visual disturbances were complained of almost constantly by these patients. In only two instances had a fit occurred prior to admission or during the patient's stay in hospital. This finding contrasted with the more frequent occurrence of fits in the older hypertensive patient, and suggested that cerebral œdema *per se* is not an important factor in the production of fits in hypertension. All cases showed papillœdema with or without retinal changes; the diastolic blood-pressure ranging from 180 to 130 on admission. Professor Alajouanine had suggested that in this group of cases when signs of cerebral œdema were established only exceptionally did they clear up; he thought that there would be general agreement on this point since these cases generally followed the well-known course of malignant hypertension. Exceptionally one might come across a case of marked hypertension over the age of 50 with mild papillœdema which later subsided. In addition there were also rare cases in whom all the features of malignant hypertension were present but after some months these cleared up, the patient subsequently enjoying good health for a number of years. He recalled the case of a young woman aged 24 who was under the care of Dr. Bedford in 1931, complaining of severe headache, dimness of vision and loss of weight. She showed 5D of papillœdema with retinal hæmorrhages and exudate. The blood-pressure was 220/150 and C.S.F. pressure was high. The urea clearance test gave her a figure of 36% of normal. After several weeks in hospital she was discharged free from headache and with considerable subsidence of the papillœdema. In 1932 she returned to work having gained 1½ st. in weight. Her blood-pressure became stabilized about 220/140. She remained at work symptom-free until 1942 when she died of a subarachnoid hæmorrhage. A case of equal interest was the following:

J. M., male aged 42, in January 1936 following an attack of influenza, complained of headache, particularly at night. In March he noticed dimness of vision in the right eye, frequency of micturition at night and loss of weight. Between April 14 and 15 he had eight generalized epileptiform attacks. When examined on the 14th by Dr. E. V. Slaughter he showed early papillœdema with retinal hæmorrhages and exudate. Blood-pressure 220/130. Urine: albumin ++. Cerebrospinal fluid pressure 250 mm.; cells and protein normal. Following these attacks he remained in a stuporose condition.

30.4.36: Admitted Neurological Ward, Middlesex Hospital. He appeared conscious but stuporose. Marked neuro-retinitis with reduction of vision. Heart not enlarged; apex beat thrusting; heart sounds normal; pulse small volume. Blood-pressure 210/130. C.S.F. pressure 230 mm. Blood urea 40 mg.%. Despite repeated venesection and hypertonic salines intravenously, his condition worsened and oliguria became marked.

4.5.36: Patient in coma; Cheyne-Stokes respiration. Papillœdema about 3D.

5.5.36: 4 p.m., coma deeper. Pupils inactive. Blood-pressure 190/150. 1 c.c. mercurial diuretic (salyrgan) given.

6.5.36: a.m., semi-comatose. Signs of right-sided hemiplegia. Profuse sweating. Blood-pressure 118/90. Still incontinent. Blood urea 120 mg.%.

7.5.36: Conscious. Partially aphasic. Can move right arm and leg. Blood-pressure 130/90. No longer incontinent. Urinary output 90 oz. in twenty-four hours.

Subsequent progress: A mercurial diuretic was given daily until May 13. The hemiplegia and aphasia quickly cleared up. Blood-pressure rose and became stabilized at about 190/110-120. Papillœdema subsided and retinal changes slowly resolved. The albuminuria ceased, the blood urea fell to normal but the urea clearance test showed 50% diminution in function. 29.6.36: patient was discharged from hospital free from symptoms. He gained nearly 2 st. in weight in the next three months. He returned to work in the autumn of 1936 and has remained at work since then.

In 1939 Dr. E. Bedford reported that his heart was not enlarged. Blood-pressure 190/110.

March 1947: Free from symptoms. No nycturia. Discs both pale; arteries constricted; otherwise fundi normal. Vision: right J4, left J1. Heart not enlarged. Blood-pressure 190/108. E.C.G. normal. Urine: no albumin.

This case presented a picture of malignant hypertension in its early phase. A mercurial diuretic produced widespread vasodilatation with a dramatic fall in blood-pressure. Presumably the vicious circle of vasoconstriction and hypertension was broken before the irreversible changes in the arterial wall, characteristic of the malignant form of hypertension, were reached.

Dr. McAlpine hoped that as a result of Professor Alajouanine's paper neurologists might study afresh some of the cerebral problems presented by arterial hypertension.

Doctors Clovis Vincent, Jacques Le Beau et Gerard Guiot (*Hôpital de la Pitié, Paris*) : *Brain œdema in neuro-surgery.*—The present study on brain œdema is divided into four parts.

(1) Subacute and chronic brain œdema associated with tumours of the brain with special reference to two of its complications, i.e. temporal herniation below the tentorium and cerebellar herniation above the tentorium.

(2) Acute brain œdema as seen during operation, experimental surgery and in cases of severe head injury.

(3) The classification of different varieties of brain œdema.

(4) The surgical treatment of brain œdema with particular regard to temporal herniation.

To us brain œdema and brain swelling are considered as one thing from a practical point of view even if they have a different underlying pathology. Neuro-surgeons speak of "cerebral œdema" when they find a brain tending to increase in volume. This cerebral turgescence may occur independently of ventricular dilatation as for example in craniocerebral injuries. It may also occur to a marked degree in association with small new growths and may be seen in an exploratory burrhole when the dura is opened. The volume of the brain increases and the different parts of the brain tend to bulge out through the foramina and dura. In the process the convolutions are broadened and flattened, the sulci tend to be eliminated and the brain matter is often so soft that a ventricular needle sinks in under its own weight. Œdema caused by cerebral tumour is not distributed evenly throughout the whole brain for it is more marked in the cerebral hemisphere and in the areas adjacent to the tumour. As a result of this other parts of the brain are compressed, even at a considerable distance from the point of maximal œdema.

I.—Subacute and Chronic Brain Œdema in Tumours and Cerebral Abscess

(*a*) *Supra-tentorial tumours.*—Cerebral œdema in fact dominates intracranial pathology in neuro-surgery and clinically is responsible for the production of intracranial hypertension (as evidenced by headache, vomiting and choked disc) more than the actual tumour itself, which, in the case of slowly growing lesions, may reach an enormous volume without raising the intracranial pressure [3].

Cerebral œdema may also be responsible for mistakes in diagnosis as symptoms might appear related to parts of the brain which are unaffected directly by the tumour. Death in all cases is due to a lesion of the brain-stem, either from neoplastic invasion, local traumatic injuries of the brain-stem or lesions due to cerebral œdema. Such lesions may be either an œdematous swelling of the brain-stem, altering or suppressing its functions, or direct pressure on the stem by a "temporal pressure cone" (fig. 1). Temporal pressure cone is the major complication of tumours involving the cerebral hemispheres and may develop very insidiously [2], [3], [7]. In the early stages many cerebral tumours are diagnosed clinically either by local symptoms only or by cerebral œdema. It is only after some time has elapsed that new symptoms and signs, due to the temporal herniation, appear in the form of stiffness of the nape of the neck, rotation of the head, dimming of the intellectual faculties, flushing of the face, dry lips, inability to stand, monoplegia or hemiplegia, convulsions or decerebrate fits. Radiographs show thinning of the underlying bone, and in particular, of the sella turcica [4]. Ventriculography, which may be dangerous, often shows a dilatation of one foramen of Munro with deviation of the third ventricle to the side opposite to the tumour. The whole of the third ventricle is deviated when the temporal herniation is complete but is only partially deviated in incomplete herniation; in the latter case only the superior part of the third ventricle is shifted (figs. 2 and 3).

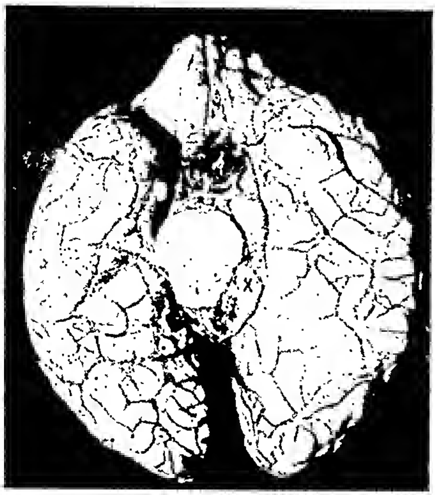

FIG. 1.—Typical temporal herniation (x).

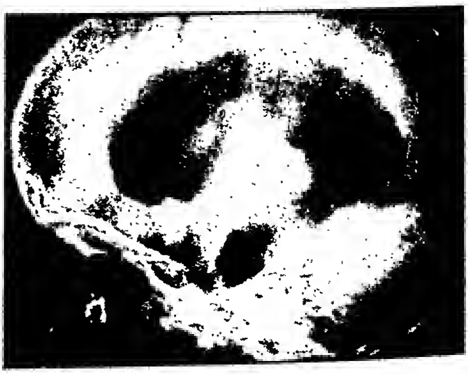

FIG. 5.—Ventriculogram. Gross appearance of tumour of posterior half of third ventricle. Actually it is a shift upward and forward of the third ventricle by upward cerebellar herniation (cerebellar tumour).

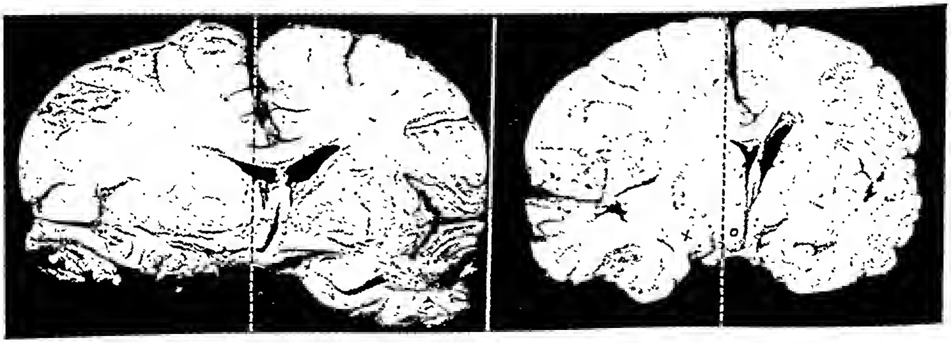

A B

FIG. 2.—Third ventricle and temporal herniation. (A) Brain œdema without temporal herniation; third ventricle oblique. (B) Brain œdema and temporal herniation (X); third ventricle shifted *en masse*. Note a downward herniation of the hypothalamus (O).

The different clinical signs just described make the exact localization of brain tumours a difficult matter and render their prognosis most serious. The condition existing in temporal herniation may be aggravated by sudden increase of œdema by lumbar puncture or by ventri-

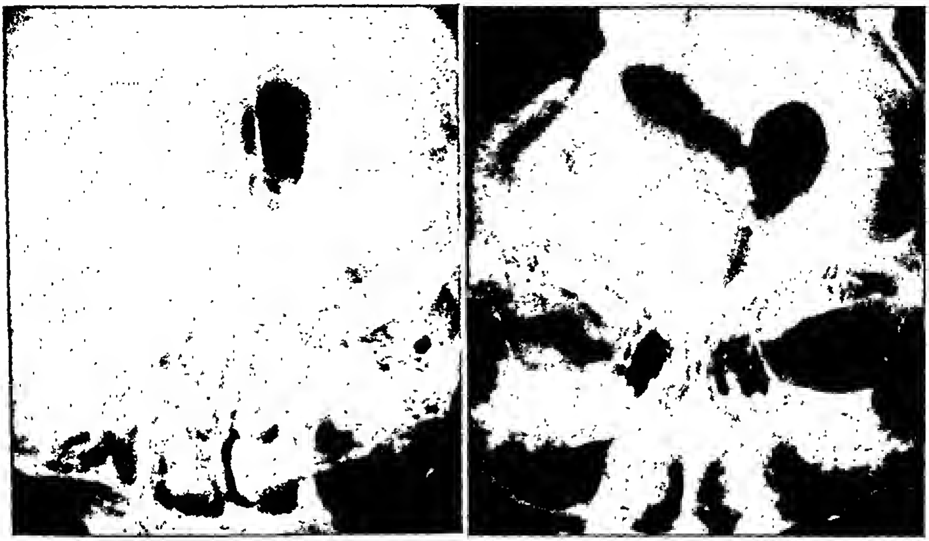

FIG. 3.—Ventriculograms. (A) No temporal herniation, third ventricle oblique. (B) Temporal herniation, third ventricle shifted *en masse*.

cular puncture on the normal side. The patient then becomes drowsy and comatose, stiffness of the neck increases, the heat-regulating mechanism is affected and there is visceral vasodilatation particularly affecting the lungs.

(*b*) *Infra-tentorial tumours.*—Tumours situated below the tentorium are frequently associated with brain œdema although the signs of such œdema are far less obvious than in those cases where it occurs above the tentorium. Displacement by a tumour, even a small one, may be rapidly followed by remote phenomena due to compression of the bulb and pons. The most revealing signs of such compression are stiffness of the neck, tendency to lateral inclination of the head and possibly decerebrate fits.

Œdema of the cerebellum has important anatomical consequences, with an increase of downward tonsillar herniation and the development of marked ventricular dilatation.

Cerebellar œdema rarely occurs in association with œdema of the cerebral hemispheres, the latter being found particularly in the brains of patients who have died following operation.

A particular complication of cerebral œdema occurs in cases of tumour and abscess situated in the upper half of the cerebellum in the form of an upward herniation of the cerebellum above the tentorium [5], producing at ventriculography a shift of the third ventricle which may lead to confusion and suggest the presence of a tumour in the posterior part of the third ventricle (fig. 4 *below* and fig. 5 *see p. 38*)

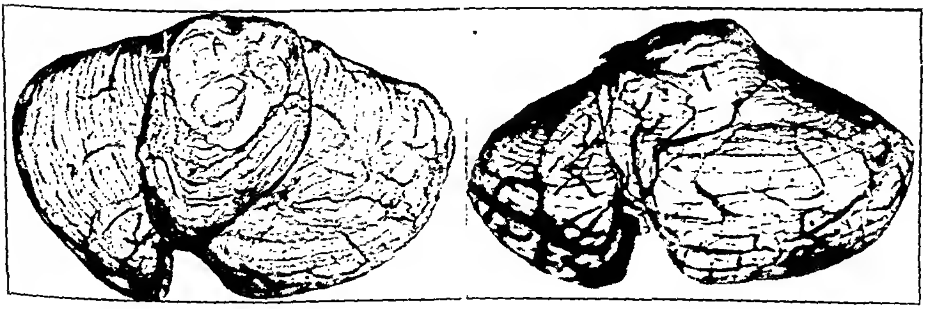

FIG. 4.—Upward cerebellar herniation. (A) From above. (B) From the side.

II.—ACUTE BRAIN ŒDEMA

(*a*) *Operative œdema*.—As described by one of us at the International Neurological Congress in London in 1935, the neuro-surgeon may see œdema developing during operations in the subfrontal region as for the removal, for example of a suprasellar meningioma. The œdema is seen as a tremendous swelling of the cerebrum which is solid and unassociated with change in blood-pressure. Should the patient die petechial hæmorrhages may be found disseminated throughout the frontal lobes.

Acute swelling of the cerebellum may occur during subtentorial operations, resulting from sudden compression or decompression; in such cases a marked rise of blood-pressure always precedes the œdema and is accompanied by dilatation of all the arteries.

(*b*) *Experimental œdema*.—This is an acute swelling of the brain produced by small traumatic lesions of the brain-stem (pons and crura). Most of this work was started at La Sorbonne [6], and was continued during 1942 at the National Institute for Medical Research, Hampstead with the support of the Medical Research Council (fig. 6).

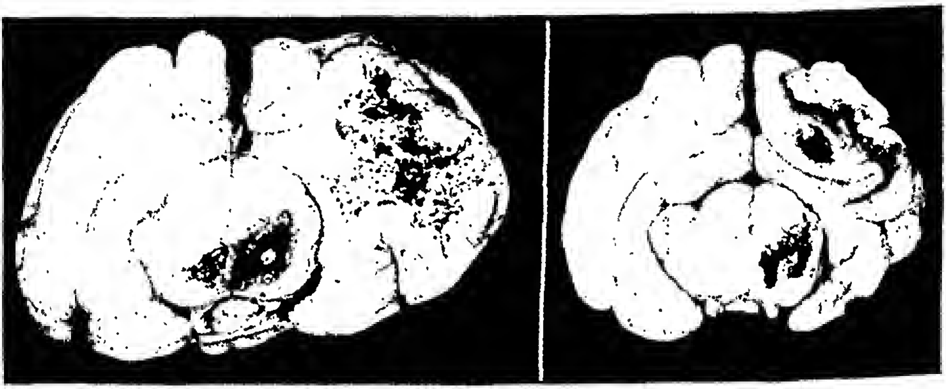

FIG. 6.—Cat. (A) Acute brain œdema from peduncular lesions.
(B) Peduncular lesion without acute brain œdema.

Such acute swelling is usually associated with a great increase in blood-pressure although this is not invariable. The occurrence of this swelling, associated with brain-stem trauma, we call *active* brain œdema and the mechanism of its production is still obscure.

(*c*) *Acute œdema in head injuries*.—We believe the occurrence of generalized œdema is frequent in cases of acute head injury and can be demonstrated by making supra-tentorial burrholes where swollen brain can be seen in the absence of a serious hæmorrhage. A possible cause for such œdema could be some lesion of the brain-stem as in the experiments mentioned above.

III.—CLASSIFICATION

Variations in morphology, ætiology and development (chronic or acute) in brain œdema may be analysed as follows:

(1) An œdema which appears to be the consequence of obstruction of the venous circulation, i.e. due to compression of veins and dural sinuses stretched and collapsed by high intracranial pressure. This circulatory defect when it reaches the intracerebral vascular pattern increases the cerebral swelling and thus creates a vicious circle.

(2) "Active œdema" which appears to be independent of a mechanical process and is due to vasomotor changes.

(3) Œdema in association with brain tumour depends in varying degree on one or other of the above-mentioned types:—

(*a*) Many brain tumours may develop pressure on the brain-stem which may produce "active œdema".

(*b*) Some large tumours may cause œdema through venous stasis which is relieved when the tumour is removed.

(*c*) Tumours, such as metastases, may produce "active œdema" quite out of proportion to the small size of the tumour.

IV.—TREATMENT OF CEREBRAL ŒDEMA AND ITS COMPLICATIONS

(*a*) The large decompressive flap has had much success especially for subacute œdema. It has been much employed for lesions requiring two-stage operations as, for instance, in cases of cerebral abscess, which are allowed to mature under decompression. The decompressive flap is less useful in cases of acute traumatic or infective œdemas because the dura stretches only very slowly. In addition the turning of a bone flap is by itself a trauma and may increase the œdema. The danger of cerebral œdema is not only related to the mechanical pressure on the brain but also to the swelling of the brain-stem whose functions may be altered or destroyed as a result of hæmorrhage.

(*b*) When it is impossible to remove the cause of brain œdema (as by excising a tumour) the best treatment remaining is the classic one of dehydration. For intracranial hypertension magnesium sulphates have given the best results and in some cases we inject as much as 240 c.c. in twenty-four hours at the rate of 20 c.c. every two, three or four hours.

The method of dehydration has replaced the decompressive bone flap and extensive experience has proved that it is safe. The important point is to establish through trephine openings the presence of cerebral œdema.

(*c*) Because of its practical importance the complication of temporal herniation in brain œdema has justified attempts at direct surgical treatment and such herniation should always be reduced at once if the patient's life is in danger. The best technique for reduction of temporal herniation seems to be "simple reposition" by the subtemporal route. The line of approach is in the plane passing through the external auditory meatus which lies between the two venous anchorages of the temporal lobe, the veins of Sylvius and Labbé. This has the advantage of exposing the middle portion of the tentorial incisura. When this point is reached the herniated convolution is lifted backwards with the production of an immediate flow of cerebrospinal fluid. We now as a routine, explore the Bichat opening when removing a tumour from the temporal region, reducing the herniation if it is present (fig. 7).

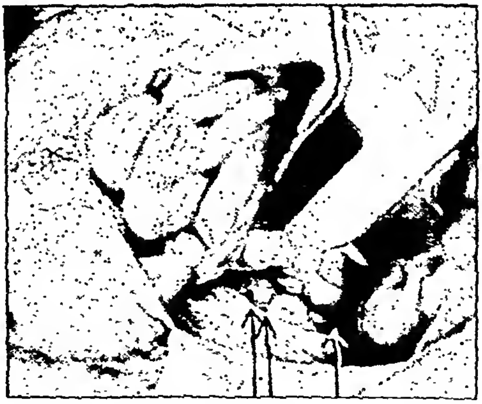

FIG. 7.—Surgical reduction of temporal herniation.
↑ Third cranial nerve. ↑↑ Free edge of tentorium.

For patients with other tumours showing temporal herniation we prefer to reduce the herniation at a second stage procedure if the patient does not recover after the primary removal of the tumour. If temporal herniation has not yet caused definite lesions in the brain-stem operative reduction improves the patient's condition and on the day following operation he is again conscious without headache or stiffness of the neck.

Our results support similar observations on the reduction of temporal herniation made by other surgeons and have convinced us of the importance of this manœuvre in the management of cases of brain tumour [1].

Professor Geoffrey Jefferson: Cerebral œdema cannot be regarded as an entity existing by itself because it is invariably secondary to something else, something affecting the brain primarily or else derived from some toxic or disordered state affecting the whole body in greater or lesser degree, but again with a local exciting cause.

I must speak of the condition as a clinician, as a neuro-surgeon in particular, concerned chiefly with brain tumours and infections of the central nervous system The ordinary methods of histology are not sufficiently informative to tell us all that we wish to know about œdema, except that it exists. It can say little directly of its causation except by inference. I should be on much firmer ground had I the authority to speak as a biochemist, for it is only by chemical researches that the missing answers can be found. I feel sure that neuro-pathologists would agree if in future we were to send three-quarters of any tumour that we remove to the biochemist and a quarter to themselves. It is just over sixty years ago that Thudicum published his famous "Chemical Constitution of the Brain" (1884) and thereby gave a sure starting place for further researches into the properties of the salts, proteins, sterols, fatty acids and those intensely hygroscopic substances, the cerebrosides, of which the brain is ultimately compounded. Researches have advanced our knowledge much further since those days and beginnings have been made in relation to cerebral œdema. But too much is still a matter for speculative inquiry, the exact causes so far largely escape us. Gross facts we certainly have. The observation that increase in brain volume is always greater than can be accounted for by the actual dimensions of a brain tumour or abscess is an old one. The overplus is œdema. I can see only two explanations: (1) that there are peculiarities in the osmotic pressure in the capillaries of tumours, or (2) that tumours shed toxic metabolites that affect the rest of the brain mass. The third possibility put forward by Dr. Le Beau is still *sub judice.*

On the first alternative, work that James Hardman did in my Unit some years ago seems to me suggestive. Using the Pickworth stain he demonstrated the extremely rich blood supply of malignant tumours, those in which œdema is most evident. True capillaries scarcely exist in these tumours; their place is taken by great numbers of sinusoids, which are neither capillaries, arteries nor veins and seem to be arteriovenous communications. These are impressive. Furthermore, in many operations on malignant tumours, veins may be seen leaving the tumour district filled with bright red blood. This could only be because either (*a*) the tumour is unable to abstract oxygen from the blood, or (*b*) that the arterial blood has been short-circuited in its way through the tumour. The latter, judged by Hardman's morphological studies, seems to be more probable and since we know that fluid exchange depends on intracapillary pressure and on the state of the capillary walls, it is possible that œdema might be the result of changes in hæmodynamics alone.

That this is not the only explanation seems to be certain from the fact that œdema occurs not only with actively growing tumours but with some that have a more ordinary internal vascular architecture, tumours that grow slowly and are, one might surmise, inert, e.g. many meningiomas. Sometimes a small anterior polar meningioma, neither of a size nor in a position where it could exert much pressure on the brain, is associated with a massive œdema of the ipsilateral hemisphere. What can be the cause except it be toxic? I conclude therefore that the cause of œdema is often toxic, although the exact kind remains to be discovered, but that it may be contributed to by capillary peculiarities in the tumours themselves. The toxic factor in infections is scarcely to be debated.

Œdema does not seem to be so serious a problem to the surgeon as it was twenty years ago. Or is it that it is less often invoked as an explanation of neurological disablement since we have learned better the nature of neuronal methods of working? In the main the clinical effects of cerebral œdema are mass effects showing themselves in tentorial or foraminal herniation in ways which the previous speakers have illustrated. This is a subject to which I have nothing much to add to what I wrote ten years ago. There is something, however, which should be said about the effects of œdema on nervous functions. It is not yet proven that œdema alone will block transmission either in axons or at synapses. It may do so, but we do not know that for certain. If it seems to do so, have we the right to assume that it is the œdema which is the active factor? I think not. When a neurone is swollen and is functionless the real reason for its paralysis must be the cause that made it swell. We know that thrombosis of a cerebral vein is often accompanied by swelling of a relevant area, great or small, and that, for example, a paresis may result. The reason is, surely, not because of œdema but because of disturbances of metabolism, of the supply of oxygen and other substances necessary for cell function. Œdema and paralysis are not to be taken, then, as a plain sequence of cause and effect; both are more likely to be due to a common factor which produced the two. My plea is for scepticism in our thinking until the truth is learned by experiment fortified by clinical observation.

Dr. J. G. Greenfield: *The problem of cerebral œdema in neuro-surgery* is a difficult one, not least because of the question of nomenclature and definition. The term *œdema* should properly be reserved for instances in which the excess of fluid in the brain is entirely interstitial. If such cases occur they are exceptional. In all the forms I have encountered there is some swelling of the tissue elements, especially those of the white matter. The term *brain swelling* was used by the older German writers to indicate intracellular swelling as opposed to interstitial œdema. But we do not know whether such a condition exists in a pure form since the artefacts necessarily accompanying fixation make histological differentiation impossible. The chemical evidence favours the supposition that most of the fluid is interstitial, at least in the œdema of cerebral tumours. It appears therefore that the two conditions are always associated. The excess of fluid is partly interstitial, but there is also swelling of the tissue elements. One word may therefore be used for the condition, and that of *cerebral œdema,* although perhaps not scientifically exact, is preferable both for euphony and distinction to that of *brain swelling.*

I do not include increase of fluid in the ventricles or subarachnoid space under the term "cerebral œdema" as I think that such a grouping tends to confusion.

Criteria of Cerebral Œdema

Various criteria have been suggested for œdema of the brain or brain swelling. The first was that of Reichardt who compared *brain volume* with *skull capacity.* A difference of less than 8% was held by him to indicate brain swelling. This criterion has recently been used by Alexander and Looney (1938), and by J. C. White and his associates (1943). It is assumed in using this criterion that no vascular lesions such as undue congestion, or hæmorrhage, exist. *Herniation* of the *hippocampal gyrus* between the incisura tentorii and the brain-stem, was used by Le Beau as his criterion, and up to a point it is a valid one, although difficult to estimate quantitatively. Recent work on œdema of the brain following burns by Walker and Shenkin (1945), and in the M.R.C. report on burns (1944) is also based on this criterion. Tonsillar herniation, or cerebellar coning, is less easily assessed. The *chemical criterion* of increased ratio of wet to dry weight of the brain, must be applied separately to white and grey matter as these have different normal ratios. In fact different areas of white matter normally show some variations in this ratio. Some of the American work on traumatic cerebral œdema was vitiated by a failure to recognize these differences. Stewart-Wallace has shown that an excess of sodium chloride in the tissues of the brain may also be a valuable criterion of œdema.

Finally there are the *histological criteria* to which I propose to devote most of my remarks.

(1) *Œdema in relation to cerebral tumours and abscesses.*—The histological changes seen in œdema of the brain surrounding tumours or abscesses were described by Jaburek in 1935 and I devoted a study to them in 1939. They consist in diffuse pallor of myelin staining in the centrum ovale on the side of the tumour, with comparative sparing of the subcortical fibres and of the larger commissural tracts such as the corpus callosum and the optic radiations. The pallor of staining is associated with irregular swellings on the myelin sheaths and axons. It was constantly associated with swelling of the cell bodies of the astrocytes, affecting all the astrocytes in the œdematous area, usually to a similar degree and in a similar manner. Where the œdema was severe, the change in the astrocytes might be of regressive nature, producing the amœboid glial cells described by Alzheimer and Spatz, or the clasmatodendrosis of Cajal. The nucleus was often pale or was shrunken and pyknotic, or its membrane was folded. In less damaged cells the nucleus was often enlarged along with the enlargement of the cell body. It might be reniform, and not infrequently showed mitoses. Intermediate

forms were not uncommon. In cases of œdema of longer standing there was evidence of increase in number of neuroglial fibres as well as of astrocytes. I could find no such constant change in the oligodendroglia but in acute and severe cases there was some swelling of the cell body. Later writers, however, have found some amœboid swelling of the oligodendroglia in the œdema surrounding cerebral tumours and Courville (1942) has seen the same change in traumatic œdema. There is always some spacing-out of the tissues, but only in the most severe examples is there any stainable interstitial fluid. This is probably because, as Professor Clovis Vincent has suggested, the fluid contains very little protein. I found no evidence of dilatation of perivascular spaces in the white matter but other writers, especially those who have used paraffin sections, have found this to be fairly constant. The cortex also was normal in the less severely affected cases which I studied. In one case the neurons of the fifth layer showed slight swelling resembling axonal reaction which may well have been secondary to the lesions in the underlying white matter. In another case more severe changes resembling those of ischæmia were present in the third layer. In cases of cerebral abscess, where the œdema was usually of more severe degree, degenerative changes in the cortical neurons were not uncommon. These were associated with swelling of the cortical astrocytes and proliferative changes in the microglia.

(2) *Traumatic cerebral œdema.*—(i) *Local form*: Œdema with similar histological characters is found in most cases of cerebral trauma in restricted zones which surround areas of bruising or hæmorrhage in a more or less concentric fashion. The width of this zone rarely exceeds 2 cm. In some of our cases, examined during the war years, there was also evidence of periventricular œdema. The outline of this zone shades off gradually, and in this respect differs from that of the areas of ischæmic degeneration of white matter, due to damage to the vessels entering it from the surface, which are commonly found in cases of cerebral trauma. In cases of cerebral hæmorrhage, traumatic or otherwise, the width of the zone of œdematous pallor usually varies with the size and to some extent with the duration of the hæmorrhage.

These histological changes in the white matter are so definite and characteristic that not only is it possible to say from the study of a section that œdema is present but also to estimate its degree and duration. There may, however, be forms of cerebral œdema, especially perhaps affecting the grey matter, in which a different histological pattern is seen, or in which the histological changes are so slight as to be recognized only by the most minute study.

(ii) *Diffuse traumatic œdema:* The occurrence of diffuse traumatic œdema is still a matter of dispute. Some authors, among whom I must include myself, have never seen it. Others consider it fairly common. Many of the chemical investigations which have been undertaken to prove its presence have, as I have indicated previously, been vitiated by using for examination material containing both grey and white matter, and are therefore valueless.

Experimental investigations are equally contradictory. Pilcher in his experiments in which he allowed weights of 500 and 1,000 grammes to fall on the heads of dogs from a height of 5 feet, could find no definite evidence of œdema. His experiments showed a gradual increase in cerebrospinal fluid pressure beginning in one to two hours after injuries with the kilogramme weight; this was associated with a very slight increase in water content in all parts of the brain. But this never exceeded 1-2%. White and his co-workers using pendulum blows on the heads of cats, after the method of Denny-Brown and Russell, also found a slight rise of cerebrospinal fluid pressure from the normal range of 55-90 mm. up to a range of 97-135 mm. From one hour to twenty-four hours after mild degrees of concussion, from which the animals appeared to have recovered completely, they found an increase in brain volume in relation to skull volume of 2% or 3% and in one case of 5·6%. They examined the brains of 20 cats histologically finding no evidence of cerebral congestion and only slight evidences of œdema, e.g. swelling of oligodendroglia cells, enlargement of perivascular and pericellular spaces, hydropic changes in the ependyma or vacuoles in the white matter, but none of these changes was found in more than 3 of the 20 brains, and most of them in only one or two. They can therefore be considered minimal or nugatory. What seems clear from this and earlier work by White and his collaborators is that an increase in size of the brain up to 5% or even more, need not be associated either with definite quantitative chemical or with obvious histological changes.

The experiments of Le Beau and Bonvallet indicated that œdema of the cerebral hemispheres might result from lesions of the brain-stem. There is a certain resemblance between these results and those of White and his collaborators seeing that blows given by the pendulum technique which they adopted produce demonstrable histological lesions only in the brain-stem (Windle *et al.*, 1944). The changes in the nerve cells of the cerebrum found by Del Rio Hortega in Le Beau's material were not found by myself in his later experimental material, but in any case they were slight, consisting only of swelling and occasional vacuolation of cytoplasm and eccentricity of nucleus of nerve cells, especially in the basal ganglia. They appear to me to be of doubtful significance.

Courville has recently supported the thesis that generalized cerebral œdema of the "dry brain" type may occur after trauma. He finds such brains congested on the surface. Histologically they show diffuse swelling of the oligodendroglia, with some increase in the number of these cells, at a later stage. Oligodendroglial swelling in his view precedes the formation of interstitial vacuoles in the tissue and may account for much of the increased volume of the white matter. He has also found widespread vacuolar changes of minor degree in the cortical nerve cells which resemble in some respects those seen in experimental hydration of the cortex. He considers, however, that generalized traumatic œdema is a rare condition, and he illustrates it with a photograph of a brain in which there are hæmorrhages in both lenticular nuclei which may well have contributed to the œdematous state.

The nature of cerebral œdema remains a mystery. There appears to be a double process, an increased permeability of the walls of the capillaries on the one hand, and a metabolic change leading to swelling of the tissues of the brain, especially those of the white matter, on the other. It is presumed that both may be caused by the same metabolic disturbance, e.g. alterations of hydrogen-ion concentration, anoxia, or the presence of toxic substances. This disturbance may come from the blood, resulting in generalized cerebral œdema as in the cases after extensive burns or scalds, and in those where it is secondary to disease of the liver or kidneys, or alterations in the hydrogen-ion concentration of the blood. Where the œdema is more localized we must suppose that the metabolic change or the toxic substance arises within the brain, e.g. in a bruised or infected area of brain tissue. In cases of cerebral tumour the œdema may be in this sense toxic, i.e. due to metabolites arising in the tumour—as is widely held—or it may be due to widespread ischæmia of the tissues resulting from the compression of the capillary bed or obstruction to venous outflow. Both factors may of course be at work. But it is clear from the distinction between areas of œdema and those of ischæmia in brain trauma, that we cannot consider anoxia as the only cause of œdema. That anoxia may cause swelling of the brain and histological changes some of which are similar to those seen in cerebral œdema is well known, but it seems necessary to postulate some other factor to account for other histological characteristics of cerebral œdema.

The fact that cerebral œdema is not entirely interstitial may account for its resistance to treatment with hypertonic solutions. Undoubtedly such treatment may relieve symptoms of intracranial pressure, but I believe that it does so by producing shrinkage of the brain as a whole, and not a disproportionate shrinkage of the œdematous area. This opinion is based on my observations in the œdema surrounding cerebral tumours, and I do not uphold it strongly in respect of other forms of œdema of which I have less experience. But I have seen no evidence that treatment with hypertonic solutions can directly and specifically affect the œdema surrounding cerebral tumours. The brain may shrink, but the œdema remains. The effect of this treatment is therefore at best temporary and palliative.

Dr. A. M. Stewart-Wallace: *The physico-chemical investigation of cerebral œdema* [Abstract].—The term œdema has a definite pathological meaning which has been defined as "an effusion of watery fluid into the intercellular spaces" and should therefore only be used to denote those conditions in which such an effusion is present. The problem that presents itself therefore is that of how to determine conclusively the presence of an increase of interstitial fluid in cerebral tissue. The severe œdematous tissue in the neighbourhood of cerebral tumours, with corresponding tissues from the opposite hemisphere as a control, seemed to offer good material for an analysis of the fluid changes.

By drying the tissue to a constant weight it was found (Stewart-Wallace, 1939, *Brain*, 62, 426) that the cortical grey matter (average 84·3%) contains considerably more water than the forms were not uncommon. In cases of œdema of longer standing there was evidence of increase in number of neuroglial fibres as well as of astrocytes. I could find no such constant change in the oligodendroglia but in acute and severe cases there was some swelling of the cell body. Later writers, however, have found some amœboid swelling of the oligodendroglia in the œdema surrounding cerebral tumours and Courville (1942) has seen the same change in traumatic œdema. There is always some spacing-out of the tissues, but only in the most severe examples is there any stainable interstitial fluid. This is probably because, as Professor Clovis Vincent has suggested, the fluid contains very little protein. I found no evidence of dilatation of perivascular spaces in the white matter but other writers, especially those who have used paraffin sections, have found this to be fairly constant. The cortex also was normal in the less severely affected cases which I studied. In one case the neurons of the fifth layer showed slight swelling resembling axonal reaction which may well have been secondary to the lesions in the underlying white matter. In another case more severe changes resembling those of ischæmia were present in the third layer. In cases of cerebral abscess, where the œdema was usually of more severe degree, degenerative changes in the cortical neurons were not uncommon. These were associated with swelling of the cortical astrocytes and proliferative changes in the microglia.

(2) *Traumatic cerebral œdema.*—(i) *Local form*: Œdema with similar histological characters is found in most cases of cerebral trauma in restricted zones which surround areas of bruising or hæmorrhage in a more or less concentric fashion. The width of this zone rarely exceeds 2 cm. In some of our cases, examined during the war years, there was also evidence of periventricular œdema. The outline of this zone shades off gradually, and in this respect differs from that of the areas of ischæmic degeneration of white matter, due to damage to the vessels entering it from the surface, which are commonly found in cases of cerebral trauma. In cases of cerebral hæmorrhage, traumatic or otherwise, the width of the zone of œdematous pallor usually varies with the size and to some extent with the duration of the hæmorrhage.

These histological changes in the white matter are so definite and characteristic that not only is it possible to say from the study of a section that œdema is present but also to estimate its degree and duration. There may, however, be forms of cerebral œdema, especially perhaps affecting the grey matter, in which a different histological pattern is seen, or in which the histological changes are so slight as to be recognized only by the most minute study.

[*March* 20, 1947]

Parapsoriasis, Retiform Variety.—J. E. M. WIGLEY, F.R.C.P.

B. H., boy aged 9. First seen in February 1941 when the eruption was said to have been present two and a half years. He then had red, mottled areas affecting both legs and lower halves of thighs. There was some slight scaling over the erythematous areas and some hyperkeratosis about the knees and ankles. There was no complaint of irritation then and he seemed a perfectly healthy child otherwise. The eruption has been present both in summer and winter.

I saw him again in January 1947 when the lesions were said by his mother to have altered very little. It was then noted that the area of skin affected reached from about the junction of the upper and middle third of each thigh to the ankle. A small area on the side of his neck, below and behind each ear, and a similar small area on the under surface of the chin were affected. The lesions on the legs present a striking appearance. The whole area is slightly scaly and made up of gyrate narrow bands of erythema producing a figurate appearance recalling that shown by the condition known as erythema ab igne. The scaling is dry and thin and the skin between the erythematous lesions gives some impression of false atrophy. The lesions about the neck and chin are simply dry and scaly and do not show the arabesque figures present on the legs. There are a number of scaly papules scattered over the arms.

The eruption irritates slightly on exposure to heat.

Wassermann and Kahn reactions are negative.

Histological examination (Dr. Muende).—"Beyond a vacuolation (desiccative) of the superficial layers of the stratum corneum and a slightly increased cellular infiltration in the neighbourhood of the superficial capillaries, there are no pathological features suggestive of any specific skin condition."

The condition appears to me very characteristic of that described by many authorities as parapsoriasis lichenoides and grouped by Dr. MacLeod (*Brit. J. Derm.* (1943), 44, 569) as the reticulate variety. MacLeod mentions the occasional resemblance to erythema ab igne. The only really unusual feature seems to me to be the extreme youth of the patient at the onset.

Dr. F. Parkes Weber: The only objection that I should make to this description is the use of the term "retiform". Parts of the body may show this appearance, but the most typical parts of the thighs show a linear distribution of the dermatosis. I would suggest, considering the boy's age and the history that he gives of having had this condition ever since he can remember, that the case is really a *forme fruste* of a congenital ichthyosiform erythrodermia.

Acne Conglobata.—L. FORMAN, M.D.

W. W., aged 20. At the age of 16 he was 6 feet tall, plump, with well-developed penis and testicles. The hair growth was profuse over the face and limbs. The skin was intensely seborrhœic over the face, chest, and back. The striking clinical feature during the period of observation has been the development of large abscesses in the axillæ and perianal area involving the buttocks. The abscesses develop slowly, commence in the deep layers of the dermis, and may reach a size of 1 to 1½ in. across. They communicate with each other and, after discharging, heal leaving epidermal bridges. The depth of the abscesses and the absence of comedones raise the possibility of the infection occurring in the apocrine glands.

white matter, both of the cerebral (70·7%) and the cerebellar (70·6%) hemispheres, while intermediate values are found for the thalamus (75·1%) and corpus callosum (75·7%).

The total water content of seven specimens of œdematous cerebral tissue was determined and contrasted with corresponding tissue from the opposite hemisphere. It is perhaps worth pointing out here that in spite of the wet appearance of the œdematous brain, fluid does not actually drip or run from it as is often stated. All methods of draining, suction, filtering and squeezing failed to separate any fluid for analysis. A marked increase was found in the water content of the white matter on the side of the lesion (average 81·8%) compared with tissue taken from the opposite side (average 69·6%). There was no material difference between the grey matter of the cortex on the two sides. Moreover a more detailed analysis in three of the cases suggests that the changes are restricted to the centrum ovale and do not involve the corpus callosum, internal capsule or thalamus. These figures indicate a considerable addition of extra fluid in the œdematous white matter—an average addition of 59·1 c.c. per 100 grammes of whole tissue.

Since interstitial fluid contains a large amount of chloride and sodium and a very small amount of potassium and phosphate (the former being the principal extracellular ions and the latter the chief intracellular ions), an analysis of these electrolytes in tissue from the œdematous and normal hemispheres was carried out with a view to determining whether this additional fluid represents a simple increase of the interstitial fluid or some more complicated fluid change involving the cellular tissue. There is a very large increase in the amount of Cl in the œdematous tissue compared with the normal (average 29·6 milli-equivs % and 7·6 milli-equivs % respectively), a large increase in the Na (58·9% and 27·0% respectively, a negligible change in the K (22% and 21·3% respectively). In the grey matter, in which it has been shown that no change in the fluid content occurred, analysis of these electrolytes showed no significant change in the two cases examined. From these figures, showing the difference between the water and electrolytes on the two sides, the electrolytic composition of the additional fluid can be calculated and compared with serum.

	Na	Cl	K	Na/Cl ratio
Serum filtrate.. ..	14·8	11·1	0·25	1·33
"Œdema fluid" ..	13·3	9·2	0·21	1·44

It is thus shown that the electrolytic composition of the œdema fluid, determined in this way, closely resembles that of serum filtrate, and has therefore the same composition as lymph, serous transudates and œdematous fluid elsewhere in the body, and interstitial tissue generally. This demonstrates clearly that the cerebral œdema associated with cerebral tumours is an extra-cellular effusion derived from the blood plasma. Identical changes were found in one case of œdema associated with a recent cerebral hæmorrhage. It is almost certain, therefore, that local œdema in the neighbourhood of traumatic contusion of the brain is of the same nature.

It is felt that these experiments suggest that further biochemical investigation of biopsy and autopsy specimens of cerebral tissue would contribute to our knowledge of the occurrence and nature of cerebral œdema.

(A full account of this joint meeting will be published in *La Revue Neurologique*.)

The scaling is dry and thin and the skin between the erythematous lesions gives some impression of false atrophy. The lesions about the neck and chin are simply dry and scaly and do not show the arabesque figures present on the legs. There are a number of scaly papules scattered over the arms.

The eruption irritates slightly on exposure to heat.

Wassermann and Kahn reactions are negative.

Histological examination (Dr. Muende).—"Beyond a vacuolation (desiccative) of the superficial layers of the stratum corneum and a slightly increased cellular infiltration in the neighbourhood of the superficial capillaries, there are no pathological features suggestive of any specific skin condition."

The condition appears to me very characteristic of that described by many authorities as parapsoriasis lichenoides and grouped by Dr. MacLeod (*Brit. J. Derm.* (1943), 44, 569) as the reticulate variety. MacLeod mentions the occasional resemblance to erythema ab igne. The only really unusual feature seems to me to be the extreme youth of the patient at the onset.

Dr. F. Parkes Weber: The only objection that I should make to this description is the use of the term "retiform". Parts of the body may show this appearance, but the most typical parts of the thighs show a linear distribution of the dermatosis. I would suggest, considering the boy's age and the history that he gives of having had this condition ever since he can remember, that the case is really a *forme fruste* of a congenital ichthyosiform erythrodermia.

Acne Conglobata.—L. FORMAN, M.D.

W. W., aged 20. At the age of 16 he was 6 feet tall, plump, with well-developed penis and testicles. The hair growth was profuse over the face and limbs. The skin was intensely seborrhœic over the face, chest, and back. The striking clinical feature during the period of observation has been the development of large abscesses in the axillæ and perianal area involving the buttocks. The abscesses develop slowly, commence in the deep layers of the dermis, and may reach a size of 1 to 1½ in. across. They communicate with each other and, after discharging, heal leaving epidermal bridges. The depth of the abscesses and the absence of comedones raise the possibility of the infection occurring in the apocrine glands.

To-day, pustular acne is still present over face and trunk. The axillæ show indurated areas with epidermal bridges, and granulomatous ridges covered with pyogenic membrane. The buttocks and perianal area are peppered with projecting granulomata and the sites of sinuses, and the area is generally indurated.

Cultures from unbroken abscesses have grown acne bacilli alone, or scanty *Staphylococcus albus* (hæmolytic) and *Staphylococcus aureus.* No tubercle bacilli were seen. Section of the wall of a buttock abscess showed a chronic granuloma with no evidence of tuberculosis.

The causal relationship of the acne bacillus in these abscesses is still undetermined. Cultures of acne bacilli rubbed over the back of this patient did not produce any signs of follicular reaction.

With regard to recent endocrine therapy for acne, in my experience with severe acne, small doses of œstrogens by mouth are ineffective. Implantation of the synthetic œstrogens, in addition to causing enlargement of the breasts and loss of libido, may have a definite inhibitory action on the pituitary and indirectly on the gonads.

Investigations have been reported on the effects of œstrone and œstradiol implanted as compressed tablets of pure hormone under the skin of male rats and mice. Inhibition of some of the functions of the pituitary gland were observed, with depression of the growth rate and shrinkage of the gonads.

There are also the possible psychological effects to be considered on potentially bisexual adolescents.

Pringle's Disease (Adenoma Sebaceum).—Hugh W. Gordon, M.C., M.B.

The patient, aged 14 years, was noticed two years ago to be developing red spots on the face. These were treated at St. John's Hospital for Diseases of the Skin with an "electric needle" and were said to improve very considerably. They have, however, reappeared during the last four to six months.

The patient is one of five brothers, and there is no history of the complaint in any other member of the family. He is said to be a little backward at school, but is in every other way perfectly normal.

On examination.—A large number of small papules are present on the cheeks and round the alar nasal folds with a well-marked telangiectatic element.

Dr. Gordon said that the patient appeared to be that rather uncommon phenomenon, the perfect textbook case of the disease. He was showing him for this reason and also for possible advice in regard to treatment. He was proposing to cauterize all the lesions thoroughly under a general anæsthetic.

Dr. Freudenthal: I would suggest that thorium X be tried.

Mycosis Fungoides.—Hugh W. Gordon, M.C., M.B.

The patient, a previously healthy man of 67, has noticed an abnormal thickening of the skin on his back for three years, which has slowly increased in size. Subjective sensations have been slight. During the last three or four months he has noticed a slight swelling in both armpits. His general health has been unimpaired.

On examination.—There was a sharply marginated plaque about 5 cm. × 4 cm. raised in the centre about a cm., the increase in thickening tapering off towards the edges, which have a waxy look.

The colour is purplish, the surface shiny with no suggestion of ulceration or granulation.

There is an enlarged gland in each axilla, and glands are slightly enlarged in both groins.

When first seen two months ago, a tentative diagnosis of mycosis fungoides was made with possible alternatives of Bowen's disease or a primary sarcoma. A section taken from the centre of the lesion on that occasion was reported on by Dr. Freudenthal as excluding Bowen's disease, but no diagnosis was possible on account of the high degree of chromatotaxis.

One X-ray treatment, dose 350 r was given to the lesion and to both axillæ.

On 18.2.47 considerable flattening had occurred which has, however, not persisted.

Another section taken on 5.3.47 shows a profuse cellular infiltrate with pleomorphism typical of mycosis fungoides.

Blood-count normal. The Wassermann test was negative.

Dr. Gordon added that the diagnosis of this condition rested almost entirely on the histology which he felt excluded everything other than reticulosis. The response to X-ray had been disappointing but he proposed to give a further X-ray with higher voltage.

Postscript (1.5.47).—Under high-voltage therapy the glands have completely regressed but the main lesion in the back has shown disappointing response.

Dr. W. Freudenthal: The friability of cells which Dr. Gordon met in his first biopsy, is, in my experience, frequently seen in mycosis fungoides and in other conditions of the reticulosis group, including the leukæmias: I look upon it as a diagnostic help. I have met it also fairly frequently in lupus erythematosus, which may be more than a coincidence.

Dr. P. J. Feeny: The fact that this case did not respond to a dose of X-rays points very much against the diagnosis of mycosis fungoides.

Dr. L. Forman: Would Hodgkin's disease be considered? Solitary cutaneous plaques have been described in this disease.

? Erythema Multiforme.—C. H. WHITTLE, M.D.

M. B., woman aged 24, a shorthand typist.

History of swellings on the lower posterior third of the legs for twelve weeks. She had a similar but much milder attack the previous winter.

Family history.—A brother has chronic red spots on his face (not seen).

The lesions consisted of two bluish-red circular infiltrated plaques 5 cm. in diameter with sharp edges raised above the surface of the surrounding skin on inner and posterior aspect of left ankle. There were several more recent lesions on the right ankle, posterior aspect, up to 1 cm. in diameter. They have an elastic almost rubbery feel and are slightly tender. At first glance they look like large blisters, with a yellowish translucent character. The larger plaques have resolved leaving bluish-brown discoloration. The remaining lesions are superficially reminiscent of colloid milium.

X-ray of chest: No evidence of disease. Mantoux reaction: Human and bovine 1 : 1,000 both positive. The sites of intradermal inoculation showed ten days or so later an increase in size and redness which has gradually subsided.

Wassermann reaction negative.

Biopsy.—There is an intense inflammatory perivascular and perifollicular exudate in the corium. The cells are chiefly small round cells and polymorphs. The clear yellow zone visible to the naked eye appears to be due to œdema and/or degeneration of colloid type in the papillary and subpapillary layers, which are thickened. No amyloid or mucin present. The epidermis is flattened and the rete pegs much diminished. The changes do not suggest tubercle or sarcoid, but might fit with the diagnosis of erythema multiforme.

Dr. F. Parkes Weber: Possibly this might turn into a case of erythema induratum; it might be an early form of that condition, although the microscope does not seem to support that view.

Congenital Ichthyosiform Erythrodermia (Brocq).—IAN MARTIN SCOTT, M.D.

Miss J. H., aged 17 years.

History.—Two weeks after birth the skin of the wrists became dry and cracked, and shortly afterwards this condition became generalized. Her mother did not notice any undue reddening of the skin, and treated her with daily baths of olive oil.

The condition has continued throughout her life, but she has noticed a gradual improvement during the past ten years. The skin has never blistered.

At the age of 8 years she was advised to wear spectacles for a slight visual defect, and possibly also for her bilateral ectropion.

She prefers cold weather; in warm weather she becomes intensely hot, and only sweats slightly from the palms, soles, axillæ and central portions of her face. With variations of external temperature she takes a longer time to become warm or to cool down than normal people.

On questioning, she states that her nails seem to grow more quickly than normal, but in contrast her hair seldom needs to be cut. The patient has always had moderate dandruff and washes her hair every week. Her teeth have always required much attention. Desquamation inside the auditory meatus causes occasional discomfort. The skin does not cause irritation during her working day, but in the warmth of bed is slightly itchy. She anoints herself with an emollient each night after her bath. She enjoys good general health, but occasionally suffers from sore throats, chilblains, and slight rheumatism of the shoulders and hips.

Family history.—The patient has a younger brother who is normal in all respects. There is no consanguinity of her parents, and none of her immediate relatives has ichthyosis.

Past health.—At the age of 7 years she had a mild attack of chicken-pox, but cannot describe the eruption. At 8 she had measles and then whooping cough. The measles rash caused a general desquamation which was very slow in the neck. Her tonsils were removed at the age of 10.

Present condition.—General systemic examination reveals no abnormality. Menstruation is of normal duration and rhythm. The teeth are sound and well cared for. The nails appear normal. The hair is of normal texture, but there is moderate dandruff.

The skin.—There is general dry scaling of the skin, which also involves the folds covering the large joints. Erythrodermia is seen to a moderate degree on the face and ears, and is well marked around the knees and elbows.

Detailed examination of the skin: The skin of the face is taut, parchment-like, and shows fine scaling. On the posterior and lateral aspects of the neck it is of more horny consistency, and greyish-brown. This type of skin extends into both axillæ, where there is little growth of hair.

Quadrilateral scaling is present on the limbs, and there is marked reddening over the elbows, wrists, and knees. The palms are moist and the skin of more normal texture with slight peeling at the joint flexures. The skin of the soles appears normal except for several callosities and a wart.

On the breasts the skin is pink and of fine parchment-like texture—it appears as though painted with a film of clear varnish and then cracked into quadrilaterals.

The skin of the abdomen is hyperkeratotic and yellowish-green. The hair of the pubic region is scanty. On the back the skin is dry and light brown; over the buttocks there is quadrilateral scaling with red lines between the scales.

Histology (8.2.47).—Biopsy from the right anterior axillary fold. The surface of the skin is irregular. The epidermis including the horny layer forms depressions, at the deepest parts of which the rete pegs are flattened; at the elevations the rete pegs are thickened. There is a well-marked hyperkeratosis consisting chiefly of compact horn, and no parakeratosis. The keratohyalin layer is thickened up to three to five layers in some places. There is patchy acanthosis, and in some places the rete pegs are elongated. In the papillary layer there is moderate œdema, and a slight perivascular infiltration of lymphocytes and fibroblasts. A small number of lanugo hairs with associated sebaceous glands are to be seen. The eccrine sweat glands are numerous and appear normal. In some places the blood-vessels are rather numerous, and the cells of the endothelial lining are swollen and conspicuous.

Comments.—So far as I am aware no similar cases have been published in this country since 1928. The principal features of this present case, which conform with those originally described by Brocq, are as follows: Onset within two weeks of birth; long duration; erythrodermia, most marked around the large joints; general ichthyosis, which includes the large joint folds; and a seborrhœic condition of the scalp.

Brocq also mentioned the following inconstant features: (*a*) Hyperkeratosis of the palms and soles—not present in this case. (*b*) Rapid growth of hair and nails—not a marked feature in this case.

The disease has been divided into two types depending on the presence of bullæ; there is no history of bullæ in this girl.

In addition to the essential features of the condition this patient also has a bilateral ectropion. It is of interest to note that in two of the three cases where there were no bullæ, in Brocq's original paper, bilateral ectropion was present, although not stressed by him as a feature of the disease. A further two cases showing bilateral ectropion have been described more recently.

I should like to record my thanks to Dr. W. N. Goldsmith for kindly allowing me to present this case.

Myxœdema Papulosum.—BERNARD GREEN, M.R.C.S., L.R.C.P., and W. FREUDENTHAL, M.D.

Mrs. M. D., aged 72.

In good general health. First noticed a "group of pimples" on the antecubital fossæ, the inner aspects of the arms and on the back of the neck. These all appeared eighteen months ago (October 1945) and are symptomless. She had a similar eruption about August 1944 which disappeared when she was treated for an attack of sciatica in February 1945, and remained clear for several months.

Past history.—In January 1943 she had a tumour on the left side of her neck, immediately below the angle of the jaw, the nature of which she does not know. Radium was used for treatment. She has varicose veins, ulcers and eczema of legs.

General examination.—A well-nourished woman of healthy appearance. Blood-pressure 200/100; other systems apparently normal.

Skin examination.—There are a large number of closely aggregated, non-confluent skin-coloured papules, 1 to 3 mm. in diameter, in both antecubital fossæ, (fig. 1) flexor aspects of the forearms, inner aspects of the upper arms extending along the anterior and posterior axillary folds and on the shoulders extending along the sides of the neck. There are also a number of grouped papules on the lower part of her back on either side of the intervertebral sulcus. She has slight perniosis on the posterior aspects of the upper arms, varicose veins and pigmented scars from healed ulcers on the ankles.

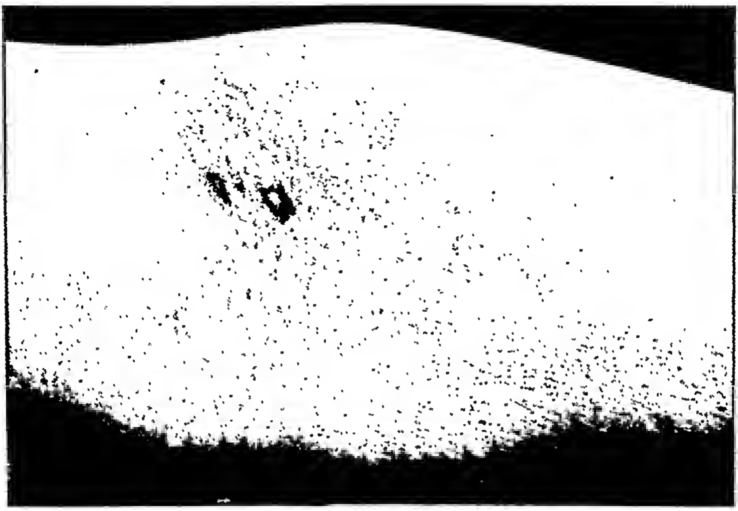

FIG. 1.—Myxœdema papulosum.

Biopsy.—Three discrete papules, arranged in a line, from the right upper arm, were excised. In the sections these papules show as well-defined round or oval areas in the middle and lower third of the cutis. They contain lymphocytes and fibroblasts and, chiefly in the central parts between the collagen bundles, thin strands of fibrinoid masses stained yellow with van Gieson; the elastic fibres are slightly diminished. The lymphocytes are mainly found towards the periphery of these areas and often arranged around small vessels. Each of these areas contains a small to moderate amount of mucin, forming a fine network that stains metachromatically pink with thionin.

The exhibition of tab. thyroid grain ½ t.d.s. was not well tolerated, but one tablet daily made her feel well; this did not influence the eruption.

Comment (B. G.).—I made a tentative diagnosis of pseudoxanthoma elasticum, which, however, was not confirmed by biopsy. I made an alternative diagnosis of myxœdema papulosum, and asked Dr. Freudenthal to make a biopsy.

A similar case, showing papular and annular lesions, was shown at this Section by Drs. Freudenthal and Brünauer in January 1942 (*Proc. R. Soc. Med.*, 35, 388).

Trotter and Eden (*Quarterly Journal of Medicine*, 1942, 35 (N.S. 11), 229) described cases of localized pretibial myxœdema in association with toxic goitre and summarized their findings in a series of cases and discussed the local and general factors governing the deposition of mucin in the skin. It would appear that this type of eruption of the skin occurs both in hypothyroidism and thyrotoxicosis and the condition is unaffected by the administration of thyroid extract or thyroidectomy. It would seem, therefore, that these cases are a form of dysthyroidism due to an overactivity of the pituitary gland.

Cases of pretibial myxœdema have been shown at this Section by Bamber, Forman and others. Dowling (*Proc. R. Soc. Med.*, 1934, 27, 1361), when showing a case, mentions another in which the lesions of the skin appeared several years before the onset of typical symptoms of Graves' disease.

Dr. W. Freudenthal: Three groups of cases of myxœdema may be distinguished: (1) The generalized myxœdema of cretins; (2) The pretibial myxœdema in Graves' disease of which Trotter and Eden have made a careful critical study (*Quart. J. Med.* 1942, 35 (N.S. 11), 229); (3) The "atypical" myxœdema (Jadassohn-Doessekker, *Arch. Derm. Syph., Wien*, 1916, 123, 76) which was the subject of a discussion at this Section in January 1942 when a case with papular and annular lesions in a patient with nodular goitre was shown (*Proc. R. Soc. Med.*, 35, 388). To this group belong the present case, the case with papular and plaque-like lesions (after thyroidectomy) shown at this Section in December 1946 (*Proc. R. Soc. Med.*, 1947, 40, 258); also Mumford and Barber's case of myxœdema moniliforme, shown January 1943 (*Proc. R. Soc. Med.*, 36, 286).

This third group deserves our attention and careful investigation, expecially from the endocrinological point of view.

Dr. W. R. Trotter: I agree with Dr. Freudenthal that we are here dealing with three quite separate conditions which affect the skin. There is first generalized myxœdema—hypothyroidism. Then pretibial myxœdema, which is invariably associated with a toxic goitre, although it may not appear until after the toxic goitre has been treated by thyroidectomy; nevertheless, it always appears in association with a toxic goitre. Finally there is the third group of which the present case is a good example. One would like to find some association with thyroid disease, but so far there is no direct evidence. Here, I think, we have to beware of falling into a terminological trap, for the term "myxœdema" is used in two quite separate senses, namely, the sense commonly used in general medicine for the clinical picture produced by deficiency of thyroid secretion, and the literal sense in which it is used in dermatology for a mucinous infiltration of the skin. In this connexion I think the dermatologists have the right on their side, and if we could choose the sense in which the word is to be used it would be better if the term "myxœdema" were kept for use in its literal sense. However, I am afraid things have gone too far, and the term "myxœdema" is in such common use in the sense of hypothyroidism that there is no hope of recalling it. But as long as the term is used in two different senses there will continue to be a considerable amount of confusion. All we can say is that in Dr. Freudenthal's third group none of the cases has responded to oral thyroid extracts. That is certainly true of the pretibial type also, and they are unaffected by thyroidectomy. Only in the first group, associated with hypothyroidism, does the skin change at all when thyroid extract is administered. At the moment the third group remains a baffling and extremely interesting problem.

Dr. Freudenthal: Could the pituitary gland play a role in these conditions?

Dr. Trotter: All we can say in that connexion is that pituitary over-activity may occur and may be a common factor linking the cases of hypothyroidism and the cases of pretibial myxœdema and toxic goitre, but again I have nothing to say about the third group.

Dr. E. Lipman Cohen: The name "pretibial myxœdema" is becoming so firmly entrenched as descriptive of a group that it is liable to be misleading if it is taken too exclusively. Lesions have been found on the lower part of the abdomen and on the thighs. I have suggested the name "myxœdema circumscriptum thyrotoxicum".

Dr. Freudenthal: As long as so much uncertainty exists as to the pathogenesis of all three groups of myxœdema it may be best to keep this term and use it simply as a descriptive one. Or, we may try to introduce the term "mucinoses" to cover all conditions in which the presence of mucin is an esssential factor; it may include granuloma annulare (*Proc. R. Soc. Med.* 1945, 38, 333).

Sarcoidosis.—BERNARD GREEN, M.R.C.S., L.R.C.P., and C. W. F. MCKEAN, M.B.

Mrs. M. L., aged 41. Two children. In good general health. The eruption first commenced on her legs and forehead eight years ago. She now presents a striking appearance. On the forehead there are gyrate brownish lesions with a slightly elevated scaly edge, the centre being smooth and slightly atrophic. There are also several reddish-brown nodules on the face, and irregular infiltrating purplish and brownish plaques on the upper and lower limbs and shoulders. All the lesions are symptomless.

The eruption was not influenced during pregnancy.

Her brother died of pulmonary tuberculosis five years ago.

A biopsy was done and the section shows some granulomatous tissue in the dermis. The lesion consists of round aggregations of endothelial cells with an occasional foreign-body giant cell. There is no evidence of caseation, and the Ziehl-Neelsen film shows no tubercle bacilli to be present.

W.R. is negative. Mantoux test negative. E.S.R. 27 mm. in first hour (Westergren). A skiagram of the chest shows slight enlargement of the right upper mediastinal glands, but no pathological changes in the lungs. A skiagram of the bones of the hands reveals nothing abnormal.

Dr. Hugh Gordon: The lesions on this patient's face are similar to those of a patient of mine shown to the Section in January. She has two circular plaques on the right lower arm with raised edges and a scaly atrophied centre. The histology was that of a sarcoid. In this present case there are both these superficial scaly lesions with scarring present together with the more typical indurated lesions on the limbs.

Dr. Gordon said that he had not previously seen this superficial scaly type of scarring though there was an excellent picture in Jadassohn's Handbook. His case was improving satisfactorily on calciferol.

Dr. C. H. Whittle: I should like to ask whether it is a frequent experience to see scarring in sarcoids. One has the opportunity of watching the course of very few cases of sarcoidosis, because they are rare, but in my experience resolution is not usually accompanied by atrophy.

Epidermolysis Bullosa Dystrophica.—C. W. F. McKean, M.B.

Irene M. P., aged 13 years 11 months.

On examination.—Admitted to the South Eastern Hospital for Children suffering from a bullous eruption involving especially the elbows, extensor surfaces of the forearms and hands, the abdomen, lower spine and buttocks, the thighs, legs and feet, also slightly the shoulders, neck and scalp. The bullæ were in all stages. Some contained serum, and some were hæmorrhagic. The epidermis between the bullæ in the more severely affected parts was extremely atrophied. There were many milia-like epidermal cysts, especially on the loins and extensor surfaces of the forearms. All the finger- and toe-nails had been lost. Her hair was fine and sparse, though her mother considered it to be thicker than ever before. Her teeth were soft and very badly decayed, many almost completely lost. Her tongue was small and shiny, with patches of leukoplakia, and could not be protruded beyond the teeth. Though of good average height, she was painfully thin. Finally, it was interesting when dealing with one congenital abnormality to find another, namely, that the right first and second toes were conjoined.

History.—She was born at home, weighing between six and seven pounds. After birth the right foot was found to be denuded of the epidermis, and at 3 weeks of age she was first brought to the hospital. She has been brought regularly every Thursday ever since, till the war began, and then she was evacuated with her mother, who cared for her till she returned to the hospital last month. Her notes go back to the age of 4, and the condition has remained much the same throughout. The birth injury to the foot healed quickly, but within the first seven days of life blisters were seen on the fingers, and thenceforth any knock or rub would cause a blister to develop. She is said to have been forward rather than backward with her teeth, and with walking and talking. She was fairly fat as a baby, but has been thin ever since she began to walk. She has never been to school, and was never allowed to play with other children. Having been taught solely by her mother and sister, it is a little hard to judge of her intellectual capacity. She reads children's books, writes interesting letters, and has a good memory.

Family history.—The parents are not related, and there is no history of any similar skin disease in the family. But her father exhibits transposition of the viscera. He also suffers from a gastric ulcer. There are no other familial congenital abnormalities.

Pathological investigations.—Wassermann and Kahn reactions negative. Urine: No porphyrins observed. Biopsy of blister (Dr. I. Muende): The epidermis has separated from the corium at the epidermo-dermal junction.

Treatment.—In the absence of specific treatment: confinement to bed, and penicillin dressings to prevent infection. The bullæ continue to arise, particularly with skin contact, for instance where the legs are crossed during sleep.

Discussion.—Epidermolysis bullosa usually begins during the first two years of life, and may subside at puberty. It is more frequent in males. It is divided into simple and dystrophic types, with intermediate cases. The simple type does not often affect the mucous membranes and does not leave scarring, nor are the nails affected. In the severe form the nails show many dystrophic changes, but are not often all lost.

The simple form is said to be inherited as a dominant, whereas the dystrophic may be as a dominant or recessive, the severest cases being recessive.

Senear-Usher Syndrome.—E. Colin Jones, M.B.

Miss I. R., aged 57, states that her skin trouble began in March 1946, with numerous blisters over the back, followed very shortly by similar lesions over the whole body—the outbreak coinciding with an attack of lumbago.

Initially she was treated with sulphanilamide ointment but the various areas were aggravated.

When first seen by me in July 1946 the condition resembled dermatitis herpetiformis. Irritation was marked, but potassium iodide patch test was negative. There was no response to either arsenic or tablets of M & B 693.

Dr. W. Freudenthal: Three groups of cases of myxœdema may be distinguished: (1) The generalized myxœdema of cretins; (2) The pretibial myxœdema in Graves' disease of which Trotter and Eden have made a careful critical study (*Quart. J. Med.* 1942, 35 (N.S. 11), 229); (3) The "atypical" myxœdema (Jadassohn-Doessekker, *Arch. Derm. Syph., Wien*, 1916, 123, 76) which was the subject of a discussion at this Section in January 1942 when a case with papular and annular lesions in a patient with nodular goitre was shown (*Proc. R. Soc. Med.*, 35, 388). To this group belong the present case, the case with papular and plaque-like lesions (after thyroidectomy) shown at this Section in December 1946 (*Proc. R. Soc. Med.*, 1947, 40, 258); also Mumford and Barber's case of myxœdema moniliforme, shown January 1943 (*Proc. R. Soc. Med.*, 36, 286).

This third group deserves our attention and careful investigation, expecially from the endocrinological point of view.

Dr. W. R. Trotter: I agree with Dr. Freudenthal that we are here dealing with three quite separate conditions which affect the skin. There is first generalized myxœdema—hypothyroidism. Then pretibial myxœdema, which is invariably associated with a toxic goitre, although it may not appear until after the toxic goitre has been treated by thyroidectomy; nevertheless, it always appears in association with a toxic goitre. Finally there is the third group of which the present case is a good example. One would like to find some association with thyroid disease, but so far there is no direct evidence. Here, I think, we have to beware of falling into a terminological trap, for the term "myxœdema" is used in two quite separate senses, namely, the sense commonly used in general medicine for the clinical picture produced by deficiency of thyroid secretion, and the literal sense in which it is used in dermatology for a mucinous infiltration of the skin. In this connexion I think the dermatologists have the right on their side, and if we could choose the sense in which the word is to be used it would be better if the term "myxœdema" were kept for use in its literal sense. However, I am afraid things have gone too far, and the term "myxœdema" is in such common use in the sense of hypothyroidism that there is no hope of recalling it. But as long as the term is used in two different senses there will continue to be a considerable amount of confusion. All we can say is that in Dr. Freudenthal's third group none of the cases has responded to oral thyroid extracts. That is certainly true of the pretibial type also, and they are unaffected by thyroidectomy. Only in the first group, associated with hypothyroidism, does the skin change at all when thyroid extract is administered. At the moment the third group remains a baffling and extremely interesting problem.

Dr. Freudenthal: Could the pituitary gland play a role in these conditions?

Dr. Trotter: All we can say in that connexion is that pituitary over-activity may occur and may be a common factor linking the cases of hypothyroidism and the cases of pretibial myxœdema and toxic goitre, but again I have nothing to say about the third group.

Dr. E. Lipman Cohen: The name "pretibial myxœdema" is becoming so firmly entrenched as descriptive of a group that it is liable to be misleading if it is taken too exclusively. Lesions have been found on the lower part of the abdomen and on the thighs. I have suggested the name "myxœdema circumscriptum thyrotoxicum".

Dr. Freudenthal: As long as so much uncertainty exists as to the pathogenesis of all three groups of myxœdema it may be best to keep this term and use it simply as a descriptive one. Or, we may try to introduce the term "mucinoses" to cover all conditions in which the presence of mucin is an esssential factor; it may include granuloma annulare (*Proc. R. Soc. Med.* 1945, 38, 333).

Sarcoidosis.—BERNARD GREEN, M.R.C.S., L.R.C.P., and C. W. F. MCKEAN, M.B.

Mrs. M. L., aged 41. Two children. In good general health. The eruption first commenced on her legs and forehead eight years ago. She now presents a striking appearance. The Diagnosis and Treatment of Tumours of the Nasopharynx

By E. D. D. DAVIS

THE tumours of the nasopharynx are difficult and unsatisfactory to treat but fortunately they are comparatively rare. I have studied the notes of 34 of my patients and the literature of a large number of other cases with the object of establishing an earlier diagnosis and more successful treatment. The 34 cases were seen during the past twenty-five years and consisted of 19 cases of carcinoma, 4 lymphosarcomata or lymphomata, 10 angiofibromata, 1 myxosarcoma of doubtful origin.

These are the types of tumours recorded by other observers but some call the fibroma or angiofibroma a fibrosarcoma. Two of the above angiofibromata turned out to be sarcomata and recurred some time after removal. This list does not include rare tumours such as ameloblastomas or adamantinomas which extend from the pituitary body along the craniopharyngeal canal or from the maxillæ into the nasopharynx. It is important to be able to recognize the degree of malignancy and the probable reaction to radiotherapy but at the present time there is considerable confusion in the nomenclature of various malignant and benign growths particularly carcinomata. The early diagnosis of these tumours is delayed because they are hidden in a cavity which is sometimes difficult to inspect. This inspection of the nasopharynx in patients who cannot tolerate the small mirror placed behind the soft palate is difficult and also in advanced cases of carcinoma when inability to open the mouth and fixation of the mandible is a symptom. Moreover a patient does not consult a doctor until the growth is large enough to produce a series of mechanical symptoms which are slow and insidious in onset and when it is frequently too late for successful treatment. Malignant growths within themselves do not produce any specific diagnostic symptoms or signs, and the general signs such as blood changes, cachexia, &c., are of no practical value in the early diagnosis. Gordon New of the Mayo Clinic reported 79 cases of malignant growths of the nasopharynx; 34 were epitheliomata and 33 were lymphosarcomata. It is interesting to note that of these 79 patients 74 had had an operation for the relief of symptoms without recognition of the fact that a primary growth in the nasopharynx was the cause of these symptoms. In 24 patients tonsils and adenoids

Differential blood-count: Leucocytes 6,900 (polys. 69%, lymphos. 26%, monos. 2%, eosinos. 3%).

The diagnosis became more uncertain, and the condition resembled chronic bullous pemphigus, but in September 1946 there was a much greater extension, the whole of the back, and to a less extent the chest, being covered with mixed, crusted hyperkeratotic and pigmented areas, with scattered bullæ and crusted impetigo-like lesions.

In January 1947 the face became involved, the whole area being covered with lupus erythematosus-like patches with seborrhœa of the scalp and the same general eruption on the trunk, only more acute. The distal parts of the extremities have never been affected to any great extent.

She was admitted to the Royal Sussex County Hospital in February, and treated by intramuscular penicillin, 30,000 units, three-hourly, for over 5,000,000 units, and during this period there was a great improvement. She was also given three small transfusions of fresh, whole blood at weekly intervals, and there is no doubt that this has checked further outbreaks up to the time of showing her.

At the time of her discharge her white blood-count read: Polys. 51%, lymphos. 39%, eosinos. 4%, monos. 6%.

On examination.—A healthy-looking woman. Partial dentures, teeth in good condition.

At present her face is practically clear, one small, pigmented scar on the forehead remains, but the trunk areas still show a rather complex picture of seborrhœa, pemphigus-like scars, and erythematoides.

POSTSCRIPT (4.10.47).—Since showing this case the patient has had an acute exacerbation, and antrypol has proved valueless.—E. C. J.

Dr. P. J. Feeny: One might possibly settle the diagnosis in this case as to whether it is pemphigus or not by giving antrypol. Dr. Burrows and I have had about 10 cases in children, mostly in Romford, during the past few years, and practically every one of them has been cured by antrypol. Included in this series were cases of "bullous eruption" such as one I showed here on November 16, 1944 (*Proc. R. Soc. Med.*, 38, 143, 1945) where the diagnosis of pemphigus is not universally agreed. Another B.P. Suramin (the German drug "Germanin") had no effect whatever. The dose of antrypol we used was 0·125 gramme intravenously or intramuscularly once a week for ten weeks and further similar courses when necessary after a two months' rest. In adults we have had considerable success on the same lines, using a dose of 0·25 gramme. In elderly people we have had no success at all.

Dr. Colin Jones: My experience with suramin and germanin is not quite so good. Recently I have had two cases of pemphigus treated with germanin without any response at all. We happened to have some of it in stock dating from pre-war days.

Dr. Brian Russell: I have recently had unfavourable results in the treatment of two cases of pemphigus with antrypol brand of suramin (B.P.) and am not convinced of its value in this disease. The occurrence of spontaneous remissions with pemphigus must also be kept in mind, in assessing results.

Recently I saw a patient clinically resembling pemphigus vegetans in a very severe form who reacted well to sulphapyridine but relapsed on its withdrawal, so presumably must be regarded as suffering from dermatitis herpetiformis.

Dr. W. N. Goldsmith: There is much confusion between the names Antrypol, Germanin, and Suramin.

Germanin (Bayer 205) first became a subject of British interest in 1921 when an expedition carried out large-scale experiments in South Africa (*Trans. R. Soc. trop. Med. Hyg.*, 1924, 17, 445, 464). After that, the Germans experimented with it, and in 1927 it became commercially available.

Antrypol has been made since 1933 by Imperial Chemical Industries, but was at first marketed for them by British Drug Houses. It is a brand of Suramin, a term which was introduced early in the war as an English equivalent of the foreign Germanin, and in 1941 was included in the 4th Addendum to the British Pharmacopœia, 1932. Suramin is the sodium salt of m-benzoyl-m-amino-p-methylbenzoyl-1-aminonaphthalene-4 : 6 : 8-trisulphonic acid.

The formula of Bayer 205 has not been given, but "there is every reason to suppose that it is identical with Suramin" (Davis).

NOTE (W. N. G).—The above remarks have, since the discussion, been corrected in accordance with information elicited from Mr. H. Davis, Ph.D., Chief Pharmacist at University College Hospital.

The superficial lymphatic glands along the posterior border of the sternomastoid are involved early. Gordon New has recorded two cases of paralysis of the nerves in the jugular foramen. A persistent sore throat is said to be an early symptom.

Nasal symptoms especially epistaxis or a blood-stained mucous discharge from the nasopharynx accompanied by headache in a patient of cancer age is suspicious, and a careful examination of the nasopharynx with the post-nasal mirror, the endoscope passed through both nostrils alternately, and with the finger, should be made. Good illumination and a direct view of the nasopharynx can be obtained by retracting the palate with a special Coolite retractor or curved pencil torch. The nasopharynx thus illuminated can be clearly seen when looking through the anterior nares with a large nasal speculum.

Beck of Chicago has devised an ingenious method of retracting the palate by passing a small bore rubber catheter through both nostrils and bringing the ends out through the mouth and applying forward and upward traction. These methods of *examination* of the nasopharynx are essential to the early diagnosis of new growths of this area. An X-ray photograph which shows the extent of the growth is useful. Nasal obstruction except in cases of angiofibroma is not common. When the growth is accessible, and it is practical, as large a piece as possible should be removed for microscopy to clinch the diagnosis and for radiotherapy. A biopsy of a nasopharyngeal fibroma is inadvisable for reasons given below. Sometimes a lymphatic gland with metastasis is available and is more useful for a biopsy than a piece removed from the nasopharynx.

The treatment of malignant growths of the nasopharynx is confined to deep X-ray therapy. These cases are inoperable and beyond surgery when first seen. Deep X-ray therapy is more hopeful now that an earlier diagnosis is made and the technique has improved. All the 19 cases mentioned above derived little benefit from radium or deep X-ray therapy and all of them died within twelve to eighteen months from the first appearance of the symptoms. Radium was most unsatisfactory because it caused considerable reaction with pain and irritation of the mucosa and was followed by metastases. The lymphosarcomata and the lympho-epitheliomata disappeared rapidly with radium treatment but the cases all died of metastases within two years. However deep X-ray therapy is the only treatment which holds out any hope of success or even relief.

The bleeding fibroma of male puberty is benign and occurs in boys between the ages of 10 and 20. I have not seen a case in a girl, or a true fibroma after the age of 25. It is a sessile, globular, solid, hard, fixed tumour usually growing from the body of the sphenoid or from the inaccessible roof of the posterior nares. It bleeds freely when touched or spontaneously. Nasal obstruction is the first symptom followed by profuse epistaxis which is more often provoked than spontaneous. The tumour grows and extends within the nasal cavity and even into the nasal sinuses. It is said to disappear about the age of 25, but that has not been my experience, though growth and extension may be slower. I do not know of, nor can I find, the record of any case which has disappeared spontaneously. Nearly all the recorded cases have been treated by enucleation, excision by diathermy or by radiotherapy. The histology of the fibroma is typical and consists of dense fibrous tissue with numerous cavernous blood spaces and in some tumours these spaces are more numerous near the surface of the growth. The tumour is very vascular and for this reason it is frequently called an angiofibroma. A biopsy is unsatisfactory and misleading because it is difficult to remove a sufficiently large piece and only a section of the whole or greater part of the tumour is of real value. The removal of a small piece results in repeated and profuse epistaxis which demands prolonged packing. This is followed by sepsis and had been removed; in 18, glands in the neck; in 12, the wisdom or third molars had been extracted. Various intranasal operations had been performed in 19, and finally a mastoid operation for the relief of pain.

The symptoms and signs of carcinoma of the nasopharynx vary with the site and type of growth and the commonest site is the lateral wall. When the growth is in the region of the eustachian tube or lateral wall the first symptom may be a unilateral deafness with fluid in the middle ear as the result of eustachian obstruction. This is known as the auricular type of growth and it was the first symptom and sign in 3 of my 19 cases. Sometimes a diagnosis has not been made until secondary growths appear in the cervical lymphatic glands. *The glandular type* of case shows the enlargement of the deep cervical glands at the angle of the jaw on both sides of the neck or the superficial group of glands along the posterior border of the sternomastoid. This was the first sign in six cases. This is the type of case for which tonsils have been enucleated or a dissection operation for glands in the neck has been performed before the diagnosis of carcinoma of the nasopharynx has been made. The enlargement of the lymphatic glands is the first sign of a lympho-epithelioma or lymphosarcoma.

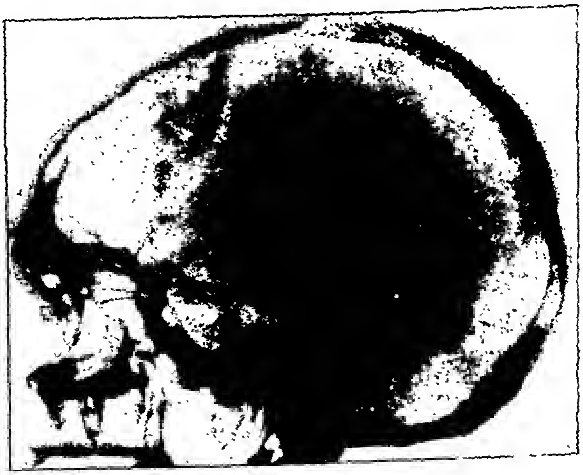

FIG 1.

Neurological symptoms such as headache, pain, diplopia and paralysis of cranial nerves were the first symptoms in six cases. These patients are seen first by the ophthalmic surgeon or neurologist and the primary nasopharyngeal lesion may escape detection. The *headache* is bitemporal or on the vertex of the skull. A *neuralgia of the fifth cranial* nerve or upper cervical spinal nerves is occasional but pain in the distribution of the auriculo-temporal nerve is more common. Paralysis of the sixth cranial nerve first on one side and then on both is commonest. It is followed by ptosis and paralysis of the third nerve and later a complete ophthalmoplegia on the one side and a partial on the other. Proptosis and displacement of the eyeball outwards is a later symptom and occurs when the tumour is very large. There is evidence to show that this growth may commence in the body or great wing of the sphenoid and later burrow to the surface in the nasopharynx particularly when a paralysis of a cranial nerve is the first sign and precedes the other symptoms by some weeks. Reproduced is an X-ray photograph of such a case showing erosion of the dorsum sellæ and body of the sphenoid. An infrasellar pituitary tumour may resemble a carcinoma of the nasopharynx but pituitary tumours more often produce a bitemporal hemianopsia, optic atrophy and other localizing signs.

In conclusion an attempt should always be made to enucleate the tumour, if that fails then Nélaton's operation should be undertaken, as described above to thoroughly expose the growth and completely to remove it by dissection and diathermy. If this is unsuccessful diathermy and radiotherapy can be tried.

A. J. Gardham said he first became interested in malignant nasopharyngeal tumours some twenty years ago. Even at that time they had been known for a considerable period. Perhaps the best clinical description of them was by Trotter in 1911, and they were quite well known in German literature long before that. He believed now that something like 2,000 cases were available for study in the literature. The reason why they were not more generally recognized was that they did not tend to go to one particular branch of the profession. In recent times they were usually sent to radiotherapists for treatment and they came almost equally from the various other branches, from laryngologists, ophthalmologists, neurologists, from general surgeons, and also from dentists.

The ophthalmological side of the picture had been dealt with recently in the Society, when it was emphasized that it was generally in late cases that the eye signs came into the picture (Godtfredsen, E., 1947, *Proc. R. Soc. Med*, 40, 131). The most common was a sixth nerve palsy followed in something like one-third of the cases by a third nerve palsy. The only other ophthalmological sign, a very late one, which was at all common was displacement of the eyeball. The appearance of ophthalmological signs in malignant tumours of the nasopharynx, meant that the tumour was very far advanced, and that prospects of success, even in palliative treatment, were poor. Paralysis of the third and sixth nerves generally indicated intracranial extension.

Intracranial extension ultimately happened in a fair proportion of cases, and was responsible for taking some of these patients primarily to a neurologist, but the majority which presented first to neurologists showed themselves as a fifth nerve neuralgia. Other cranial nerve palsies were seen in the late stages, and while many patients died of distant metastases, quite a proportion ultimately developed progressive paralysis of the various nerves round the jugular foramen and ended their days with something very like a bulbar palsy.

Those cases which came from general surgeons usually had to do primarily with the glands in the neck. Enlargement of these glands was a common initial symptom in his series. The glands were extremely puzzling to those who did not know about malignant nasopharyngeal tumours, particularly in cases arising in young adults. The glands had not the ordinary characteristics of carcinoma: they were much softer, commonly bilateral, and very easy to mistake for tubercle. The clinical difficulties were increased because cases showing enlargement of the glands of the neck as a first symptom were often in the same age-group as tubercle. Swelling in the temporal fossa was also an occasional early sign which brought patients under the notice of general surgeons.

Very often patients with malignant tumours of the nasopharynx were first seen by dentists because they had pain in the upper or lower jaw which was presumed to be due to bad teeth, and a considerable proportion were treated by dental extraction before they were ever seen by any branch of the medical profession.

Nowadays, he supposed, more of these tumours went to the radiotherapist than to anybody else. There was no doubt that radiotherapy was the treatment of choice; perhaps the only treatment except purely palliative measures, but the mechanism whereby patients came to the radiotherapist was not always satisfactory. They arrived there simply because they were suffering from obscure tumours in a difficult situation, and a good many of them arrived without any clear indication of the true nature of the disease.

He would not enter into the controversy about the microscopic characteristics of these growths. The picture, as he saw it, was that of an infiltrating tumour at the base of the skull, with a very strong tendency to spread submucously and subperiosteally without ulceration. This could often be seen in the microscopic section. As a result of this tendency there were often none of the symptoms associated with ulceration, but many, such as infiltration of the soft palate and swelling in the temporal fossa, which arose from submucous and subperiosteal spread. There was, characteristically, a quick reaction to radiotherapy, and a very strong tendency to recurrence, causing death either from local recurrence or from distant metastases within two or three years. He had seen tumours superficial sloughing. All suspicious nasopharyngeal tumours should be examined histologically after removal. The hard, solid, globular tumour seen and palpated in the nasopharynx of a young male subject renders the diagnosis of fibroma obvious. The true fibroma is benign and does not metastasize. There is no pain in spite of the fact that absorption of bone may occur. X-ray photographs should be taken to ascertain the extent of the growth. It is difficult to distinguish between a rapidly-growing fibroma and a fibrosarcoma. The fibrosarcoma is not so circumscribed. It is softer, more elastic, and spreads into the nasal sinuses and cranial cavity. The bridge of the nose is expanded and first one eye and then the other is proptosed and displaced outwards producing what is known as the "frog face". The surface of the growth in the nasopharynx ulcerates and bleeds readily. If a fibroma which has been completely removed recurs it is in all probability a sarcoma. The section shows larger blood spaces and many more round cells. A positive diagnosis cannot be made on the section alone. The choanal or post-nasal polyp arises from the middle meatus of the nose and, taking the line of least resistance, projects through the posterior nares or choana into the nasopharynx and is easily recognized. I have not seen an angioma or cavernous angioma of the nasopharynx; these are difficult to treat by surgery and should be untouched.

The ideal treatment of a fibroma is enucleation of the tumour but the difficulty of access with complete exposure of the tumour accompanied by severe hæmorrhage makes enucleation sometimes impossible and unsatisfactory. The lower edge of the tumour can be seen well if the Davis gag is used with full extension of the neck and the soft palate forcibly retracted. When the tumour is exposed the mucous membrane is incised by the diathermy needle as far round the lower pole of the tumour as possible. Then a strong, slightly curved, flat dissector can shell out the tumour, particularly if the line of cleavage is found. If the tumour is attached to the roof of the posterior nares a dissector or raspatory can be used through both the nostrils and the nasopharynx. The hæmorrhage though profuse is not so alarming as in the past because the patient is given an intratracheal anæsthetic, the pharynx is packed off and a suction pump is used freely. The hæmorrhage can always be controlled by firm packing through the nostrils and with a captive swab introduced behind the soft palate. A blood transfusion can be given at any moment. In my experience ligature of the external carotid or compression of both external carotids does not control the bleeding to any appreciable extent. Enucleation by snare is sometimes impracticable owing to the difficulty of surrounding the tumour with the loop of wire (Lack's method). If enucleation by an attack through the nasopharynx and the nostrils fails then a complete exposure of the tumour is desirable. The best exposure is obtained by Nélaton's operation in which a large window is made in the hard palate, but the soft palate should not be completely divided. If the soft palate is divided the contraction of its muscles produces a wide gap so that a satisfactory union by sutures cannot be obtained. Nélaton's operation gives a much more complete exposure and does less damage to the nose than Moore's lateral rhinotomy or trans-maxillo nasal operation or Eve's displacement of the maxilla or even Rouge's operation. The implantation of radium in my experience has no beneficial effect and does not diminish the hæmorrhage if the tumour has to be removed later, moreover the burning of the mucosa results in considerable misery and pain to the patient.

Figi, who reviewed the notes of 63 cases seen at the Mayo Clinic during a period of thirty years, favours diathermy coagulation followed by radium or deep X-ray therapy over a prolonged period of two or more years. 19 patients aged 21 to 25 were so treated with favourable results. He does not think the results were due to retrogression which, it is alleged, occurs about the age of 25. The accurate application of radium is difficult and Figi implanted radon seeds or radium. Radiotherapy is followed by atrophy of the mucosa. He does not favour enucleation or excision.

In conclusion an attempt should always be made to enucleate the tumour, if that fails then Nélaton's operation should be undertaken, as described above to thoroughly expose the growth and completely to remove it by dissection and diathermy. If this is unsuccessful diathermy and radiotherapy can be tried.

[*May* 8, 1947]

The Pre-History of Midwifery. [*Abridged*]

By I. HARVEY FLACK, M.D.

SOME years ago I began to collect material for a history of midwifery. It soon became clear that, as in every branch of medical history, there are individuals, periods, and phases about which whole libraries have been written. There are as many other periods about which there is little or no information and surprisingly little speculation. The longest and, to my mind, one of the most interesting of these periods is that which stretches backwards from the time of Soranus into man's pre-history. During this period women were presumably having babies. The birth-process was presumably much the same as to-day but the customs associated with it must have developed according to some pattern. I have been speculating as to the nature of that pattern. So much of the material on which these speculations are based is taken from Ploss, Bartels, and Bartels (1935) that I have indicated in the text only the few other authorities consulted. It may be assumed, therefore, except in the few instances attributed to other workers, that every thread in this speculative pattern is contributed by either Ploss or the Bartels. For example, they quote the Dyak legend of how midwifery began. This was originally recorded by Howell in 1906:

Kelili Badak Resa, whose wife was called Teburi, went into the jungle. Teburi was big with the child of Kelili. Kelili moved without noise seeking what food there might be. He came at length to the place of the *maias*. Unseen by the big monkeys Kelili watched. He saw what he had not seen before. A young female with a great belly was calling out with pain. She crouched upon the ground and her husband waited beside her. Kelili waited, waited for long till the birth was over, and Kelili marvelled for he saw how the husbands among the *maias* helped their wives at the birth of their young. All this he remembered and when the birth pains came to Teburi he helped her, doing all that he had seen the *maias* doing.

That is the Dyak story of how midwifery began. Every present-day savage tribe has the same kind of story, but they differ greatly in detail in different parts of the world.

In the beginning, when women gave birth to children, they might or might not be helped. Whether they were helped by men or by women or not at all depended on the degree of social development of the community. In the most primitive communities the woman remained alone and helped herself if she could. Her menfolk would welcome the child, especially a boy, but were quite indifferent to the process of bringing him into the world. Intuition—for want of a better word—would lead the primitive woman, as it does animals, to bear her young and to sever with her teeth the umbilical cord. It is likely that her labour was fairly easy.

Later, and this represented a not unimportant cultural advance, the husband no longer forsook the woman in labour, but remained with her and helped her, very much as Kelili is said to have done. This is what happens with the natives of the Brazilian interior. As soon as the woman feels that birth is beginning she lies on the ground. The husband stays with her and when the child appears he ties the umbilical cord. The tied cord he then bites through, leaving the placenta to be delivered in the usual way. The child he paints with red and black pigments before laying it ceremoniously in a specially prepared cot. Among with similar characteristics involving the upper jaw, but attempts to correlate these characteristics with microscopic appearances had not met with much success.

There was another queer thing about malignant nasopharyngeal tumours, namely, their remarkable geographical distribution. The only knowledge he had of this was based on an article describing a large series of cases from Hong Kong, where they accounted for something like 25% of malignant surgical lesions. No explanation was offered of this fact, but there was no doubt that the cases were the same as those about which they were talking. Another point which was very important was the close relation between these tumours and sepsis; he did not know which came first. One obvious septic complication was blocking of the eustachian tube by the tumour, followed by suppuration of the middle ear. That was purely mechanical, but there were many cases in which the sequence of events was less obvious: A patient who was first seen about the middle of 1946 was diagnosed as having a retropharyngeal abscess, because of a swelling in the left side of the neck, increasing in size and causing difficulty in swallowing. There was a rather indefinite past history, which included nasal obstruction on the left side of many months' duration. The suppurating swelling in the neck was incised, and the patient got better, but not well. Six months later he was seen at the radiotherapy clinic at University College Hospital, and by that time it was quite obvious that he had a growth in the pharynx. It was a lympho-epithelioma of the nasopharynx. He was turned down for radiotherapeutic treatment on the grounds that the tumour was too advanced to justify it.

With a view to making the patient more comfortable he was treated for the sepsis in his nose and mouth associated with the tumour. He then had enlarged glands, was breathing with difficulty and appeared moribund. At his next visit, six months later, his stridor had disappeared, the growth was considerably smaller, and the vocal cords could just be seen. That was in February 1947, and in view of the very marked improvement, it was thought justifiable to treat him by radiotherapy. The patient had just reported again for re-examination on the previous day. He was subjectively better than he had been for years, the glands were much smaller, and he was breathing through his nose for the first time for over a year. Here was a case that might well have been turned down as completely untreatable, and to avoid making this mistake, it was necessary to recognize that in nasopharyngeal tumours, a considerable part of the symptoms and physical signs might be due to sepsis and not to the tumour itself.

Another instructive case was that of a man aged 21 whom he saw first in 1932, when the patient reported with painless lumps in the left side of the neck. He took a gland out for biopsy and the report came back as endothelioma. On examination there was found high up in the nasopharynx around one Eustachian orifice a little firm submucous swelling, and on the evidence of the previous biopsy, they believed that they were dealing with a case of endothelioma of the nasopharynx, as these malignant tumours were then called. In those days mass irradiation, deep X-rays, and teleradium, were not readily available, and, for want of a better method, he treated this man by the insertion of radon seeds around the region of his primary tumour, and carried out a bilateral resection of the glands of the neck. He last saw the patient three or four months ago, fifteen years after the original treatment; he had a recent discharging sinus in his neck, and breaking down glands in the posterior triangle. The condition was tuberculous all the time, and it illustrated the extraordinary difficulty of making a certain diagnosis in tumours affecting lymphoid tissue. Perhaps also it served to emphasize that a pathologist's report was not infallible.

The opportunity for surgical treatment, never great in the past, was now non-existent. Treatment was purely by irradiation. He had seen a fair number of the results of treatment by deep X-rays and teleradium, and they were very impressive, but it was important to realize that total eradication of the tumour was very unlikely. Disappearance of signs and symptoms for periods of two or even three years was often achieved, but ultimate recurrence was the rule, and there was nothing to suggest that alterations in the technique of local treatment could affect this outlook. Cases with signs of intracranial involvement (third and sixth nerve palsies) with increased intracranial tension were probably better left alone.

Short-term palliative treatment was usually of little avail. Mr. Gardham had, in his time, seen cases where neuralgia of the fifth nerve had been the predominant symptom, and he had tried to relieve them by injecting the gasserian ganglion, but his results had been 100% failures.

About half of these cases died with local extensions and the other half with distant metastases which often appeared in a very widespread field, and although sometimes the accessible ones were treatable, it generally meant that the patient was going to die in the course of the next six months.

As to their knowledge of midwifery, it must have been very meagre and dictated entirely by experiences handed down by word of mouth. Certainly some of them practised thoroughly bad midwifery for some superstitious or other reason. Thus among the desert tribes of Algeria one of the functions of the midwife was to delay the birth of the child. As soon as the head appeared and the child was half out of the womb the midwife would seize it firmly and hold it in position for at least fifteen minutes. This meant that the unfortunate mother had an unhappy quarter of an hour but it also ensured that the child would benefit from the enlightening experience of being kept forcibly at that mystic threshold of existence half-way between being born and not being born.

Some midwives are known to have practised version in the case of a breech presentation, especially in the case of the Swahili who, in addition, exercised a reasonable cleanliness and refrained from unnecessary manipulation. They also removed all the pubic hairs of the mother just before labour. The hairs were singed off and never cut, which implies not a hygienic reason but a magical one. Demons who might obstruct the labour would tend to lurk in the pubic hairs and though demons could be burnt out they could not be cut out. Swahili midwives were paid by giving them some of the pregnant woman's garments.

In some primitive communities, however, the duties of the midwife would extend beyond the actual labour and into the puerperium. This was the case in Siam where the midwife would care for both mother and child during the period of sacrificial purification. The birth of the child was always followed by a month of penance for the mother. For thirty days, five days in the case of subsequent children, she had to stay in the same special room and expose her naked abdomen and back to the heat of a fire which was kept burning night and day the whole time.

Among most pre-literate peoples special tabus, particularly about touching the ground or seeing the sun, relate to a woman who is menstruating. Even greater restrictions apply to the woman who has just borne a child. The Bantu regard menstrual blood as dangerous and puerperal blood as worse. But the blood from a miscarriage, and especially a concealed miscarriage is bad enough to cause droughts or famines. Frazer (1922) describes how an Australian aborigine discovered that his wife had lain on his blanket while she was menstruating. He killed her and himself died of terror within a few days. Aboriginal women are forbidden to touch anything that a man might use during the time they are menstruating. At childbirth all the clothes and vessels they use must be burned. Among many peoples the child-bearing woman, as in Siam, was regarded as dangerous to everybody. So she was secluded in some special hut for two or three weeks after labour. In the island of Kadiak, off Alaska, a woman who has borne a child is for twenty days so unclean that even her food has to be handed to her on long sticks. At a varying period after the birth purification rites are undertaken by the medicine-man and then the woman may resume her proper place in the tribe, free again from all the tabus.

Chinese women, for much the same reasons are steamed by their midwives all through the delivery and given a decoction of roasted human hair to drink. If the delivery is very painful a mixture of the excrement of bats with wild laurel and birthwort is given washed down with half a glass of urine which must be from a boy 3 or 4 years old. After delivery the patient is given a dish of dried afterbirth to eat and must have a fire underneath her bed for three days. The Chinese midwife feels the pulse in the middle finger of a pregnant woman to determine if the hour of birth is near. For her labour the woman is placed in a sitting position on a low bed with her back against the wall. Her feet are raised slightly on two bricks. As soon as the head appears the midwife knows the sex of the child—because a boy's head is always turned downwards, a girl's head upwards. The cord is cut with a red-hot iron rod and carefully preserved. The midwife continues to look after the mother for a month, taking care that no four-eyed person shall see her because this stops the flow of milk. A four-eyed person is a pregnant woman or her husband (Morse, 1934).

This then is as much as we can ever know about the beginning of midwifery. The process of birth was repeatedly observed and the simple and obvious things were done to help the woman in labour. Knowledge of these things was handed down, and normal births proceeded normally. Abnormal births were due to demons and where the demons were exceptionally powerful the midwives might reluctantly be compelled to call in the *shaman*. The belief on which the *shaman* worked was quite simple and was shared by most primitive peoples. Labour was supposed to be a voluntary act on the part of the child which was anxious to escape from its confined quarters. If the child was slow then it would be coaxed by the promise of food. If that failed it was threatened with dire penalties. A logical advance from this point was to take the woman out into the open and get a horseman to appear to ride her down. The charging horse turned aside at the last moment but the whole manœuvre which was popular among the American Indians was intended to frighten the child and make it hurry up its own delivery. If that failed then the woman would be laid the Marquesas islanders on Nukahiva the husband severs the umbilical cord not by biting it but by means of a sharpened flint.

Indian women of the Caraya tribe, who have settlements on the Rio Araguya in Brazil, are delivered in the squatting position. The woman squats on her heels and grasps a post with her hands. The husband takes up the same position immediately behind her and with both hands presses down on the contracting womb. Much the same assistance is given by husbands to the women of Gorngay and Tungu on the Malayan islands of Kola and Kobroor, while among the Unmatjera, an aboriginal tribe of North Australia, the husband's duties begin as soon as he knows his wife is pregnant. He rubs grease into the skin of her abdomen and sings a ritual song which is intended to make the child big and strong.

Among the natives of the Sandwich Islands assistance is given by an old man rather than by the husband. The woman is delivered sitting on his lap, and this always takes place in public.

In a later phase of development the husband was not actively engaged in assisting at the labour but had a symbolic role to play. In Guiana and among certain Caribbean tribes the husband takes to his bed and groans terribly to inform everyone of the pain he is sharing. Marco Polo observed the same custom in China six hundred years ago.

The next stage of cultural development excludes the husband completely and regards parturition as an exclusively female concern. Not so much from modesty as we know it but for mixed magical and social reasons birth is a purely feminine business and a thing to be kept from profane male eyes. Almost always assistance is given by older women who have themselves experienced childbirth. In certain groups, especially the Maori, there is a strict order of precedence. Assistance must be given by the maternal grandmother, or if she no longer exists, then the paternal grandmother presides. Failing her, the mother-in-law comes next.

Among the Trobriand Islanders, whose society is matrilineal and patrilocal, the pregnant woman goes to her father's house for there she can be looked after by her mother and her mother's kinsmen. All the males leave the house but keep guard outside to prevent the approach of sorcerers. The husband helps in this duty but plays a very minor part.

Malinowski (1929) was never allowed to witness a labour but he was fairly fully informed about it by the men and women he studied for so long. When the first pains are felt the woman is made to squat on a raised bedstead with a small fire burning under it. The fire is "to make her blood liquid" and it probably helps to keep away evil spirits.

For the actual delivery the woman is seated on a mat on the ground. Her legs are apart and her knees raised and she leans back resting on her hands. Immediately behind stands a sister or other close maternal relative. She presses down on the woman's shoulders "so that the baby may fall out quickly". The mother of the woman receives the child but no attempt is made to assist its delivery. If labour is prolonged or difficult then there are charms and words to counteract the evil magic that is obviously responsible.

Only in the most difficult cases, according to Malinowski, "would the child be manipulated and even then, from what I gathered, very timidly and incompetently". For example, if there was delay in the delivery of the afterbirth, a stone would be tied to the umbilical cord, but no attempt was ever made at manual removal. The first month of the puerperium both mother and child spend in the house and again on a bedstead beneath which a small fire is kept burning. No men are allowed in the house during this period but the husband may approach the door and talk to his wife without actually entering.

Another step forward is taken when the women of the family give way to "experienced women" and these must be regarded as the forerunners of the first midwives. Formal payment of these "wise women" was a later development but it has always been customary among the wives of Borneo head-hunters to give them presents of some kind as a reward for their assistance. Among the Sudanese, the Abyssinians, the Bedouins, and the Kabyle, "experienced women" are always present at a birth and usually arrangements are made well beforehand for their attendance. The wives of Hottentots and Bushmen order their "wise women" well in advance and are delivered lying on the left side. Three or four women sit round the woman in labour and take it in turn to exert pressure on the uterus at each pain.

From "experienced women" to the first midwives proper is another long step and it is not unreasonable to assume that this step has been taken when we find a tribe has a special word for these women and one that connotes something much more than "experienced woman." On the Tenimber and Timor Laut islands *wata sitong* is the word, on the island of Ceram *ahinatukaan*, in Fiji *alewa vuku*, in the Philippines *mabutin gilot*, and among the Basutos *babele xisi*. It is the fact, too, that these more than experienced women were not only called in for the actual birth but might be consulted in early pregnancy, even though such consultation was almost invariably for an opinion as to the sex of the unborn child.

As to their knowledge of midwifery, it must have been very meagre and dictated entirely by experiences handed down by word of mouth. Certainly some of them practised thoroughly bad midwifery for some superstitious or other reason. Thus among the desert tribes of Algeria one of the functions of the midwife was to delay the birth of the child. As soon as the head appeared and the child was half out of the womb the midwife would seize it firmly and hold it in position for at least fifteen minutes. This meant that the unfortunate mother had an unhappy quarter of an hour but it also ensured that the child would benefit from the enlightening experience of being kept forcibly at that mystic threshold of existence half-way between being born and not being born.

Some midwives are known to have practised version in the case of a breech presentation, especially in the case of the Swahili who, in addition, exercised a reasonable cleanliness and refrained from unnecessary manipulation. Three or four women sit round the woman in labour and take it in turn to exert pressure on the uterus at each pain.

From "experienced women" to the first midwives proper is another long step and it is not unreasonable to assume that this step has been taken when we find a tribe has a special word for these women and one that connotes something much more than "experienced woman." On the Tenimber and Timor Laut islands *wata sitong* is the word, on the island of Ceram *ahinatukaan*, in Fiji *alewa vuku*, in the Philippines *mabutin gilot*, and among the Basutos *babele xisi*. It is the fact, too, that these more than experienced women were not only called in for the actual birth but might be consulted in early pregnancy, even though such consultation was almost invariably for an opinion as to the sex of the unborn child.

each case extending right across the abdomen and round the hips to end in a leaf-shaped area on each buttock. This scar must have been produced deliberately, possibly with a red-hot cautery, and may have been a brand indicating the slave status of these two girls. In all five mummies the pelvis is tilted forwards and its measurements correspond much more closely to those of the female ape than to those of European women, evidence perhaps that the changes in the female pelvis following the assumption of the upright posture were effected more slowly in the negroid races than in the women of the Mediterranean area.

A papyrus of about 2200 B.C. was discovered at Kahun and forms part of the Petrie collection. The text is fragmentary but lays down the rules for the diagnosis of pregnancy, stressing particularly the early vomiting of pregnancy and the condition of the breasts. The Ebers papyrus, written about 1560 B.C. (Bryan, 1930), gives the same rules much more fully. It also describes methods for accelerating the birth and methods for inducing abortion. How to determine the quality of the milk of a nursing mother is the subject of one brief section which goes on to discuss disorders of the female breasts. "If the milk be good it smells like the pollen of the VAH—grain; if the milk be bad it smells like the entrails of the Mehit fish." For treating a diseased breast there was a plaster of Calamine, Cow's Brain, and Wasp's Dung, which was to be applied for four days. There was also a magic formula addressed to the "Breast of Isis who in the City of Xebt bore the gods Su and Tefnut".

The vulva could be protected against the entry of disease by a douche of which Garlic and Horn-of-a-Cow were the main ingredients. If this failed and the vulva became inflamed the formula was changed to Bile-of-the-Cow, Cassia and Oil. If the condition grew worse a douche of Fresh Dates and Hog's Bile was the answer, and if in spite of everything pustules appeared in the vagina Fresh Dates in Ass's milk was needed.

A later part describes how the child's future may be foretold. If it cries *Ni* it will live. If it cries *Ba* it will die. It would also die if it "let a loud lamentation be heard", or if it "looks down its face", so that looking down in the mouth is not as recent an expression as might have been supposed.

A remedy to stop the crying of a child was:—

"Pod-of-the-Poppy-Plant
Fly-dirt-which-is-on-the-Wall.
Make into One, strain, and take for four days.
It acts at once!"

The Ebers papyrus also describes many of the diseases of women much more clearly than does the Kahun text and gives details of methods of treatment and prevention. Menstruation was regulated either by douches of Wonderfruit, Fennel, Honey and Sweet Beer or by douches of Garlic and Wine. The Dried Liver of a Swallow in Sour Milk would protect the virgin who anointed herself with it from leucorrhœa. A recipe "in order to cause that a woman should cease to conceive for 1 year, 2 years, or 3 years" included "tips of acacia" mixed with honey and applied to a piece of lint which was placed in the vagina (Himes, 1936). Dates, Onions, and the Fruit-of-the-Acanthus crushed with Honey and applied to the vulva would cause abortion. Strangely enough this is the only abortifacient mentioned. We do seem to have progressed in some directions.

There are, however, many methods of accelerating the birth of a child. "Peppermint: Let the woman apply it to her bare posterior," is the simplest, and was probably no less effective than any of the other treatments suggested. To correct a displaced womb The-Film-of-Dampness-which-is-found-on-the-Wood-of-Ships rubbed in Yeast-of-Fermented-Beer was taken by mouth.

The Brugsch papyrus of 1350 B.C. describes a number of contraceptive specifics and has a section—presuming the failure of the contraceptives—on the signs of pregnancy. The description of these signs is an expansion of those outlined in the Kahun papyrus seven hundred years earlier and the same signs in the same order and almost word for word reappear a thousand years later in the Hippocratic writings.

From these and other papyri, particularly the Gardiner papyrus, which is mainly gynæcological, it is known that girls were usually married at the age of from 12 to 14 years. Even younger girls were used to strengthen the failing powers of enfeebled patriarchs. At an advanced age Mohammed selected two more wives aged 7 and 8 respectively, to help restore his health. The belief that young girls radiated vitality was shared alike by Mohammedans and Jews. The excision of girls was also practised extensively. This involves removal with a sharp knife of the clitoris and most of the labia minora. Mohammed himself said "Circumcision is an ordinance for men and honourable in women" but he was merely approving what had been practised for hundreds of years. There is still in existence a plaque of about 163 B.C. which records the details of a legal suit to recover the costs of clitoridectomy.

on her back so that her swollen abdomen might be jumped on, or she might be suspended from a tree while the enthusiastic midwives pulled down heavily on a strap round her abdomen and the *shaman* cheered them on.

The Hos of West Africa call a magician to aid the woman at any specially difficult birth. He says solemnly that the child is bound in the womb and so cannot be delivered. All the women entreat him to loose the bond. After some time he allows himself to be persuaded. Then creepers are brought from the forest and used to tie the woman's hands and feet. The magician takes a knife, calls the woman's name, and cuts through the creeper saying "I cut through thy bonds and the child's bonds". This is straightforward imitative magic and the same line of thought prompts the rule in many parts of the world that a woman in labour should have no knots near her person. All the knots in her garments and shoes are undone and all the locks in the house are solemnly unlocked.

In other pre-literate communities (Frazer, 1922) a rational approach may be combined with the magical. Thus among the Dyaks of Borneo any wizard who has to deal with a hard labour brings an assistant. Inside the birth-hut the wizard tries the obvious manipulations and tuggings, often with some success. Outside the hut his apprentice imitates the mother. A large stone is fastened to his belly by a cloth. This represents the child in the womb and, following the directions shouted to him from inside the hut, he moves the make-believe baby about, imitating exactly what is supposed to be going on in the process of birth.

So it was that men who had been excluded from the birth-hut returned to it, and sometimes if they were shepherds or swineherds they might apply to the obstructed labour the knives they had used on their animals. Carving up the child in the mother's womb and extracting it piecemeal was almost certainly the first phase of operative midwifery. The first step in operative gynæcology was removal of the ovaries which was practised by Indian and Australian natives. Himes (1936) quotes an account describing how the tribes living on the banks of the Condamine River operated on selected women, who were then turned over to all the men of the tribe. These tribes are also known to have attempted Cæsarean section.

So much and no more can be seen in the tribal mirror. We never can know the degree of distortion of that mirror. All we can do is to jump nearly a quarter of a million years and take up the earliest known writings of man. People who can write and record their customs are at an advanced stage of civilization, and there must be just as great an advance in their practice of obstetrics. The transition must have been long and probably slow, but its exact phases we can only guess at, remembering the enormous gulf that separates the unlettered savage from the priests and law-givers who committed to stone tablets and to papyri their laws and their customs.

Yet the savage and the lawgiver are descended from a common stock and the gulf between them is crossed over and over again by threads which show their unity. This is especially true of the customs relating to pregnancy and parturition.

In recent years obstetricians have been stressing the importance of posture in labour. Primitive women knew all about posture as an aid to easy delivery and automatically assumed the sitting, squatting, or kneeling position. Elaborations of these positions were the setting up of posts or crossbars to which the woman could cling. Only in civilized communities, and particularly after the discovery of anæsthesia, were women delivered in the recumbent position, which abandons one powerful factor in promoting the expulsion of the child, the pressure of the thighs on the abdomen. Now we are tending to return to the primitive postures because they were obstetrically effective (Jarcho, 1934).

Be it noted then as we turn from the mirror of tribal obstetric practice to the oldest written records we have that folklore is all of a piece the world over. If we find that Cleopatra's midwives were not very different from Queen Victoria's there is no need to attribute special prescience to the former or incredible conservatism to the latter. They were all women and they were handling the same problem. The process of birth has not changed, nor have the fears and joys to which it gives rise. But the customs surrounding it have become more specialized with the passing of time.

A careful study has been made by Derry (1935) of the bodies of five women of the 11th Dynasty, bodies that showed how well the *Taricheutae* had done their work. Menuhotep II reigned about 2050 B.C. The mummies are of five Nubian women who belonged to his harem. Two of them, Ashait and Henheit, must have died at the age of 22 or 23 years. The mummy of Henheit is so well preserved that it was possible to say why she died at this early age. She died as a result of a difficult labour which had torn both the vagina and the bladder so that a tear in the bladder communicated directly with the vagina. Two other mummies are of dancing girls and show extensive tattooing of the arms, legs, and feet, and of the lower abdomen just above the pubis. In addition there is a peculiar scar in palate. There is also a reference to an abnormally long pregnancy of 11/12 months, which implies that 9 months was known to be the usual duration of pregnancy. Of normal births there is no record except a mention of the assistance given by a midwife who was designated "knower of the inside". Demons abounded in Babylon and might be good or bad. Ishtar was an essential demon and without her help the fœtus would die before delivery. Labartu was another female demon but of a different complexion and given to tearing children prematurely from the mother's womb, and to carrying a child-bed fever which often proved fatal. Suckling, either by the mother or by a wet nurse, was carried on for three years quite commonly and charms and amulets were used to promote this extraordinarily prolonged flow of milk. An interesting case described in one of the tablets is that of a wet nurse who had a cancer of the breast which caused her death.

Next to the Egyptian papyri in antiquity are the four Vedas of Brahma. Again these are Sacred Books but the author is not Thoth but Brahma and one book proceeded from each of his four mouths somewhere about 140 B.C. Later Brahma produced a second group of sacred books, the Upavedas, one of which is the Ayurveda, and this contains the oldest Hindu medical and surgical writings. The section we are most concerned with is the Charaka Ayurveda of 120 chapters, which was actually written in the second century A.D. Linked with it is the *Sushruta Samhita*, and though Sushruta was supposed to be the pupil of Charaka the *Samhita* clearly dates from about 600 B.C. The exact order of appearance of these works never can be known and it may well be that there was a version of the Charaka Ayurveda which preceded the Sushruta Ayurveda (Bhishagratna, 1907).

Leaving the legends on one side, these two works by Charaka and Sushruta reveal clearly the practice of the ancient Hindus in both obstetrics and gynæcology. Their knowledge of anatomy was very superficial although dissection was not forbidden. It was the technique of preparing a body for dissection that probably created some difficulties. The usual procedure was to leave the body for some days in a stream until it became putrid, then the skin was removed with a stiff brush and the parts examined. Even so there are some anatomical points of interest. In women there are "two canals, the roots of which are the uterus, and the *Dhamanee* vessels, which convey the menses. When they are wounded, barrenness is caused, and the menses cease". This seems to be one of the earliest references to the fallopian tubes.

Twenty-four diseases of the female organs of generation are described very sketchily. Typical examples quoted by McKay (1901) are:

Bandhyá: difficult menstruation. Rub the genitals and lower abdomen with oil and ghee, and keep the vagina distended by a roll of cloth.

Biplutá: continuing pain in the genital organs.

Pariplutá: severe pain during intercourse. A piece of cloth soaked in oil is to be kept in the vagina.

Prodokoh: excessive bleeding at the periods accompanied by fever, giddiness, fainting and thirst. Apply cold and astringent medicines; avoid venery; and live on cool simple food.

Patragani: when the infant dies, or abortion has taken place, with a great discharge of blood.

Palani: when a large man has connexion with a small and young female, he injures the parts and produces this disease.

Mahati: when the vagina is very large.

In dealing with a difficult labour the obstetrician "having cheered the woman up" was told to use the knife but "in such a way that he by no possibility cuts a living child with it; for if a child is injured, the physician may destroy both child and mother together". For a normal labour Sushruta directs that the patient should be delivered by four women, "stout-hearted and of ripe age, who shall trim their nails well". These were midwives and were quite distinct from the women surgeons of a race in Rajputana, the Bhils. Their surgery was of the most primitive kind and consisted for the most part of applying a red-hot iron to cauterize anything and everything of which the patient might complain.

The *Sushruta Samhita* has also an excellent chapter on infant hygiene and nutrition and in this the purgative effect of honey on the newborn infant (sugar diarrhœa) is noted. Surgery is referred to at length and it seems that Cæsarean section was undertaken fairly often. Yet despite this advanced attack on the problem of obstructed labour the cause of the obstruction was still believed to be a demon. The *Rigveda* has an exorcism for such a demon, and in this as in other Indian charms the name of the demon is not spoken, and the appropriate god is called on to help: "May Agni, the destroyer of Raksha, joining in this prayer, drive away the disease of evil name which dwells in thy womb and bowels".

The duration of pregnancy was known to be ten lunar months and there were many ceremonies to guarantee a normal issue and keep away demons which might be hunch-

Incidentally, as recently as 1945 I myself saw in Egypt a score of young women who had had this mutilating operation performed. This was not in the uncivilized reaches of the Western Desert but in the even more uncivilized slums of Cairo, the capital city. In these girls, and presumably the same has always applied, the operation appeared to have achieved its anatomical but not its physiological objective. In this instance even the custom has not altered very much in 3,000 years.

With the important part that sexuality played in the life of the women of Ancient Egypt, it is easy to understand the importance that was attached to the cosmetic care of the genitalia. These papyri contain innumerable prescriptions for pastes to be applied to the genitals and for fumigants, many of which were elaborately scented and perfumed. There were also a number of prescriptions for substances to be rubbed on to the male organ "for increasing the love of the wife for her husband". In some of the smaller chemist's shops in Cairo I have seen very similar medicaments rubbing anachronistic shoulders with sulphonamide tablets and penicillin lozenges.

The duration of pregnancy was known and in the seventeenth century B.C. Westcar papyrus instructions are given for calculating the expected date of delivery. It must be realized that to relate intercourse with pregnancy and determine the duration of pregnancy was a big step forward. Many primitive peoples know of no such relation. The Ingarda tribe in Australia believe that the child is a product of some food the mother has eaten. The Buduna tribe firmly believed that their women bore half-caste children because the white settlers had introduced bread made of white flour instead of the dark native bread. The women ate the white bread and therefore they had half-white children. Malinowski (1929) describes how the Trobriand islanders believe that pregnancy follows rupture of the hymen by whatever means and that intercourse is intended purely for pleasure and has nothing to do with procreation. Fatherhood is a social rather than a biological concept with most primitive groups. Other tribes believe that someone other than the socially recognized "father" sends an invisible spirit-baby to enter the woman. The sender in some tribes is called the child's *Wororu* and while the *Wororu* is often the father's brother it may even be his sister or some other female relative who wishes the spirit-baby on to his "wife".

This absence of knowledge of the exact part played by the male in conception is also shown by the contraceptive practices of certain pre-literate societies (Himes, 1936). One primitive group, the Dahomey in West Africa, use a particular root which is crushed and applied as a high intravaginal plug. The natives of the Kasai Basin in Central Africa plug the vagina either with a cloth or with chopped grass. In both these groups the contraceptive intention is clear and the practice is rational. Among many other pre-literate peoples, however, the intention is the same but the practice is irrational or magical. Isleta Indians in New Mexico obtained from the medicine man a specially treated buckskin belt. Worn continually this will ensure barrenness. Stepping three times over a recently buried corpse is believed by the Ait Sáddĕn of Morocco to prevent pregnancy. Drinking water which has been used to wash a dead person is equally effective. Eating the hoof-parings of a mule will render a woman as sterile as the mule. Or else the man should eat before intercourse the oviduct of a hen. If this has been tied into a knot pregnancy cannot possibly result. And of course almost every tribe has decoctions and potions to ensure infertility.

In most tribes normal labours were conducted entirely by women. The same custom applied in Egypt and is well shown in bas-reliefs of the Royal birth-rooms at Luxor and in other temples. One of the best known of these shows a queen of the 18th Dynasty. She is in labour on an obstetric chair and has four midwives in attendance. Another is a bas-relief at the Temple of Esneh which is believed to show the labour of Cleopatra. The queen is in a squatting position and is assisted by a group of five women, one of whom holds two ankhs or Tau-crosses, royal symbols of generation. The child is almost full-grown at delivery, another symbolic recording of royal power.

The Westcar papyrus mentions the special birth-chair. In its simplest form this consisted of two stones, one to support each buttock of the bearing-down woman. Wall pictures of lying-in rooms at Philae and at Dendrah show that it was the custom for women to have their labours in special houses, all of which were decorated with pictures of Isis, the birth-goddess, with little Horus in her lap. Sometimes the principal figure represented was the cat-headed Pacht, the god of parturition. In Isis were later merged all the other gods and goddesses connected with birth and with fertility, excepting only the one male god of fertility who is always depicted with an enormous phallus. The Westcar papyrus also contains the only reference in any of these papyri to the birth of triplets. The birth of twins was apparently fairly common.

Relatively little is known of Babylonian obstetrics. There are in existence a few tablets with cuneiform inscriptions which treat of congenital deformities such as hare-lip and cleft-maidenhead. Considering this wildly improbable explanation, which has been believed apparently for centuries, it seems clear that there must have lived in Judea at one time an erstwhile virgin sufficiently quick-witted to tell a good story and stick to it.

The biblical laws about menstruation are well known. The book of Leviticus contains the sternest mandates about the purifying of women after childbirth, about the hygiene of menstruation, the abomination of sexual perversion, and the prevention of contagious diseases, and notably of leprosy and gonorrhœa, if it was gonorrhœa. It is easy to interpret these laws as showing an advanced knowledge of public health and preventive medicine. This, however, seems to be a too rational and civilized interpretation of practices which were more likely to stem from irrational savage tabus. So far as we can follow primitive lines of thought the belief seems to have been that each man or woman had an inherent godliness which was at its best when intact. A flow of any kind from inside the body to the outer world—and this would include the lochia after parturition, menstrual fluids, and any genital discharge whether from the male or female organs—exposed the personal god to harm. The outer world was full of demons awaiting just such an opportunity and the harm that might result could easily affect other members of the community. Therefore a menstruating woman, a woman after childbirth, and a man or woman with "an issue" was tabu or "unclean" and to be avoided. The whole concept is animistic, which is not to say that continuing experience had not affected it, so that the periods of tabu were more exactly defined. The point to remember is that the prohibitions were tabus however exact the regulations that framed them.

Thus no explanation other than irrational tabu will fit the regulation that a woman who had given birth to a boy was unclean for seven times thirty-three days but a woman who had given birth to a girl was unclean for fourteen times sixty-six days. There is a basis of tabu and an overlay of Assyro-Babylonian numerology. The same numerologists laid it down that seventh days or multiples of seventh days were unlucky (*Dies Atra*), which may well account for the prohibition of all activity on the seventh day. Seven also recurs over and over again in connexion with men and women who have "an issue".

Jewish midwives, again like their Persian and Indian sisters, had goddesses to aid them. Ashtaroth who is mentioned in the Bible was also called Astarte and was known to the Babylonians and Assyrians as Ishtar. Pomegranates and doves as symbols of fertility were sacred to the Syrian Ishtar and the dove was regarded as a "bringer of children" which links Ishtar, the primordial mother goddess, with Mary to whom the Holy Ghost came in the form of a dove.

I began this far-reaching and inevitably incomplete survey by giving the legendary Dyak answer to the question: How did midwifery begin? Any other legend would have served as well. There is no hope now of finding anywhere Neolithic man and Neolithic woman in a state of nature, and only such a finding would give us the correct answer. The life of the most primitive tribes studied in recent times may approach more or less closely to the natural state, and a study of their obstetric habits is as near as we can get to the beginnings of midwifery.

Women must have been helped when their birth-pains came on from the earliest times, if only because their cries, whether exaggerated or not, awaken sympathy in even the most primitive peoples. Help by the husband, for want of the right primitive term, by other women in the same family, and later by experienced women, does seem to follow a progressive pattern, though here again we are just as likely to have got the pattern wrong as right. The change from the obvious crude mechanical assistance to experienced assistance is an appreciable advance, but the next step forward represents the difference between the Stone Age and the Iron Age, the change from the family of cave-dwellers to the organized communities of pastoral tribes. It is the change from *babele xisi* kneading a Basuto abdomen to the operative obstetrics of the priest-physicians of Egypt and India and Israel. Simple observation of the recurring natural processes of birth in women and in animals allowed the young savage woman to prepare for her own hour of need a simple procedure which would meet the normal contingencies. A rather wider formula for the actions needed to meet different circumstances would be known to the women who had seen many births and assisted many different women. That much we can follow fairly easily, but the next step is the important one and we know nothing about it. We know about *babele xisi* and about the priest physicians but we cannot know where one took over from the other. It may be that midwives became more experienced to the point at which knowledge began, knowledge of their own limitations. At that point they would seek help from the surgeons and physicians, the men concerned with the sufferings and the physical afflictions of mankind. That is a guess, but it will bear scrutiny. There were surgeons long before there were obstetricians, though there must have been midwives before there were surgeons. Whatever the backed, fingerless, doublemouthed, and so on. All these demons tried to contort the unborn child to their own fearful shapes. Other "sealing spirits" were the demons responsible for female sterility. Phantom pregnancy was due to a special demon called *Naigamesa.*

The signs of approaching delivery were known and included the sinking of the belly, a feeling of heaviness in the abdomen, frequent passing of water, and a mucous discharge from the genitals. To expedite parturition the abdomen was to be pounded while the woman was made to walk about. Amulets would help and so would sneezing powders. Then at the end of the phase of dilatation of the cervix the child's head would press down more heavily, causing the bladder to be irritable and increasing the frequency of the pains. At this stage the midwives were enjoined to put the woman to bed and they were not to press on her abdomen except when she was having pains. Pressing down between the pains was not only useless but might make the child deaf, dumb, or deformed. Finally when delivery was effected the umbilical cord was to be tied with thread eight fingers-breadths' from the navel. The other end of the thread was passed round the child's neck and the cord was cut above the ligature. The afterbirth was awaited and once that had been delivered the woman's genitals were anointed with a special unguent.

The midwives undertook the handling of most normal deliveries but in any case of doubt a doctor was consulted and in unusual difficulty he could call in a sort of obstetric specialist. A doctor was always needed for anything other than a vertex presentation. If both legs presented then the fœtus would be drawn down gently by traction on the legs. If only one leg appeared, the other must be sought. If the breech presented it was to be pushed back so that the legs could be pulled down. A transverse presentation should be manipulated till the child's head could be brought down first as in a normal delivery.

When manipulation failed and the presentation was "irremediable" the doctor must resort to the knife. The skull was to be cut first and removed piecemeal, then the child's body could be extracted with a special pair of forceps. If this was not possible the head should be cut off and delivered in one piece by grasping the eye-sockets or the mouth. If the shoulders were stuck fast in the birth passage the child's arms must be cut off. These directions in the Sushruta are detailed and provide for every possible contingency.

The doctor was of course a priest and he was also responsible for consecrating the child's nurse, and for some reason this was always done on a Monday. High-caste women were always delivered by the priest-physician even for normal labours and delivery took place in a special birth-house which they entered some time during the ninth month. After delivery both mother and child were washed. The mother's milk for the first few days was not considered fit to use. When the priest approved she could start feeding her child and at the end of forty days or so she was regarded as free from "the uncleanness attached to her during confinement".

This period of forty days applied also to the women of Ancient Persia and in their case sexual intercourse during this period was regarded as a crime deserving death. The four midwives which Indian women expected were increased to ten in Persia, five to superintend the cradle, one for the left shoulder, one at the right, one to support the mother's neck, one to hold her fast round the middle and one to receive the child and divide the umbilical cord.

The Persians believed that there was a female as well as a male seed. If the male seed was stronger a boy would result, if the female a girl. If the male and female seed were equally strong then the woman would have twins or triplets. The references to female seed suggest that by this was meant the menstrual blood of which part was used for conception and the remainder flowed back into the woman and was converted into milk.

The Talmud makes it obvious that the Jews too had skilled midwives who were held in high esteem. The Talmud represents the oral law of the Jewish people. The text of the work is called the *Mishna* and the commentaries on it are the *Gamara* which were compiled during the first five centuries A.D. These midwives, or *Femina Vivida,* all seem to have used special stools or labour chairs. They examined the genitals with their fingers and occasionally with the whole hand, though this was discouraged. For their most difficult cases they called in doctors who were always Rabbis. These Rabbis vivisected female animals and knew that the womb could be removed without necessarily causing death. As a development of this experimental work it is believed that they undertook embryotomy and attempted Cæsarean section in the living as well as immediately after the death of a pregnant woman. They also made careful vaginal examinations and observed and described the hymen. The virgins of Judea till quite recent years were distinguished by a mincing walk and the tinkling of tiny bells. They all wore a chain of these bells just below the knees, and the explanation given for their use is that they confine the lower limbs within certain limits and do not allow of any striding or running, which might "rupture" the maidenhead. Considering this wildly improbable explanation, which has been believed apparently for centuries, it seems clear that there must have lived in Judea at one time an erstwhile virgin sufficiently quick-witted to tell a good story and stick to it.

The biblical laws about menstruation are well known. The book of Leviticus contains the sternest mandates about the purifying of women after childbirth, about the hygiene of menstruation, the abomination of sexual perversion, and the prevention of contagious diseases, and notably of leprosy and gonorrhœa, if it was gonorrhœa. It is easy to interpret these laws as showing an advanced knowledge of public health and preventive medicine. This, however, seems to be a too rational and civilized interpretation of practices which were more likely to stem from irrational savage tabus. There were surgeons long before there were obstetricians, though there must have been midwives before there were surgeons. Whatever the course of development there are no clear records of it. Development there must have been, unless we are to assume that Sushruta sprang fully-equipped from the womb of the Great Mother, but how it all happened cannot be known. Increasing observation led to certain customs and even to legal prohibitions and elaborate ritual. Then birth ceased to be something observed by the unknowing and became a subject for study. The study advanced more rapidly when men who had a surgical background and a wider culture were called in by midwives not as a last resource but in any case which promised to be difficult. However the transition came about it is true to say that for thousands of years everything that was done in obstetrics was done either by the midwives or by the surgeons. The surgeons would be women only rarely, only indeed at those few high peaks of civilization when women were given greater freedom and could become poets, or philosophers, or even doctors. The first such peak of which we have any detailed knowledge was the civilization of ancient Greece and there the midwives were skilled and the physicians and the surgeons more advanced than any that had been known previously.

Section of Odontology

President—Professor H. Stobie, F.R.C.S., L.D.S.E.

[*March* 24, 1947]

Three Cysts in the Same Mandible, Not of Dental Origin. ? Solitary Cysts or Osteitis Fibrosa.—George T. Hankey, O.B.E., T.D., M.R.C.S., L.D.S.Eng.

14.3.46: The patient, a boy aged 15½ years, first attended the London Hospital complaining of toothache.

Family history.—Father died recently of phthisis; mother and two brothers alive and fit.

Previous diseases.—At age of 2½ years he fell on front teeth and broke them; the teeth were extracted later. He had measles, pneumonia and diphtheria when aged 4, and was ill thirteen weeks. No other illnesses.

Treatment.—$\frac{5|}{6|}$ were extracted for advanced caries; no other treatment.

11.9.46. Six months later patient again attended the London Hospital.

Complaint.—Inflammation, pain, and swelling of gum in $\lceil 8$ region of one day's duration, accompanied by tenderness left side of the neck.

On examination.—Gum behind $\lceil 7$ swollen and inflamed; left submaxillary glands enlarged. Slight general toxæmia. Advanced caries of $\frac{|6}{|7}$; $\frac{5|}{6|}$ missing; extracted six months earlier. General condition of the other teeth, good; a well-formed dentition had erupted normally.

Fig. 1.—X-ray of left lateral jaw—Irregular cystic area lying below roots of $\lceil 567$, with greatest thinning of bone below $\lceil 56$, similar to the appearance of a multilocular cyst or adamantinoma; but the youth of the patient was against this diagnosis. Advanced distal caries of $\lceil 7$ and mesial caries of $\lfloor 6$; $\frac{|8}{|8}$ unerupted, in normal position.

Immediate treatment.—Expectant, until acute inflammation subsided. Mouth cleaned up; penicillin lozenges by mouth.

course of development there are no clear records of it. Development there must have been, unless we are to assume that Sushruta sprang fully-equipped from the womb of the Great Mother, but how it all happened cannot be known. Increasing observation led to certain customs and even to legal prohibitions and elaborate ritual. Then birth ceased to be something observed by the unknowing and became a subject for study. Fig. 4.—Left lateral jaw, same as fig. 1, but six months after extraction of $\lvert\overline{567}$, and marsupialization of cyst cavity by removing outer wall. The cavity has been almost completely filled in with new bone.

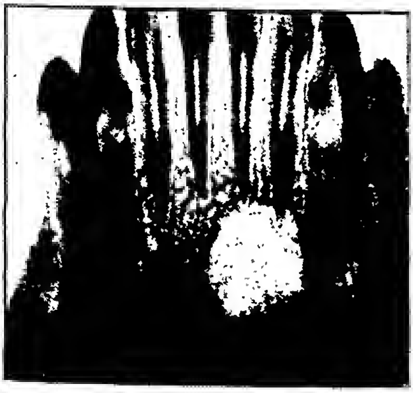

FIG. 3.

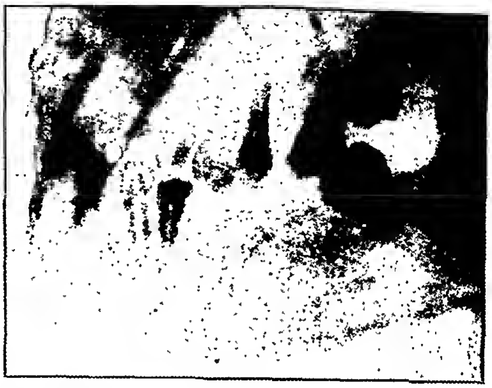

FIG. 4.

The points of interest in this case are:

Three cysts in the same mandible were only discovered through routine X-rays. An unusual X-ray appearance on one side always calls for a control view of the other.

The cysts were completely symptomless.

All the long bones were normal radiographically; the blood calcium and phosphorus were normal, thus excluding parathyroid disease. 14.4.47: X-rays taken of the skull, facial bones and teeth all showed normal structure.

The three cysts are situated in the regions of the marrow cavity present in young persons but later usually obliterated.

The cavity in the left body was unconnected with the teeth and the X-rays suggest that neither are the other two cysts connected with the teeth.

There was no tumour in the cavity.

The X-ray and operation appearances of the cyst in the left body closely resemble that of a "Solitary Bone Cyst in the Mandible" (Rushton, M.A., 1946, *Brit. dent. J.*, 81, 37); but in this case there are also two other similar cystic areas—one in the same region of the right body and one in the region of the symphysis.

Ætiology: The ætiology of "Solitary Bone Cysts" is obscure, but most explanations include trauma as the exciting cause. The only history of trauma in this case is the fall on the chin at 2½ when the front teeth were broken. According to Rushton there are three main hypotheses as to how the trauma may act: (*a*) intramedullary arterial hæmorrhage resulting in a blood cyst; (*b*) injury to the main endosteal artery resulting in loss of vitality in the area most remote from a collateral circulation; (*c*) a subperiosteal hæmatoma with temporary severance of the cortical circulation, osteoclastic absorption towards the cortex from the medulla, this in turn contained later by the restored cortical bone—the end-result being either a cyst or a giant-celled tumour.

The third view (*c*) brings the ætiology into line with the observed pathology of osteitis fibrosa. In 1938 (*Proc. R. Soc. Med.*, **31**, 1141) I demonstrated that microscopic views of different areas in the same case could give the appearance singly of (1) the typical resorption of bone and replacement by fibrous tissue, of osteitis fibrosa, (2) new bone formation taking place in fibrous tissue, suggestive of osteogenic sarcoma, (3) an intervening stage, after resorption, where the whole field is very rich in giant cells, suggestive of a myeloma.

18.9.46: *Later treatment.*—Swelling of gum almost subsided after one week. Hard bony expansion of outer plate below $\overline{|56}$ just palpable but scarcely visible. $\overline{|4567}$ unresponsive to tests for vitality.

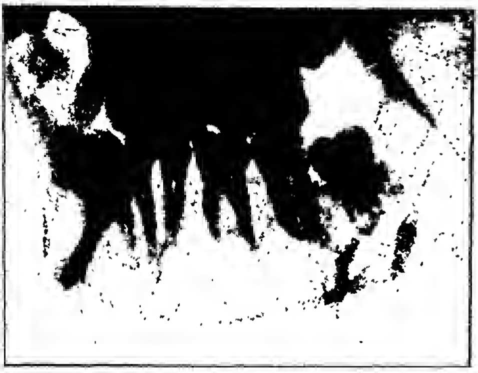

FIG. 1.

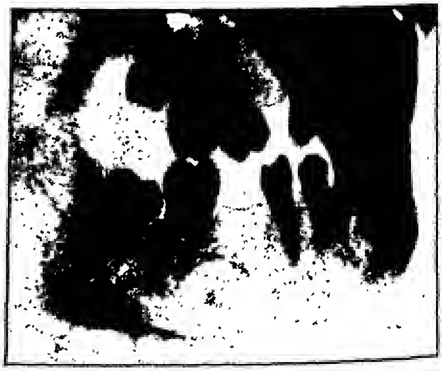

FIG. 2.

Fig. 2.—X-ray of right lateral jaw for control purposes. Irregular cystic area below $\overline{76|}$ region, with an island of sclerotic bone in the centre. The mental foramen lies just forward below root of $\overline{5|}$.

$\overline{6|}$ had been extracted six months earlier; sockets completely filled. $\frac{8|}{8|}$ unerupted, in normal position.

Fig. 3.—X-ray of symphysis, intra-oral: clearly-defined cystic area below $\overline{21|}$ unconnected with the teeth. The lines of the lamina dura and periodontal membrane are unbroken.

$\frac{|6}{|7}$ were extracted under N_2O+O_2; and it was evident that the socket of $\overline{|7}$ did *not* connect with the cyst below; the infection had only involved the soft tissue covering the $\overline{|8}$.

The patient's blood calcium and phosphorus were normal as was also the X-ray of all long bones.

25.9.46: Operation under general intratracheal anæsthetic in a clean field. $\overline{|56}$ extracted—no connexion with cyst (the extraction of these teeth could have been avoided if the cyst had been opened first). Gum flap reflected downwards towards buccal sulcus and bony window in outer plate below sockets of $\overline{|567}$ removed. The cavity in the bone now clearly exposed—no infection, no lining membrane, no contents. Inner surface of the bone was bare and smooth. The nerve was apparently lying uncovered in the floor. The gum flap was turned into the floor and the cavity packed.

There was nothing to send for pathological examination.

28.10.46: Uneventful convalescence. Rapid granulation and epithelialization of cavity. Obturator fitted. Later X-rays show regeneration of bone and filling in of cavity.

24.3.47: Clinically the cyst cavity has completely filled in, six months after operation.

There is a very considerable increase in the consumption of cereals (including bolted wheat flour and biscuits). The consumption of sugar has reached—and at some trading stations even surpassed—the top levels of countries like the United States and Denmark.

Greenland is a closed country. Nobody can go there without the permission of the Danish Government. All trade with the natives is a State monopoly. The turnover of all goods is on record and well known. Useful information is obtainable from the Colonial Administration on the sale of food by each trading post as well as on many other aspects of native life.

Under the joint sponsorship of the Danish Government, the Dental School in Copenhagen, and the P. Carl Petersen Foundation the author, with a varying number of co-workers, made three expeditions to Greenland in order to study dental conditions and allied subjects.

During 1935 motor-boat journeys covering more than 1,500 miles took the author all over the Julianehaab district, South-west Greenland, in which about 25% of the West-Greenlanders are living. A total of 1,634 natives representing all degrees of urbanization were examined. On top of this a good deal of dental treatment was done.

During 1936 the author examined teeth and jaws of 525 Eskimo skulls from Greenland in the Copenhagen University Institute for Medical Anatomy.

During 1937 East Greenland had its first experience of dental surgeons. 915 Eskimos (i.e. 96% of the population) were examined. X-ray series were made of 140 Eskimo jaws, and casts were made of 150 native dentitions.

During 1939 the third Danish dental expedition to Greenland visited the Julianehaab district, South-west Greenland, to re-examine the natives there. Four dental surgeons and a biochemist participated in the work which included clinical, biochemical, X-ray and other studies of about 700 natives. Part of the saliva studies were made in collaboration with Drs. Karshan, Siegel and Tenenbaum of the Columbia University, New York (*J. dent. Res.*, 1940, **19**, 303). Further objects of biochemical studies were viscosity of saliva, inorganic phosphate and calcium of saliva, caries susceptibility (Fosdick tests), inorganic phosphate and ascorbic acid contents of the blood (Farmer and Abt).

The following are some of the principal results of the aforementioned dental investigations.

DENTAL ANATOMY

The Eskimo dentition exhibits a number of characteristic features the more interesting of which are given in the following paragraphs:

The crowns of the molar teeth are superior in size to those of whites whereas the crowns of premolars, canines, and incisors are not. This is noteworthy in so far as it shows that the proportion of size of the crowns is not necessarily the same within the dentitions of all ethnic groups.

The third molar is vestigial in a very high proportion of pure-bred Eskimos and congenitally missing more often in the East Greenland Eskimo than in any other group on record.

Shovel-shaped incisors are almost universally met with.

Cusp numbers and occlusal pattern of the molars come closer to conditions found in fossil apes such as *Dryopithecus* than do cusp numbers and occlusal pattern in other modern racial and ethnic groups hitherto studied. The lower second molars are quintitubercular in a high percentage of cases.

Prognosis: The opening of these cysts allows rapid growth of new bone to take place and the cavity fills in; this has already happened in this case after six months.

The patient will be kept under careful observation; any sign of activity in the two unopened cysts will indicate surgical interference.

Dental Investigations of Greenland Eskimos. [*Summary*]

By P. O. Pedersen
Associate Professor of Dentistry, Copenhagen.

Greenland is the largest island in the world. The greater part of the country is covered with ice. The ice cap completely separates East Greenland from West Greenland. Greenland has only 17,000 inhabitants, of whom approximately 1,000 live on the eastern coast.

During the greater part of the year *East Greenland* is isolated from the outside world by an impenetrable ice girdle. All the natives of East Greenland live in the areas around the trading stations of Angmagssalik and Scoresbysund. The Eskimos at Angmagssalik were unknown till 1884 when the tribe was discovered by an officer of the Royal Danish Navy. In 1894 the Danish Government established a trading station at Angmagssalik to prevent the natives from perishing. The Scoresbysund area became inhabited in 1924 by Eskimos emigrating from Angmagssalik. The Eskimos of East Greenland are practically without white admixture. In remote parts of the Angmagssalik area they still largely subsist on Eskimo protein-fat diet and—at most—taste white man's food. The Eskimos who have settled down at the two trading stations, however, have to no small extent adopted the dietary habits of white men.

Contrary to East Greenland *West Greenland* had early white contact and Danish colonization was firmly established more than two hundred years ago. The western coast is more easily accessible than is the eastern coast and white influence is more predominant. The natives, among whom are a large number of mixed blood, have settled down under urbanized conditions and largely depend on imported food. This is especially true of the main trading stations. The degree of urbanization in the native villages entirely depends on the distance to and accessibility of the trading post. In 1901 the estimated calorie requirement of the West Greenland population was covered to the extent of 17% by imported food. In 1930 the import covered 63% of this requirement. The latter amount being an average for trading stations and villages, the extremely high proportion of imported food in the diet of the West Greenland trading-post natives clearly stands out. In some areas it even surpasses 90%. The radical and sudden change of nutrition which has taken place in West Greenland during the past thirty to forty years is illustrated by the figures in Table I.

TABLE I.—AVERAGE YEARLY CONSUMPTION OF IMPORTED VICTUALS IN WEST GREENLAND
(*Kilos Per Head Per Year*)

	1855-1856*	1901-1903†	1930-1933†
Fats	—	0	5·4
Cereals	15·3	33·3	92·2

Sugar (and chocolate) ..	3·7	5·0	39·5

*According to Rink.
†According to Bertelsen.

Dental fluorosis was not observed except for a number of cases near the cryolite mine of Ivigtut, South-west Greenland. The natives concerned had absorbed cryolite (Na_3AlF_6) during their early childhood while living close to the mine. A few cases were also observed of which it could be proved that their mothers ten to twenty years ago used to mix their snuff—to which they were very much addicted—with cryolite powder. In this extraordinary way the mothers seem to have absorbed sufficient cryolite so that breast-fed young natives showed mottling of their teeth (for further details—*see Dtsche zahnärztl. Wschr.*, 1940, 43, 623).

TRAUMATIC LESIONS OF THE TEETH

The Eskimo puts great demand upon his teeth. Mastication is strenuous and the teeth are used as a tool for many kinds of work. The women use their teeth for preparation of seal hides. The hides are thoroughly chewed. This applies for instance to the hides to be used for boot-soles. Sinews are pulled across the teeth and rolled against the cheek to make them apt for sewing. Prepared in this way the sinew will wear a groove in the " masticatory surfaces" of the incisor teeth. This groove has a transverse course and remains somewhat ahead of the general attrition.

The general attrition of the teeth is severe during maturity and in the old Eskimo—male as well as female—the teeth are often worn down to the gums. In females the chewing of hides accounts for part of the wear. On the whole, however, the bearing of this kind of work upon the attrition of Eskimo teeth has been overemphasized since the male Eskimo, who does not chew hides, also shows exceedingly pronounced wear of his teeth.

Exposure of the pulp due to attrition is comparatively rare. In most cases abundant formation of secondary dentine protects the pulp cavity from being opened.

Multiple small fractures of the teeth are seen in almost all adult Eskimos living in primitive areas. Extensive fractures exposing the pulp are rather frequent.

DENTAL CARIES

We do not know of any case of caries in Eskimo skulls dating with certainty before contact with white people. Among 525 Greenland Eskimo skulls with 5,606 permanent and 146 deciduous teeth only two were found with caries. These two cases are, however, not properly dated and may be more recent than early white contact. They have two and one of the third molars affected respectively. Caries incidence in the total skull collection examined thus amounts to a few permanent teeth per thousand, and no deciduous teeth are affected. This is about the same magnitude of caries incidence as that reported by Mummery who examined 69 Eskimo skulls (*Trans. odont. Soc. Lond.*, 1870, 2).

The principal facts which can be derived from our studies of present-day Greenlanders are the following:—

Caries incidence has risen from nil or practically nil in the pre-Danish time to a considerable level in modern East Greenland and to a simply alarming level in modern West Greenland (fig. 1). This increase has mainly taken place during the last fifty years in West Greenland. In East Greenland it is quite recent.[1]

Caries in villages as well as in trading stations is much more frequent and of a much more severe type in (civilized) West Greenland than in (primitive) East Greenland (fig. 1).

Both in West Greenland and in East Greenland one finds a great difference in the caries incidence in villages on the one hand and in trading stations on the other. The trading stations are everywhere more seriously affected (fig. 1).

---

[1] Incidence of dental caries according to sex, age and locality, *Dent. Rec.*, 1938, 58, 191.

The tubercle of Carabelli—present in about 75% of whites if we include the groove—is almost entirely absent in the Eskimo of unmixed descent. In West Greenland hybrids about one-third of upper first molars exhibit Carabelli's cusp or groove.

Paramolar and distomolar tubercles of Bolk, i.e. supernumerary buccal and lingual cusps on molars, are frequent.

There is a tendency for the Eskimo to develop small pearl-like excrescences on the occlusal surfaces of premolars and molars as well as on the lingual aspects of the canine cusps.

Buccal pits and grooves on lower molars are frequent and quite often pronounced. They may be surrounded by a hypoplastic area, especially so in the primitive Eskimo.

Enamel extensions from the gingival margin opposite root bifurcations and grooves (originally described by Leigh in Eskimos, Indians, and Polynesians and dealt with in England by Watson and Woods) are normal in the Eskimo of Greenland. Such extensions are frequently present to an extreme degree. They are closely related to enamel nodules which are found on upper third and second molars in a much higher percentage of cases than in whites. As many as 25% of upper third molars exhibit enamel drops distally and/or mesially. This seems to be far the highest incidence recorded for any group.

Average root height is reduced during lifetime to a striking degree. In many cases root absorption of vital incisors occurs even during adolescence. More or less pronounced absorption of the apical part of the roots with hyperostosis of the remaining part of the roots seems to be an almost normal occurrence in the primitive Eskimo. Cases have been observed indicating that function can become so strenuous that the parodontal tissues respond with root absorption on a large scale.

Supernumerary roots are frequent. On the lower first molars disto-lingual roots are found ten times as often as in whites (Bolk). High incidence of this root has been reported by Professor Tratman of Singapore in Mongols living in Malaya.

Failure of root-branches to divide is common. Such fusion is similar to that found in certain specimens of early man in Europe. The Eskimo also exhibits a moderate degree of taurodontism, the condition dealt with by Sir Arthur Keith and Professor Middleton Shaw. The pulp cavity is large during childhood and young adult age. Later on secondary calcifications including enormous pulp stones are widespread. Large pulp stones suggestive of vitamin-C deficiency are also found in young teeth.

Our studies of Eskimo tooth morphology confirm that the Eskimo is closely related to the Mongolian stock with which he shares at least the following features: (1) High incidence of shovel-shaped incisors; (2) Very low incidence of Carabelli's tubercle; (3) High incidence of three-rooted lower molars.

Incidence and type of dental numerical variations—omitted in this paper—point in the same direction (*Acta odont. Scand.*, 1939, **1**, 93–134).

DENTAL STRUCTURE

In the primitive Eskimo very few cases of gross enamel hypoplasia are met with. Not a single case of pits and grooves in the incisors has been seen in such groups. Rickets is unknown in the primitive Eskimo. The degree of mineralization as indicated by the surface texture is generally perfect both in the skulls and in present-day East Greenlanders. Among the young West Greenlanders slight M-hypoplasia (classified according to standards kindly supplied by Lady Mellanby) has been observed to a certain extent.

It is a new disease in Greenland leaving the older natives less affected than the younger. However, caries may attack even natives whose teeth have developed under Stone Age conditions. Adult natives leaving primitive localities and settling down in urbanized areas—especially when young—frequently become afflicted with rampant acute caries although their teeth are of perfect structure. This applies, for instance, to young Greenlanders who temporarily stay in Denmark.

A close study of conditions in East Greenland seems to indicate that caries in this area will not occur to a greater extent when imported food amounts to about 20% of the native diet than when this figure is 5%. If, however, the total intake of imported food averages 80%, caries incidence in the permanent teeth will be of the magnitude shown in fig. 1 for the trading station of Angmagssalik.

In the author's opinion we are not entitled to draw far-reaching conclusions from these studies as to the point so much debated in this country, viz. whether the tooth structure or the carbohydrate factor plays the greater rôle. Those who hold the latter view may find some support in our findings, but there are also hints to the opposite effect. Generally speaking, the author does not think that field studies of the kind here presented will definitely solve the caries problem. In all probability the final solution will have to depend on pure experiment. However, we need a sound basis for discussion. As far as caries is concerned our principal aim has been to provide facts for such discussion from a remote corner of the world governed by Denmark.

PARODONTAL DISEASE

In the primitive Eskimo of East Greenland we have not observed any cases of generalized parodontal disease. Nor did we find any in West Greenland. Apparently this dental ailment will enter urbanized groups later than caries. This statement, however, is only true of marginal parodontal disease affecting the bone to such an extent readily detected by means of X-rays. Gingivitis was widespread also in East Greenland. Here the gum disease, however, did not affect the marginal parodontal bone to any appreciable extent. On an average the men were afflicted with gingivitis in greater numbers and also to a more severe degree than were the women. This is, among other things, to be put down to the fact that the men are still more addicted to the use and abuse of tobacco and tobacco ash than the women. Another gingivitis-producing factor, no doubt, is the very frequent mouth-breathing. Ulcerative gingivitis was absent in Greenland during the late thirties.

Loose teeth are only met with in the primitive Eskimo under very special conditions. In one case the lower incisors were loose because their antagonists had been lost at an early date due to an accident, which means that from want of use the teeth may become loose. Excessive use results in loosening of the teeth only when the roots have become so shortened by attrition from the one end and by root absorption from the other that only short stumps not surrounded by bone are left.[1]

Localized traumatic injuries of the marginal parodontal tissues as well as food impaction in connexion with severe attrition are conditions responsible for the loss of some molars in the primitive Eskimo. In modern East Greenland and in some West Greenland villages the use of tobacco-ash-quid ("eroq") produces a localized severe chronic marginal parodontal disturbance around the lower molars of many middle-aged and old people, females as well as males. The ultimate result is loss of one or more teeth (*Paradentium*, 1941, **13**, 25).

---

[1] For further details on parodontal disease see *Paradentium*, 1940, **12**, 69.

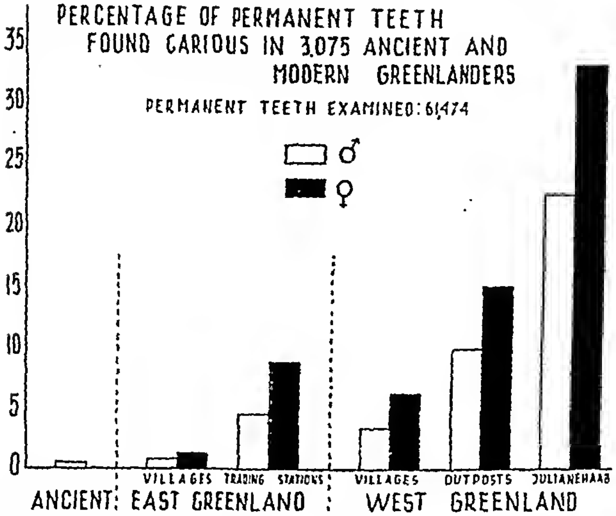

FIG. 1.—Summary of caries incidence in the permanent dentition of ancient and modern Greenlanders 1935-1937. Outposts are small trading stations. Julianehaab is a main trading station.

The natives employed and salaried by the Colonial Administration are everywhere more seriously affected than are hunters of the same age and locality (fig. 2).

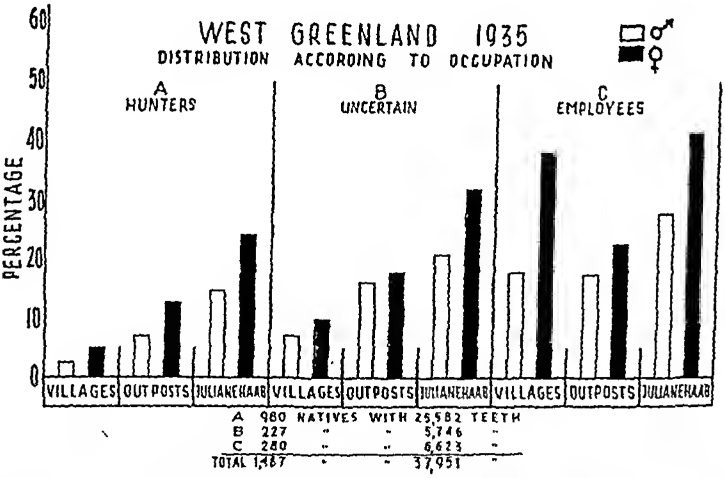

FIG. 2.—Incidence of dental caries in 1,487 West Greenlanders according to occupation. Percentages of carious permanent teeth. Outposts are small trading stations. Julianehaab is a main trading station.

Young natives, *ceteris paribus*, are more seriously affected than are middle-aged and old natives. Caries is a new disease in Greenland.

From whatever angle these principal results of the gigantic nutritional experiment forced upon the native population of Greenland are surveyed it is beyond doubt that the natives who abandon the dietary habits of their ancestors and adopt white man's industrialized carbohydrate food are those who become afflicted with caries.

Caries, which for clinical, biochemical and bacteriological reasons seems to be basically the same disease in the Eskimo as in whites, is seen to be largely independent of racial mixture, since the same rise occurs in the East and West Greenland groups.

Painful Disability of the Shoulder in Coronary Disease

By A. Schott, M.D.

From time to time patients with coronary disease are seen in whom the outstanding symptom is a painful disability of one or both shoulders resembling scapulo-humeral periarthritis. If this occurs a short time after an attack of coronary occlusion during which pain radiated to the affected shoulder the condition may wrongly be considered to be just the usual manifestation of myocardial infarction, and not being recognized as a separate lesion, appropriate treatment is not considered, or is delayed. If, on the other hand, periarthritis is diagnosed, the question arises: what relationship, if any, exists between coronary disease and periarthritis of the shoulder?

So far, this question seems to have attracted attention chiefly amongst cardiologists and is not considered in papers on periarthritis (Dickson and Crosby, 1932; Douthwaite, 1938) or discussed in textbooks on orthopædic surgery (Jones and Lovell, 1929; Whitman, 1930; Tavernier, 1937; Mercer, 1943). In his monograph on the shoulder Codman (1934) actually disagrees with the view that referred pain in coronary (and other) disease can produce limitation of movement or true localized tenderness in the scapulo-humeral joint. Only Moseley (1945) seems to have listed chronic cardiac disease amongst the general conditions which may produce scapulo-humeral periarthritis.

However, perusal of papers dealing with this subject from the cardiological angle (Howard, 1930; Edeiken and Wolferth, 1936; Boas and Levy, 1937; Leech, 1938; Ernstene and Kinell, 1940; Spillane and White, 1940; Askey, 1941) leaves little doubt that, at least in quite a number of cases, a definite relationship seems to exist between coronary disease and periarthritis of the shoulder and this association does not appear to be very rare; Ernstene and Kinell found it in 12% of 138 cases of myocardial infarction, and Fishberg (1940) was so impressed with the frequency with which cardiac pain manifests itself exclusively in the shoulder that in his opinion the practitioner should bear the possibility of coronary disease in mind "in all middle-aged individuals who complain of pain and limitation of movement in the shoulder, *especially the left*". As, however, both conditions are common in patients over 40 investigations of the cardiac condition of a larger number of patients with this kind of shoulder lesion are required, to throw light on the frequency and nature of the association between the two conditions.

A short report is presented on 6 patients who were seen in cardiological practice and who had coronary disease associated at one time or another with a painful disability of the shoulder.

Case I.—Male aged 52. Eight years' history of intermittent claudication, five years of angina of effort with pain in the left chest and left arm, one month of nocturnal angina of rest, relieved by trinitrin, but some pain in the left axilla persisting continually.

On examination (25.1.43).—Moderate emphysema of the lungs and hyperpiesia; B.P. 175/100. *Resting E.C.G.:* R absent in CR_3; otherwise normal. Anginal pain and marked electrocardiographic signs of myocardial anoxia in the limb leads after a small amount of exercise. One week

IRREGULARITIES OF TOOTH POSITION

Perfect development of the jaws and regular position of the teeth were predominant in ancient Eskimos and are still so in present-day East Greenlanders. Irregularities are, however, not at all rare with the latter. This not only holds good of young natives, but also of adults who have, during their childhood, practically never seen a white man, still less lived on white man's food. These irregularities (mainly crowding of upper and lower anteriors as well as irregularities in the premolar regions) have nothing to do with the crowding of the upper incisors observed by Weston A. Price in semi-civilized and civilized peoples in various parts of the world and so energetically maintained by him to be caused by civilization.

Failure of eruption of permanent teeth is not infrequent, and the author has observed several cases of aberrant eruption or impaction (*Tandlægebladet*, 1943, 47, 1). Impactions of lower third molars are fairly common, but do not seem to be associated with lack of space for the accommodation of the wisdom teeth.

In 1931 Sir Arthur Keith in his foreword to Professor Middleton Shaw's book on the dentition of the South African Bantu, said:

> "The greater part of the world still remains in a state of dental darkness. Even in Europe and America much still remains to be done to complete a preliminary survey of the mouths of mankind. . . Teeth are key structures—providing clues to race and to bodily health. Our knowledge of man's past has to be based very largely on a study of fossil teeth and jaws. . . .Teeth are more susceptible than other structures of the body to the changes which are produced by civilization. . . .We cannot know too much about teeth."

In 1947 we have not gone much farther than when these words were written. We have still many lessons to learn from the study of dental conditions in primitive peoples all over the world.

to exertion or emotion and does not respond to trinitrin. In the acute form the shoulder is diffusely tender and may be extremely painful, particularly at night, the pain being continuous and described as dull, burning or wrenching. The arm feels heavy, leaden, useless. The shoulder may be quite immobile, "frozen", owing to muscle spasm, the patient resenting even the slightest movement and carrying the arm in a sling. In the less acute stage there is pain only on certain movements, chiefly abduction and external and internal rotation, and there is limitation of these movements. If these persist after the acute stage has completely subsided, they are due to adhesions, particularly in the subdeltoid bursa. Putting on a coat or brushing the hair involves movements most readily affected. It is not proposed to discuss in further detail the symptomatology of periarthritis (*see* Douthwaite, 1938) or the various conditions which sometimes are summarized under the name of periarthritis (*see* Burns and Ellis, 1937; Moseley, 1945).

In all patients of this series anginal pain with or without signs of myocardial infarction preceded periarthritis, the interval varying between a few weeks and five years, though in Case IV there was a dull continuous ache in the left upper arm for one year prior to an attack of coronary occlusion. Shoulder pain, however, may precede coronary occlusion (Spillane and White, 1940; Askey, 1941), though this is less common.

It has been observed by various authors that in cases with left-sided anginal pain the left shoulder tends to be affected, whereas with right-sided radiation of the anginal pain the right shoulder is more commonly involved. The present small series illustrates this relationship well: of the 4 cases where the left shoulder was affected (in 3 exclusively and in 1 predominantly) anginal pain was left-sided in 3, and in the mid-line without radiation in the remaining 1; of the 2 patients with periarthritis on the right the anginal pain had involved the right chest in 1 and in the remaining 1 had radiated into both arms, chiefly into the right one. Although perusal of the literature shows that this relationship does not exist in all cases, the predominance of the left shoulder in cases of periarthritis with coronary disease is striking; amongst 114 published cases of this kind the left shoulder was affected in 65, the right in 34 and both shoulders in 15. On the other hand, in a series of 200 cases of periarthritis of the shoulder without any reference to coronary disease the right shoulder was affected in 103 cases, the left in 84 and both in 13 (Dickson and Crosby, 1932), and in Douthwaite's series of 37 patients the right shoulder was affected in 21, the left in 15 and both in the remaining 1. There is also a striking difference in the sex incidence between patients with and without coronary disease. Periarthritis as seen by the orthopædic surgeon seems to occur with equal frequency in the two sexes (Dickson and Crosby, 1932) and in Douthwaite's series 22 of the 37 patients were females; this contrasts with a marked preponderance of males in patients with coronary disease and periarthritis : of 68 published cases in which the sex of the patient was stated 50 were males, i.e. a preponderance of males of nearly 2·8 : 1. Moreover, the appearance of periarthritis in such cases has been observed often to coincide with, or shortly follow, an increase in anginal pain.

There seems little doubt that some relationship between these two conditions exists although the mechanism is obscure. Some suggestions about its possible nature are contained in Ernstene and Kinell's paper (1940).

The recognition of a possible relationship in patients over 40 between scapulo-humeral periarthritis, particularly on the left, and coronary disease is important. In patients known to be suffering from coronary disease or who have had an attack of coronary occlusion the appearance of a painful disability of the shoulder in which pain had previously been experienced may lead to the erroneous assumption that the patient had a recent attack or recurrence of coronary occlusion. A further period of rest in bed which would then be advised is unnecessary and, if anything, tends to prolong the disability of the shoulder. If periarthritis precedes anginal pain it may be a sequel to an unrecognized attack of coronary occlusion, or it may be the first symptom of coronary disease. A complete cardiological examination may then reveal the presence of hitherto unsuspected coronary disease.

The treatment of this condition may be very difficult. It seems to clear up by itself after some months but sometimes it persists for years. No single method of treatment has yet proved generally successful and there is hardly a kind of physiotherapy which has not been suggested. In the acute stage the exhibition of morphia may be necessary, especially to ensure sleep, as the pain tends to be particularly severe at night. The arm should be rested in abduction. Infiltration of the painful area with 1% procaine without adrenaline, not exceeding 8 c.c. at one sitting, repeated daily, and combined with calcium aspirin, 15 grains q.i.d., seems to deserve a wider application. When the acute stage has subsided physiotherapy in a form suitable to the individual is indicated. Carefully graded active and passive exercises are important in order to prevent adhesions. Deep X-ray treatment which produced good results in Case I has been reported without success in other cases; diathermy gave good results in some. Manipulation under an anæsthetic, which is contra-later continuous pain started in the left shoulder, radiating down the whole of the left arm and into the left hand, associated with stiffness of the second and third fingers. An X-ray of the shoulder did not show any abnormalities. The patient was admitted elsewhere to a hospital where eight short-wave treatments and wax baths were given without success. *On re-examination*, three and a half months later, the patient complained of continuous severe pain in the left shoulder, worst at night and impairing sleep in spite of morphia. The shoulder was "frozen", hardly any movement being possible without producing excruciating pain, and there was also some limitation of extension in the left elbow. There was marked tenderness over the anterior aspect of the shoulder-joint and the insertion of the deltoid as well as, to a lesser extent, over the elbow and thenar. Subdeltoid bursitis was diagnosed by an orthopædic surgeon who advised careful manipulation under an anæsthetic; this greatly aggravated the condition and when seen again five months later the patient complained of even more severe pain in the shoulder, particularly at night, carried the arm in a sling, and resented the slightest attempt at any movement. He then also complained of pain in the knees and hips, particularly on the left, and there was limitation of movement in the left hip-joint. At the same time, he had more severe substernal pain at rest, relieved by trinitrin which had no effect on the shoulder pain.

The patient was referred to Dr. Douthwaite who diagnosed scapulo-humeral periarthritis of both shoulders, more advanced on the left, with adhesions particularly in the subdeltoid bursa, and fibrositic changes in the region of the left hip-joint. The sedimentation rate was normal. He advised infiltration of the tender muscles with 1% procaine without adrenaline, starting with the left deltoid, calcium aspirin and subsequently treatment by deep X-rays. This treatment resulted in such marked improvement that on re-examination five months later pain and disability in the shoulder had completely disappeared, but pain in the hips on walking had become more marked.

CASE II.—Male aged 64. Eighteen months' history of angina of effort (substernal pressure without radiation, and choking), with three attacks of cardiac asthma. Raised blood-pressure for ten years.

On examination (19.3.43).—Congestive heart failure, auricular flutter with varying block; X-ray: considerable dilatation of the heart with grossly enlarged left ventricle and congestion of the lungs. With appropriate treatment the condition improved until January 1944, when cardiac asthma and angina of rest recurred. By readjusting the dose of digitalis the cardiac condition improved, but three days later pain in the left shoulder started and on examination there was limitation of abduction, external and internal rotation. An orthopædic surgeon (Mr. L. S. Michaelis) reported: Slight wasting of the left deltoid, supra- and infraspinatus muscles, slight tenderness on pressure over the anterior aspect of the joint, limitation of abduction to 60 degrees, of external rotation to 10 degrees and internal rotation to 25 degrees. No signs of acute inflammation. The suggested treatment was radiant heat, gentle massage and passive and active exercises, but all treatment had to be discontinued. The pain disappeared gradually without any treatment in the course of a few weeks. He died suddenly in February 1946.

CASE III.—Male aged 43. Attack of coronary thrombosis in August 1944 with pain across the left chest radiating into both arms, chiefly into the right. Pain in the right shoulder on moving the right arm started eight weeks after the attack. In Spring 1945 this pain occurred also without moving the arm and, in addition, affected the right forearm and a small area in the third and fourth interspaces in the anterior axillary line of the right chest. He was referred for a cardiological examination as the appearance of shoulder pain led to the assumption that another attack of coronary thrombosis might have occurred. On examination, there was no clinical or electrocardiographic evidence of coronary occlusion, but tenderness over the right trapezius, below the coracoid process, over the right upper quadrant of the right chest and the right upper arm. Backward movement of the right arm produced pain of the same character and distribution as the pain which occurred spontaneously. Fine crepitations were palpable over the right shoulder. One treatment by gentle manipulation without an anæsthetic by a physiotherapist followed by massage and active exercises produced rapid improvement. *On re-examination* (17.12.45) the pain had disappeared and all movements were normal.

CASE IV.—Male aged 67. Contracted syphilis at the age of 22, serological tests consistently negative. Angina of effort for two years, and pain in the left upper arm not related to exercise for one year, prior to an attack of coronary thrombosis in July 1944.

On examination (24.11.44).—E.C.G. Q_1-T_1 type of old infarction. No complaints except for some slight pain in the left shoulder on backward movement (putting on coat) which had started a few weeks after the attack of coronary thrombosis and had persisted ever since. There was slight limitation of abduction and internal rotation which had remained stationary during several subsequent re-examinations. 7.2.45: Recurrence of slight præcordial discomfort on exertion, relieved by trinitrin which had no effect on the shoulder pain.

CASE V.—Male aged 56. Periarthritis of the left shoulder three weeks after an attack of coronary thrombosis with pain in the left chest and left shoulder.

CASE VI.—Male aged 49. Periarthritis of the right shoulder three years after an attack of coronary thrombosis with pain in the right chest.

Detailed description of Cases V and VI is omitted owing to lack of space.

Discussion.—The clinical features of the painful disability of the shoulder closely resemble those of scapulo-humeral periarthritis, the post-traumatic form of which was first described by Duplay in 1872; trauma, however, played no part in these cases. The condition is distinct from the common radiation of anginal pain to the shoulder region: it is not related

Markedly enlarged mediastinal glands are rare in whooping cough and play little part in the production of pulmonary collapse.

The part played by tuberculous mediastinal glands is difficult to assess. Occasionally bronchoscopic examination reveals obvious bronchial occlusion due to pressure from without, fibrous stenosis or caseous material, but more often cases present with permanently damaged collapsed lower lobes and radiological evidence of hilar calcification. In this latter group, bronchoscopy usually shows no abnormality and one is tempted to assume that tuberculous glands were at least partly responsible for the original bronchial occlusion.

Infections of the nose or throat, principally chronic antral infections, were found in 16 of the present series of 50 cases. They occurred mainly in association with collapse of long-standing and saccular bronchiectasis. Their chief importance was to act as a source of septic material which, on aspiration, gave rise first to pulmonary infection and later to permanent changes in the lower lobes after they had collapsed.

Lobar collapse may arise in two ways, either by failure of expansion of the lobe at birth or by bronchial occlusion with subsequent absorption of air distal to the obstruction. It may be impossible to distinguish between these two mechanisms in any given case, but the frequency with which collapse is seen to occur in pulmonary affections and its rarity as an incidental finding in children dead of non-pulmonary diseases, confirms the view that the condition is acquired after birth in the great majority. Occasionally, the cause of the obstruction is obvious, as by foreign body, ulcerating tuberculous mediastinal gland or viscid post-operative secretion. Far more often, however, the collapse appears to date from an attack of pneumonia, bronchitis, whooping cough or measles, in which case the most important precipitating cause is bronchial secretion.

On the right side, should the obstruction occur in the main descending bronchus, the whole of the middle and lower lobes collapse; if the secretion subsequently be drawn beyond the orifices of the bronchi to the middle lobe and the dorsal segment of the lower lobe, one or other or both of these may re-expand, leaving the basic segments collapsed. On the left side, collapse of the lingular process is less commonly associated with collapse of the lower lobe than is collapse of the middle lobe on the right side, the probable explanation being that the point of origin of the bronchus to the lingular process is normally from the bronchus to the antero-lateral segment of the upper lobe. It is common experience that the left lower lobe collapses more frequently in children than does the right. Figures for this series were: Left 28; right 18; bilateral 4. This difference may be related to the close proximity of the arch of the aorta to the larger bronchi on the left side leading to kinking of the bronchi by degrees of mediastinal glandular enlargement which would not produce such kinking on the right.

Re-expansion occurred in only 10 of the 50 cases during the period of observation; this figure is misleading as many cases of persistent collapse are referred to chest hospitals for treatment of established bronchiectasis, the collapse being an incidental finding, consequently no true incidence of re-expansion can be deduced. When it occurs, re-expansion is nearly always complete within two months of the diagnosis having been made—it is very rarely seen after more than six months in the absence of an obvious obstruction to a large bronchus. There is no reason why collapse should not persist for years and then be followed by complete re-expansion in the absence of infection; this is seen not infrequently in suitably treated cases of spontaneous pneumothorax or giant cyst of the lung. In the case of the lower lobes, however, collapse persisting for more than a few months is almost invariably complicated by permanent inflammatory changes due to the accumulation of septic material in the bronchi. In the 40 cases which failed to re-expand, bronchiectasis was found in the following proportions: Bronchiectasis—saccular 21; cylindrical 16; cystic 1; no bronchiectasis 2.

The time required for the development of bronchiectasis and pulmonary fibrosis is very variable. One case showed gross fibrosis and saccular bronchiectasis at operation eight months after the inhalation of a peanut; another showed mild cylindrical bronchiectasis and little in the way of sputum in association with a lobe which was known to have been collapsed for eight years.

With viscid sputum as the commonest cause of collapse, treatment must be directed towards its expectoration. Postural drainage and expectorants, such as a saline-hot water mixture or inhalations of friar's balsam may be effective in older children but are often difficult of application in babies for whom an oxygen tent is essential. Sulpha drugs or penicillin should be given as a routine and breathing exercises are valuable as an aid to re-expansion after the sputum has been loosened. Bronchoscopy has a place, particularly in older children, and should be performed within a day or so of the development of collapse and after postural drainage has been tried and failed.

In long-standing cases, the treatment is that of bronchiectasis.

indicated in the acute and subacute stages, is the method of choice and often curative when limitation of movement persists owing to adhesions.

Further experience is needed to show how far this method is applicable in coronary disease.

Summary.—Six cases of coronary disease with painful disability of one or both shoulders are described. The condition of the shoulder resembled scapulo-humeral periarthritis. The literature is briefly reviewed and reasons are given for the belief that some relationship exists between the two conditions. It is suggested that examination for coronary disease of larger numbers of patients over 40 with painful disabilities of the shoulder—especially the left—without obvious cause is desirable in order to establish the frequency and nature of this relationship.

Collapse of the Lower Lobes of the Lungs in Children

By Neville C. Oswald, M.D., F.R.C.P.

Fifty cases of collapse of the lower lobes of the lungs in children were collected from the records of the Brompton Hospital, the sole criteria for selection being that they were adequately investigated and that there was a radiological follow-up of at least six months. Cases showing partial collapse only were excluded.

The average age of onset of pulmonary symptoms was 3 years; in 29, or more than half the cases, pulmonary symptoms started during the first two years of life. The mode of onset of symptoms was as follows:

Pneumonia	17	Tuberculous mediastinal glands	3
Bronchitis	13	Infected antra	1
Whooping cough ..	7	Diphtheria	1
Measles	4	Foreign body	1
Tonsillectomy	3		
	Total 50		

These findings suggest that pneumonia, bronchitis and the specific fevers form the starting point of pulmonary infection which leads eventually to collapse in the great majority. Unfortunately, in nearly all instances, collapse had occurred by the time the first radiograph was taken and, with a long previous history of respiratory disease, it was often difficult to decide how long it had been present. However, as more than half the children had had recurrent pneumonia or bronchitis dating from an acute pulmonary infection during the first two years of life, and in the majority of these permanent structural changes were demonstrated either by bronchography or at operation in the collapsed lobe, it must be presumed that collapse occurred before the age of 2 in a high proportion. Probably the most important single factor in the production of collapse at this early age is the small calibre of the bronchi, enabling plugs of tenacious bronchial secretion to cause bronchial occlusion.

In the past, measles and whooping cough have given rise to much chronic pulmonary infection and collapse. The routine use of sulpha drugs has greatly reduced the incidence in measles but in whooping cough serious pulmonary complications are to be expected in not less than 10% of cases, largely as a result of collapse produced by tenacious mucoid sputum.

(3) Apparently specific to osteomalacia are small irregular spaces in the cancellous bone of the vertebræ; which also show well the bulging of the intervertebral discs into the osteoporotic bodies.

The differences found on pathological examination in fœtal rickets, infantile rickets, adult rickets and osteomalacia are those due to differences in the skeleton, rate of growth, and amount of decalcification, with the formation of fibre bone (i.e. derived from fibrous tissue) in the child, and to a much less extent in the adult.

Chemical pathology.—In a well-marked case of osteomalacia there are certain chemical changes: (*a*) The serum calcium is low, 5 to 8 mg%. (*b*) The inorganic phosphorus is low, 1 to 2·5 mg%. (c) The phosphatase units per 100 c.c. are low, 4 to 5. (*d*) The calcium supply in the milk in a parturient woman with osteomalacia is below standard figures.

These figures are paralleled in the child with fœtal rickets and, in the latter case, the hæmoglobin and red cell counts of the cord blood are also below normal.

The urine and fæces show a negative calcium balance, and a positive phosphorus balance.

In the adult the cortex of the bone is poor in calcium; whilst in the analysis of bones from fœtuses born from mothers suffering from osteomalacia, there is a definite calcium and phosphorus deficiency, whilst the relation of calcium to phosphorus remains about normal.

Valuable work has been done by Liu (1935) and his associates in the study of the calcium and phosphorus metabolism in osteomalacia. Some of their conclusions are given below:

"While their basic abnormality of poor calcium conservation because of vitamin-D deficiency remains identical, two types of osteomalacia are recognizable by the levels of serum calcium and inorganic phosphorus, in one type serum calcium is low, but inorganic phosphorus normal, and in the other type inorganic phosphorus is decreased, but calcium normal. In low calcium osteomalacia tetany is the predominant feature and lenticular opacities are often present; while in low phosphorus osteomalacia, the presenting symptoms are bone tenderness and skeletal deformities. Osseous decalcification in the first type may be mild or early, whereas in the second type it is more likely to be advanced.

"In low phosphorus osteomalacia the normal serum calcium may be lowered and the low inorganic phosphorus raised by diets low in calcium and high in phosphorus.

"Both types of osteomalacia respond readily to vitamin-D therapy. When skeletal decalcification is extensive, the improvement in calcium and phosphorus retention is prompt and marked. When skeletal decalcification is slight, such improvement may not be striking. Likewise calcium and phosphorus retention slackens as the bony stores are replenished under treatment.

"After the administration of vitamin D, serum calcium, when low, is raised to normal and its rise is more rapid in the case of slight skeletal osteoporosis than in the case of pronounced decalcification. Serum inorganic phosphorus, when low, rises rather slowly, being susceptible to the influence of factors other than vitamin D."

Another matter also comes under consideration when one deals with the question of associated tetany; i.e. the matter of calcium-ion concentration, for this trouble seems to depend on this rather than on the total serum calcium. If the former is over 4% there is osteomalacia without tetany. Howland and Kramer laid down that if the product of the concentration of calcium and phosphorus in milligrams per 100 c.c. of serum falls below 30, rickets is invariably present in children. The same figure apparently holds good for osteomalacia though it must be remembered that the normal figure in adults for phosphorus tends to be lower than in children.

In the question of the possible prediction of fœtal rickets in a case of osteomalacia; if the product of calcium and phosphorus in the mother's blood, near term, is below 20, the baby will exhibit the signs of fœtal rickets.

Radiological appearances.—In the beginning of the disease little is to be observed. As the disease advances there is decalcification, and the structure of the spongiosa becomes more grossly reticular. The decalcification may proceed to such an extent that satisfactory X-ray films cannot be obtained.

The characteristic changes in the pelvis are easily seen, and in the early cases the yielding of the lateral wall due to pressure about the acetabulum is manifest. Gradually the typical triradiate pelvis is developed, sometimes fairly regular, sometimes with considerable asymmetry, depending to a certain extent on the patient's posture. The edge of the iliac bones tends to flatten and the increased convexity of the sacrum may result in the formation of a sharp angle.

Osteomalacia [*Summary*]

By J. Preston Maxwell, M.D., F.R.C.S., F.R.C.O.G.

History.—Osteomalacia was first recognized as an entity in the middle of the seventeenth century. Lambert wrote on it in A.D. 1700 (Ribémont-Dessagnes and Lepage, 1894).

In 1885 Pommer insisted on the identity of osteomalacia with rickets, countering the view of Virchow that the two were separate entities. Clinical evidence gradually accumulated to show that early rickets, late rickets, and osteomalacia, occurred endemically and at the same time. In 1922 Mellanby (1921, 1925), McCollum (1922) and Hess (1929) proved that for both diseases a deficient vitamin intake was of paramount importance, and shortly after this researches in Peking and India established that this disease is rickets in the adult, and is part of the series, fœtal rickets, infantile rickets, late rickets, and adult rickets. These researches have been confirmed and extended by Snapper (1943) in Peking.

Distribution.—The two world centres in which the disease is now found are parts of India and North China. But given the requisite conditions, i.e. avitaminosis D, one may get it anywhere. It used to be endemic in the Rhine and Danube valleys, especially in the upper reaches.

Both men and women are affected, though on account of the calcium strain of pregnancy, more cases have been seen in women, and parturition may become a death-trap for both mother and child. Race is no barrier to the affection.

General clinical manifestations.—The most common early symptoms both in men and women are pain in the back and thighs, with spasm of the adductor muscles, often accompanied by disturbances of sensation in the hands and feet. The lumbar pain is the earlier, and is of an aching character, worse in winter months and in sunless periods.

At first there is no bone tenderness, but as the trouble progresses, the bones become tender, especially the lower ribs and pelvic girdle, and softer spots may be felt on the ribs. Two forms of pelvic deformity manifest themselves. The first is the formation of a funnel pelvis, and this is apt to take place in cases of late rickets; the second is the typical triradiate pelvis of severe osteomalacia. The sacrum develops an acute convexity, the lower portion and the coccyx coming forward; the chest develops either a lateral curvature with rotation, or a pure kyphosis; the neck sinks into the upper portion of the chest, reducing the height by some inches; the chest itself becoming barrel shaped with a crumpled sternum. Irregular curvatures take place in the long bones with a tendency to fracture on slight injury. Due to rarefaction of the alveolar processes of the jaws the teeth may become loose.

Tetany is very common, but is not found in all cases. The spasms may last for hours, leaving numbness behind. Instability of gait is specially marked in pregnant cases, and, if properly treated, disappears before labour commences, so that it is not due to any physiological relaxation of the pelvic joints.

Excessive movements of the fœtus in pregnancy may be due to the disease, and fœtal rickets is now a proved occurrence in severe cases, with X-ray signs in the fœtus as early as the 35th week of intra-uterine life.

Rarer manifestations are a subcapsular cataract associated with the disease, formerly included under cataracta tetanica, though it may occur in osteomalacia cases which have not manifested tetany. The finger nails may become ridged, irregular, and tend to split.

The ovaries have been considered as the cause of the disease, but as it occurs in both men and women, and there is no histological difference between ovaries taken from active osteomalacia cases and ovaries removed from other cases, it is clear that they can be disregarded.

The parathyroids have been incriminated, and Erdheim was right when he pointed out the enlargement of the parathyroids in some cases of the disease, but this enlargement is a hyperplasia, a reaction to the disease, and clinically the administration of parathormone to osteomalacia cases makes them much worse.

Pathological changes (Histology).—Common to both rickets and osteomalacia are the following:

(1) Changes in the bone trabeculæ which are surrounded by broad osteoid seams.

(2) Changes in the costochondral junctions of the rib cartilages. "This is the only place where in the adult organism a cartilage-bone junction persists. Here in adult patients with osteomalacia the same proliferation of the cartilage is found as takes place in the epiphyseal discs of children with rickets" (Snapper, 1943).

The Complex Behaviour of High-Frequency Currents in Simple Circuits

By P. BAUWENS, M.R.C.S., L.R.C.P.

ABSTRACT.—The fact that standing wave phenomena exist along transmission lines and loops conducting high-frequency electrical energy is responsible for effects of which therapeutic use can be made.

A. Power measurements are made possible because parallel transmission lines behave as power transformers of which the ratio varies with the length of these lines. In a generator designed by the G.E.C. the dimensions of the lines are such that after a preliminary estimation of the impedance of the load in the treatment field, the sensitivity of the meter can be adjusted so that the meter subsequently registers in watts the power absorbed in this load.

B. When using cable electrodes, in practice, the presence of strong electric fields between the antinodal portions of the loop as well as strong oscillating magnetic fields around the nodal portion gives rise to two distinct phenomena (fig. 6).

Search for currents resulting from the electric field on the one hand, and for eddy currents due to the magnetic field on the other, was carried out at St. Thomas's Hospital, in liquid phantoms by means of a probe (fig. 5*a*) incorporating a small lamp capable of being rotated in every direction. Voltage measurements were recorded by matching its light intensity with that of a similar lamp in circuit with a variable resistance and a voltmeter (fig. 5*b*).

When a portion of a cable electrode was coiled around a cylindrical vessel containing an electrolyte, the effects due to the two conditions could be dissociated. The following observations were made (fig. 7):

(*a*) By using the nodal portions of the loop only, it was shown that only eddy currents are produced and that the lower the resistance of the electrolyte the more easily they are produced. They are strongest at the periphery and rapidly fall off away from it, as shown by the curves of the graph in *fig.* 8.

(*b*) By using only the antinodal portions of the loop, coiled around the same vessel, coaxial or longitudinal currents can be demonstrated. It is interesting to note that these exist both at the periphery and at the centre.

(*c*) When the whole cable is wound around the vessel, the concentration of the electrolyte becomes the factor determining the way in which the energy will be dissipated: (1) with tap-water, it is found that no eddy currents can be demonstrated whereas coaxial currents exist; (2) with strong saline solutions the converse holds good; (3) with electrolytes of intermediate concentration both types of currents can be shown to coexist at the periphery while at the centre only coaxial currents can be demonstrated.

The fact that eddy currents and coaxial currents could be detected simultaneously and did not, as might be expected, give rise to a resultant, could only be explained by assuming that although eddy currents and coaxial currents coexisted as far as their effects on the pilot lamp were concerned, these two phenomena were not coincident as regards their phase relations. On examining the system more closely it became clear that the coaxial currents must be approximately 90 degrees out of phase with the eddy currents.

By means of another type of probe (fig. 5*c*) for surface work, consisting of two metallic buttons mounted on an insulating strip and bridged by a small lamp, P^3, similar to the one used throughout the investigations, it was possible to show that the same conditions existed in the body. It could be demonstrated that both coaxial and eddy currents occurred and that the predominance of one or the other type was dictated by conditions related to impedance. In the thigh just above the knee-joint, As to the long bones, bending may take place accompanied by the development of coxa vara; and fractures, often intraperiosteal, may occur.

The spinal column presents marked osteoporosis with marked bulging of the intervertebral discs into the vertebral bodies. There may be kyphosis with scoliosis, or a pure kyphosis, the latter being the rarer form.

The costochondral junctions of the ribs may show proliferation of the cartilage similar to that seen in the epiphyseal discs in early rickets.

Differential diagnosis.—Osteomalacia has to be distinguished from the other osteodystrophies; such as hyperparathyroidism; Paget's disease; renal osteodystrophy in adults; fragilitas ossium; senile osteoporosis; malignant metastases; and Hand-Schüller-Christian disease.

A difficulty is that osteomalacia may be superimposed on some of these diseases by virtue of the character of the invalidism which they have developed, involving confinement indoors, with lack of sunshine and a deficiency diet.

This may upset the calcium excretion so that even though in a hyperparathyroidism there may be hypercalcæmia there is a low calcium excretion. The majority of these affections are easily differentiated, but in the case of senile osteoporosis the matter is not so easy as administration of vitamin D may relieve the symptoms fairly quickly.

Speaking generally, however, taking into account the clinical symptoms and the chemical and radiological findings, the diagnosis of advanced osteomalacia is not difficult.

Where, however, one meets with a single case, in a region where osteomalacia is not common, there may be considerable difficulty in diagnosis.

It must be remembered that where there is one avitaminosis other vitamin shortages are almost sure to be present.

Treatment.—The result of treatment with any of the preparations of vitamin D has been very satisfactory. The provision of cheap calcium and vitamin-D tablets has transformed the position in North China.

The question of dosage and of the combination with it of other vitamins in the treatment of the disease is still unsettled.

One must remember that it is not merely in the well-marked case that treatment is important. Early symptoms of osteomalacia are not infrequently found in pregnant women, and there is no doubt of the benefit conferred on such women by regular dosage with calcium and vitamin D during the last six weeks of gestation.

It is not yet certain whether large single doses of vitamin D may be used as a prophylactic.

QUESTIONS NEEDING AN ANSWER

Two further points have yet to be defined: (1) The relation of the disease to hunger osteopathy. Pure starvation will cause an osteoporosis. Probably one will get a bone atrophy due to osteoblastic inactivity, where the special deficiency is not due to vitamin D alone; and (2) the relation of this disease to senile osteoporosis. In these latter cases the blood picture is normal and the crushing of the bodies of the vertebræ is the principal bone sign, but there is pain in the back and thighs and apparently arrest of the disease by treatment with vitamin D and calcium.

In April 1935 I read before the Duchenne Society a short paper entitled "The Behaviour of Oscillating Currents in Complex Circuits". Since that time, I have become better acquainted with the behaviour of these currents and their vagaries. My greater respect for them has this time made me choose the less ambitious title of "The Complex Behaviour of High-Frequency Currents in Simple Circuits".

While the technical developments in the field of high frequency demanded by the exigencies of war have been considerable, their application to medicine has made but little progress.

One of the reasons for this discrepancy is that the medical man has an aversion to the mathematical way of expressing a phenomenon: while on the other hand the theoretical physicist, unfortunately, is only too well aware of the shortcomings of the non-mathematical conceptions of such phenomena.

The methods of producing high-frequency and ultra-high-frequency currents are now so numerous that the type of generator circuit employed in a particular machine is the radio engineer's problem. There are, however, in this respect two points with which the medical man may be concerned. The first relates to the abatement of radio interference. It is now moderately certain that legislation will come into being with a view to stopping incidental radiation from all types of equipment including electro-medical apparatus.

This will mean either working inside screened rooms or employing apparatus designed to work at frequencies allocated for free radiation. In order that apparatus should adhere strictly to the specified wave bands within the limits of tolerance imposed, it will have to be of very special design, probably crystal controlled.

My second point in this connexion takes me back to my lecture before the Duchenne Society, when, after demonstrating the existence of mechanical stresses in dielectrics subjected to alternating electric fields, I postulated that similar stresses might be produced in dielectrics subjected to high-frequency fields. I also propounded the hypothesis that such mechanical disturbances might provoke mild inflammatory reactions capable of eliciting defensive processes in living tissues.

At the same time it was realized that the dominant effect of high-frequency currents in the tissues was the production of heat with a consequent rise in temperature, which itself set a limit to the use of high-frequency currents at intensities sufficiently high to bring to light manifestations of another order.

It is not possible to predict what would happen if, instead of treating tissues by means of sustained high-frequency electrical energy, tissues were subjected to intermittent radio-frequency pulses of very high intensity separated by silent periods of sufficient length to allow for the dissipation of heat.

Those who have some technical knowledge of such matters will readily recognize an application of "Radar" technique in this.

It is disappointing to have to note that although this country was foremost in the field of Radar development, the only experimental work of this kind on biological materials was carried out by Dr. Johan Nyrop in Copenhagen, actually during, and after, the German occupation of Denmark.

The results of his investigations are epitomized in a letter published in *Nature* of January 12, 1946.

If the actual method of generating high-frequency currents is not of immediate interest or importance to the medical man using them, a knowledge of their behaviour in the circuit which includes the patient is essential, if they are to be used to their best advantage or if the need of measuring them arises.

One of the difficulties which appears to confront the non-technical mind is the recognition of an unfamiliar type of oscillating circuit.

Take a straight metal strip of say 1 metre in length and bend it so as to make it assume the shape of a gigantic hairpin. Few will recognize in this an oscillating circuit. Yet on closer examination the looped end may be regarded as a coil of only one half-turn and the open end as the plates of a condenser.

Thus we have inductance and capacitance which are the requisite factors for an oscillating circuit.

If brought within a short-wave field of approximately 2 m. wave-length this bent strip would become the seat of electrical oscillations of approximately 150 megacycles. This means that 150 million times per second, electrons pass from one prong of this system to the other and back again.

The presence of the electrons on one prong, and their deficiency on the other, creates an electric field across the open end of the system (C) while the to-and-fro movement of electrons in the loop (L) produces a magnetic field.

It must be realized for future reference that the electric field is strongest when no magnetic field exists and conversely.

in most cases both currents could be demonstrated. It could also be shown that when half the cable was wound clockwise and the other half anticlockwise, so as to cancel the magnetic field between the two halves, no eddy currents existed.

C. Present therapeutic applications of high-frequency currents involve the continuous dissipation of electrical energy in the load under treatment. Under these conditions the only detectable effect to which therapeutic value may be ascribed is the rise in temperature which results from heat production. This rise in temperature sets a limit to the power which can be used without risk of burns. Consequently effects other than thermal ones which might manifest themselves under higher intensities remain undetected.

It is not possible to predict what would happen if, instead of treating tissues by means of sustained high-frequency electrical energy, tissues were subjected to intermittent radio-frequency pulses of very high intensity separated by silent periods of sufficient length to allow for the dissipation of heat. Those who have some technical knowledge of such matters will readily recognize an application of "Radar" technique in this.

RÉSUMÉ—Les ondes électriques stationnaires avoisinant des conducteurs sièges de courants de haute fréquence, provoquent des effets qui doivent être pris en considération à la faveur de leurs applications thérapeutiques.

A. La mesure de l'énergie dissipée est rendue possible grâce au fait que des conducteurs parallèles se conduisent en transformateur. Dans une génératrice d'onde courte, mise au point par la G.E.C., les dimensions de ces conducteurs sont telles qu'après avoir préalablement établi l'impédance du sujet entre les électrodes condensatrices, la sensitivité de l'appareil de mesure peut être ajustée de façon à lire dès lors en watts l'énergie absorbée dans le sujet.

B. Avec l'emploi des électrodes inductrices la présence d'un puissant champ électrique entre les antinodes ainsi que d'un puissant champ magnétique oscillant, associé au node, donne lieu à deux phénomènes distincts (fig. 6).

À St. Thomas's Hospital on a recherché d'une part les courants de Foucault, et d'autre part les courants provoqués par le champ électrique. À cet effet on a fait usage d'une sonde munie d'une petite lampe électrique pouvant être orientée dans toutes les directions. Les voltages développés pouvaient être estimés par comparaison de l'intensité lumineuse émise par la petite ampoule, avec celle émise par une ampoule semblable en circuit avec une résistance variable et shuntée par un voltmètre (fig. 5*b*).

Avec une portion de l'électrode inductrice enroulée autour d'un vase cylindrique contenant une solution conductrice, les effets dûs au deux conditions existantes peuvent être séparés. Il est à noter que (fig. 7):

(*a*) en disposant la partie node de l'électrode inductrice autour du vase, seuls les courants de Foucault peuvent être décelés et que ceux-ci sont produits d'autant plus facilement que la résistance de la solution est faible. Ils sont d'ailleurs intenses à la périphérie et faiblissent rapidement en quittant celle-ci, ainsi que le démontre la courbe de la fig. 8.

(*b*) d'autre part, en n'usant que les antinodes de l'électrode inductrice enroulés autour du même vase, seuls les courants longitudinaux dûs au champ électrique se manifestent. Ceux-ci toutefois existent au centre du vase tout autant qu'à la périphérie.

(*c*) Lorsque l'électrode inductrice entière est enroulée autour du vase, c'est la concentration de la solution qui détermine la manière de laquelle l'énergie est dissipée: (1) Avec de l'eau du robinet, seuls des courants longitudinaux sont décelés tandis que les courants de Foucault sont faibles ou font défaut. (2) Avec une solution concentrée de sel marin, le contraire se manifeste. (3) Avec des concentrations intermédiaires, les deux courants peuvent coëxister à la périphérie tandis qu'au centre, seuls les courants longitudinaux se manifestent.

Le fait que les courants de Foucault et longitudinaux peuvent être décelés simultanément et sans donner lieu à une seule résultante ne peut être expliqué qu'en postulant que quoique ces deux courants coëxistent en tant que leurs effets sur la lampe exploratrice, ces deux phénomènes ne coïncident néanmoins pas quant à leurs phases. En effet, en examinant plus attentivement le circuit en question, il devient évident que ces courants doivent être déphasés d'environ 90°.

Au moyen de deux boutons métalliques montés sur un manche isolant et réunis par une petite ampoule (P^3 dans la fig. 5*c*) semblable à celles utilisées dans les expériences précédentes, il est possible de démontrer que les mêmes conditions existent dans le corps humain. Outre la présence de courants de Foucault et longitudinaux, on peut démontrer que la prédominance des uns ou des autres dépend de conditions ayant trait à l'impédance. Dans la cuisse, par exemple, on peut relever simultanément les deux courants. On peut aussi démontrer que les courants de Foucault peuvent être abolis en enroulant les deux moitiés du cable inducteur dans des directions opposées, de manière à neutraliser l'effet des champs magnétiques.

C. À présent les applications thérapeutiques de haute fréquence sous-entendent la dissipation continue de l'énergie électrique dans le sujet. Dans ces conditions, seuls les effets thermiques se manifestent. La hausse de température résultant de la production de la chaleur limite l'énergie utilisable sans crainte de brûlures. Par conséquent tout autre effet qui pourrait se manifester sous des intensités plus élevées reste caché.

Il est impossible de prévoir ce qui arriverait si au lieu de traiter les tissus à un régime de dissipation soutenue, on les soumettait à des trains d'ondes d'intensité très élevée séparés par des périodes inactives suffisamment longues pour permettre la dissipation de la chaleur dégagée. C'est une technique qui se rattacherait au "Radar".

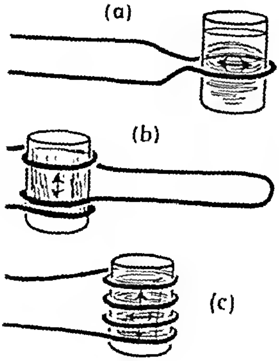

FIG. 7.

consisting of a single tuning condenser with the transmission lines and the patient's condenser field across it (fig. 3*a*) lend itself to the modifications required for power measurements by this method. Instead, a single oscillating circuit is used with the inductance, the transmission lines, the patient's condenser field and two ganged variable tuning condensers all in series (fig. 3*b*).

It is a circuit of this type, incorporating features designed to overcome the difficulties due to the complications mentioned, which has been adapted by the G.E.C. Laboratories for power measurement (fig. 4). One of its main points of interest is that the length of the transmission lines has been so adjusted that an automatic correction is effected for the power lost in the cables themselves. The sensitivity control in this instance is obtained by means of two small ganged condensers in series with the voltmeter.

The state of affairs just described exists in the patient's leads. On these transmission lines—when parallel—one can detect zones where a strong electric field exists and others where the magnetic field is strong. These conditions are referred to as standing waves and are in every way similar to the standing waves observable in analogous mechanical systems. Spectacular demonstration of this is afforded by Melde's experiment where a stretched string is attached at one end to the prong of a tuning fork and loaded at the other. Under the action of the vibrations the length of the string can be seen to break up into zones where practically no vibration occurs and zones where the amplitude of vibration is at its greatest. These zones are termed nodes and anti-nodes respectively.

That standing waves exist along transmission lines carrying high-frequency currents can equally well be demonstrated by means of a small loop of wire closed upon an ordinary light bulb in the case of voltage nodes and by means of a small neon tube in the case of anti-nodes.

An interesting feature of the standing wave phenomenon is that the voltage across one position of the parallel transmission line system bears a direct linear relation to the current in another.

If L and C (in fig. 1) represent the inductance and capacitance of an oscillating circuit in resonance with a high-frequency generator then, provided the transmission lines are $\frac{\lambda}{4}$ long, the voltage measured across the inductance L will vary directly with the current in the condenser C. So much so that a voltmeter M appropriately calibrated in amperes will give a direct reading of the current in the condenser field, that is, if the losses are negligible and the system is in resonance.

There is a definite relationship between the frequency of oscillation and the distance between the nodes and anti-nodes, the latter being equal to ¼ wave-length.

The direct consequence of this peculiarity is that transmission lines behave as power transformers which may in their effect be compared with an ordinary static transformer—provided the analogy is drawn with caution.

Imagine a transformer with an equal number of turns of wire on the primary and secondary windings. If an alternating current is fed into the primary, a current of substantially the same voltage and amperage will be available from the secondary. Should the number of turns of wire on the secondary be now progressively reduced it will be found that although substantially the same power is obtainable it will be of lower voltage but a higher amperage will be available. With, for instance, only one turn of wire on the secondary, enormous amperage and very low voltage will result, always provided the load is of the appropriate value.

With high frequencies it is important to note that whatever the length of the leads, the power supplied to the load via the leads has the same magnitude as the power fed into the leads, minus of course that proportion of the power which is lost in transmission. It is impossible to use at high frequencies the same type of power-measuring devices as are in common use at low frequencies. However, working in the G.E.C. Laboratories, Mr. Furneaux has developed a method of measuring the power supplied to the patient in short-wave diathermy. He makes use of a circuit which automatically combines a measurement of the resistance of the patient and of the current passing into him. The principles are best illustrated by outlining how the same circuit would measure power in a load subjected to A.C. at low frequency.

In fig. 2, T represents a transformer supplying power to a load Z. Its primary is supplied from a low-frequency source via the potentiometer QP. With this potentiometer set to the point O the E.M.F. has a definite value, say 10 volts. In series with the primary is a meter with a variable resistance R shunted across it. It will be appreciated that for a particular value of the shunt R the reading of the meter is a function of the current in the load, and as the power in the load is determined by the formula $W=I^2r$, then for a particular value of load resistance the meter could be calibrated directly in terms of the power into the load. But if now another load, having a different resistance, is connected to the secondary, this calibration will no longer apply. However, if the value of the shunt R is appropriately reset the meter calibration can be made to suit the changed load. Clearly what is needed is some means of measuring the resistance of the load so that the shunt R can be set to the correct value for each load. This can be achieved by setting the potentometer to the fixed point O, under which condition a predetermined E.M.F. is applied to the primary of the transformer, and the reading of the meter is a function of the resistance of the load. The meter reading under these conditions will therefore give the information which enables R to be set up to such a value that henceforth the meter correctly reads the power into the particular load under consideration.

In the case of high-frequency and ultra-high-frequency currents, the problem—although similar in its broad essentials—is complicated by the presence of standing waves and the losses due to absorption in the transmission lines. Nor does the customary output circuit

It has always been one of the drawbacks of short-wave therapy that it does not lend itself to being measured. The fact that one instrument can effect the measurement of current, or of the power dissipated must be considered an important step forward in dosimetry and will prove of invaluable assistance in technique of administration and prescription of short-wave therapy.

Other methods of computing power dissipated have been devised, notably by Mittelman, but they lack the simplicity of the one just described.

In this connexion I would, however, venture a cautionary remark to the effect that although these methods give information as to the total dissipation of energy, they give none as to where it is dissipated.

Take for example the treatment of a septic finger longitudinally and in series with the hand and forearm: the measurement of total power would in such a case not be as valuable as an assessment of the current in the finger.

From limited experience with the machine at my disposal it has already been abundantly clear that the measurement of both the current in amperes and of the power in watts must be available.

Before closing I should like to make some few remarks about that part of the output circuit more intimately concerned with the actual treatment.

Two principles are involved in the application of high-frequency currents to the patient. The first is based on the production of heat through power absorption in leaky dielectrics placed in a condenser field. The second depends on the production of heat resulting from the induction of eddy currents in tissues surrounded by a coil which is carrying a high-frequency current.

When the condenser method is used, only electric field phenomena need be considered and, provided the calculations of conditions in complex networks of impedances are regarded as a simple matter, the behaviour of the currents, as regards distribution and conversion into heat, are moderately straightforward.

In the case of treatments with the cable electrode, the problem becomes highly complicated on account of the difficulty of obtaining eddy currents only.

Experiments conducted at St. Thomas's Hospital have enabled us to come to some conclusions which I should like to put on record because they are of some practical importance and may, if noted, lead to improvements in technique with cable electrodes.

The search for the longitudinal or coaxial currents and for the eddy currents was carried out on liquid phantoms in a cylindrical vessel in collaboration with Dr. Waters and Mr. Styles. The probe used consisted of a glass tube having at one end a small electric bulb requiring a very low current and fitted with two small condenser plates (fig. 5*a*).

By turning knob K, this little lamp (P^1) could be made to rotate through 360 degrees in both the horizontal and vertical planes.

Accurate measurements of the E.M.F. impressed across the lamp (P^1) could be made by matching the light of a similar lamp (P^2) with a voltmeter across its filament and controlled by a variable resistance (fig. 5*b*).

Inasmuch as the cable electrode is a closed loop, it must have a nodal portion (A) where the current is high with a high magnetic flux and two antinodal portions (B and C) between which a strong electric field exists (fig. 6). Intermediate points (D and E) are in lesser degrees the seat of both magnetic and electrical phenomena.

When a portion of such a cable is coiled around a cylindrical vessel containing an electrolyte the effects of the two phenomena can be dissociated (fig. 7).

(*a*) By using the nodal portions of the loop only, it can be shown that only eddy currents are produced and that the lower the resistance of the electrolyte the more easily they are produced. Of course they are strongest at the periphery and rapidly fall off away from it, as shown by the curves of the graph in fig. 8.

(*b*) By using only the antinodal portions of the loop, coiled around the same vessel, coaxial or longitudinal currents can be demonstrated. It is interesting to note that these exist both at the periphery and at the centre.

(*c*) When the whole cable is wound round the vessel, the concentration of the electrolyte becomes the factor determining the way in which the energy will be dissipated: (1) with tap water, it is found that no eddy currents can be demonstrated whereas coaxial currents exist: (2) with strong saline solutions the converse holds good: (3) with electrolytes of intermediate concentration both types of currents can be shown to coexist at the periphery while at the centre only coaxial currents can be demonstrated.

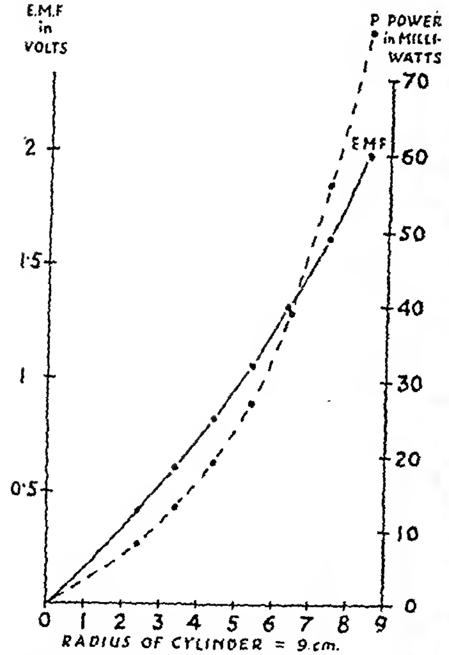

FIG. 8.—Full line curve (E.M.F.) shows the growth of the eddy current generating E.M.F. when the exploratory probe was moved from the centre to the periphery of the water phantom, along the 9 cm. radius. The broken line (P) shows the corresponding growth of the power measured in milliwatts.

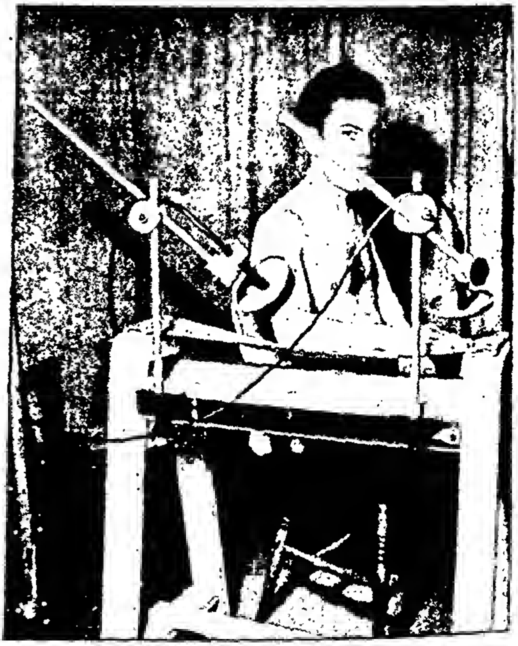

FIG. 9.

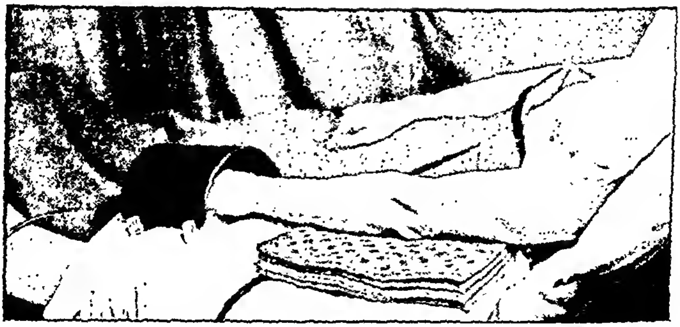

FIG. 10.

The operations involved are slightly more complicated and are as follows: The condenser electrodes are suitably placed and the generator is turned on to a definite pre-set but low output. With the sensitivity control of the meter at a standard setting the tuning condensers are then manipulated until the highest reading on the meter indicates that resonance exists. The meter now gives a measure of the resistance of the patient.

The pointer of the sensitivity control-knob is now made to point at a figure representing the resistance just noted. Once this is done, the meter registers on the power scale the watts dissipated in the patient and will continue to do so for any output of the generator provided the patient's circuit is kept in resonance. Many will have recognized that the steps taken to achieve this measurement are the same as those taken for measurements in the case of low-frequency currents.

Hæmophilus influenzæ and its Relation to Epidemic Influenza

PRESIDENT'S ADDRESS

By A. B. Rosher, M.R.C.S., L.R.C.P., D.P.H.

The majority of bacteriologists at one time or another have come under the spell of the Hæmophilus group. In this Pathological Section alone three former Presidents, namely, McIntosh, Fildes and Fleming, have all made valuable contributions to the literature of the subject and Dible, a former member of the Council, has also done likewise; furthermore Miles, a present member of the Council, has recently reviewed para-influenza bacilli in relation to endocarditis, and finally Edith Straker has provided some information as to the carrier rate of influenza bacilli in upper respiratory passages.

My interest in the group started seventeen years ago, when from 1929 to 1938 I set out to determine the carrier rate of influenza bacilli in the trachea of post-mortem subjects. I examined the best part of 1,000 strains at that time and since the war I have examined 100 or so more from various sources. When I chose the subject for an address, with this experience behind me, I thought I should have a comparatively easy task, but when I come to put my observations down on paper, I find it is not so easy as I imagined for now we have quite a large group to deal with and there are still many uncertainties to be cleared up.

In the olden days we had the respiratory type as described by Pfeiffer (1892, 1893), the Koch-Weeks bacillus which was considered identical with Pfeiffer's bacillus except for a tendency to cause conjunctivitis and, lastly, the somewhat rare strains known as para-influenza bacilli which synthesize the X factor and therefore only require V factor to be supplied in the ordinary culture medium to enable them to grow. Some comparatively rare strains of both influenza and para-influenza bacilli were known to be capable of forming a soluble hæmolysin.

This was the state of affairs until the year 1931 when two fresh observations were made on members of this group. Margaret Pittman, 1931, described a capsulated type of influenza bacillus possessing a specific soluble substance and since then she has identified six distinct serological types known as A, B, C, D, E, F, and it is of interest to note that the vast majority of cases of influenzal meningitis are due to one of these serological types, namely, type B.

Later in the year Shope described a bacillus which, in conjunction with a filtrable virus, gave rise to swine influenza. He called it *H. influenzæ suis* but pointed out that it was morphologically and culturally indistinguishable from other non-indole forming strains of *H. influenzæ*.

Table I.—Influenza Bacilli

H. influenzæ (Pfeiffer):	gives rise chiefly to infection of the respiratory tract; requires both X and V factors to be supplied for growth.
Koch-Weeks bacillus:	indistinguishable from the above but giving rise to conjunctivitis.
H. influenzæ suis:	indistinguishable from the above but giving rise to swine influenza in conjunction with a virus.
H. influenzæ (Pittman):	six serological types A, B, C, D, E and F. The type B is responsible for the vast majority of cases of influenzal meningitis.
Para-influenza bacilli:	differ from the above in synthesizing the X factor and therefore only requiring a supply of the V factor for growth. These organisms are sometimes found in connexion with infective endocarditis.
Hæmolytic influenza bacilli:	have been associated with respiratory disease but are rare in this country.
Hæmolytic para-influenza bacilli:	occasionally found in infective endocarditis.

The feature which at first appears puzzling is the fact that eddy and coaxial currents can be detected simultaneously and do not—as might be expected—give rise to a resultant. The small pilot lamp remains alight when rotated through 360 degrees. The only possible explanation is that although the eddy currents and the coaxial currents coexist as far as their effects on the pilot lamp are concerned, these two phenomena are not coincident as regards their phase relations. On examining the system more closely it becomes clear that the coaxial currents must be approximately 90 degrees out of phase with the eddy currents.

By means of another type of probe (fig. 5*c*) for surface work, consisting of two metallic buttons mounted on an insulating strip and bridged by a small lamp P^3 similar to the one used throughout these investigations, it is possible to show that the same conditions exist in the body. It can be demonstrated that both coaxial and eddy currents occur, and that the predominance of one or the other type is dictated by conditions related to impedance.

If the impedance is high, as for instance when the cable is wound around the whole length of an arm, the dissipation of energy in the form of coaxial currents appears to be favoured. If on the other hand the cable is wound around the trunk, the production of eddy currents appears to be favoured.

In the thigh just above the knee-joint, in most cases both currents can be demonstrated.

It can also be shown that when half the cable is wound clockwise and the other half anti-clockwise, so as to cancel the magnetic field between the two halves, no eddy currents exist.

The outcome of the more immediately practical aspects of some of our work is shown by the use of polythene-covered electrodes with turned-up edges and the method of clamping these electrodes to the treatment chair or limb rest (fig. 9).

Air-spaced tunnel electrodes also have their use when treating limbs or parts of limbs. They can be made out of ordinary rubber-covered electrodes held in a small wooden rack to keep them curved (fig. 10).

It will be noticed that a modification of this air-spaced tunnel electrode is used in conjunction with the machine incorporating the power-measuring instrument. Even in its prototype state this electrode has proved its adaptability to conditions.

My list of acknowledgments would be a long one if I mentioned by name everyone who had assisted me, for in addition to those directly associated with my work at St. Thomas's Hospital I am indebted to the Research Laboratories of the G.E.C. for their help, both from the point of view of technical advice and loan of apparatus. I would also mention Mr. Cox and his staff who took a lot of trouble in constructing the equipment I conceived.

strain there is a smallish circle surrounding the disc where no growth takes place (fig. 1).

If films are made from the periphery of this circle where there is obviously a struggle for existence the bizarre forms predominate, but about an inch away from this we find the coccobacillary or so-called typical forms predominating (figs. 2 and 3).

Some experiments are now being carried out by J. Fielding and myself to find out if it is a deficiency of V factor which causes this result. If this is the case penicillin probably has an antagonistic action on it. We have tried a few similar experiments with phenoxytol and streptomycin but have not been able to produce this effect with them. Therefore it looks as if the underlying principles of their antibiotic properties are different from those of penicillin.

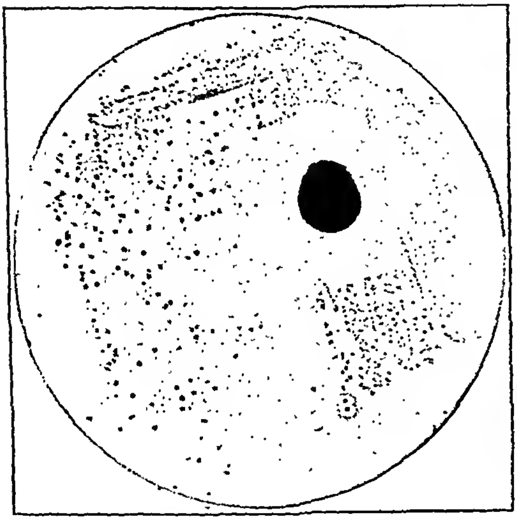

FIG. 1.—Fildes' medium inoculated with a penicillin-sensitive strain of *H. influenzæ*. The absorbent disc contains 10 units of penicillin. It is surrounded by a zone where the growth is inhibited.

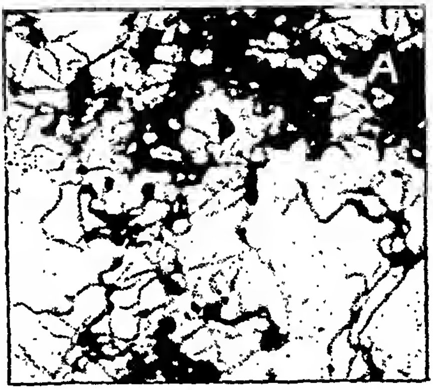

FIG. 2.—Film from periphery of inhibition zone (fig. 1 A) showing pleomorphic forms.

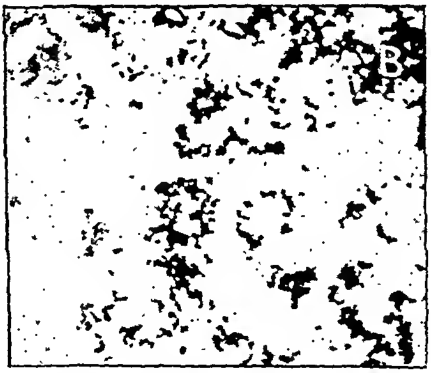

FIG. 3.—Film taken one inch from inhibition zone (fig. 1 B) showing coccobacillary forms.

The change of morphology is well marked in the case of Pittman rough and smooth colonies. Films from the rough colonies show the thread forms, &c., whereas those from the smooth show coccobacillary forms almost uniform in size. In older plate cultures, however, the bacteria from the smooth colonies also become pleomorphic and the bizarre forms are seen. The two morphological forms are interchangeable according to the nature of the food substance provided; they therefore can be regarded as environmental variants.

Table I shows a catalogue of the various members of the influenza group indicating their usual pathological propensities. However, overlapping frequently occurs and the Pfeiffer or respiratory strains may give rise to meningitis (Mulder, 1939, and Gordon *et al.*, 1944) and occasionally turn up in unexpected places, e.g. I have recently isolated a bacillus of the Pfeiffer type in pure culture from an intra-abdominal cyst and also a Bartholin's abscess. Then again Pittman strains may be found in the nasopharynx and this is, in all probability, the source of entry in meningeal infections.

In view of this probability I think no harm would be done from the public health point of view in swabbing the immediate contacts of cases of influenzal meningitis with a view to tracing possible sources of infection in this disease which, until recently, was almost always fatal.

The para-influenza bacilli are also found in unusual places (Stuart-Harris *et al.*, 1935) and I recently had one sent to me for identification from a case of ulcerative colitis. It has been suggested by Mulder (1947) that Pfeiffer's bacillus should be called *H. influenzæ bronchiale* and the Pittman B bacillus *H. influenzæ meningitidis*. If this suggestion were to meet with approval then some provision should be made, in our present state of knowledge, for the Koch-Wecks bacillus and it would probably have to be called *H. influenzæ conjunctivitidis*. The suggestion does not appeal to me in view of the diverse situations in the body where influenza bacilli may be found.

The hæmolytic influenza bacilli may be more common than we imagine, for Rivers (1919) and Lamont (1926) have shown that certain strains prefer rabbit's blood and will not grow well on sheep's blood agar, therefore some of them may be missed unless rabbit's blood is used. This also applies to the para-influenza bacilli for here again the somewhat elaborate technique required for their identification is not always carried out as a routine measure.

It is beyond the scope of this address to deal extensively with the vast literature which has accumulated regarding this fascinating group of organisms and I therefore propose to make a few observations on the morphological and cultural characteristics of strains that I have encountered and then pay attention to their pathogenicity in relation to epidemic influenza.

MORPHOLOGY

A considerable amount of confusion exists in the literature as regards the morphology of influenza bacilli. There is a tendency to regard the short and coccobacillary forms as *typical* and the longer bacillary, thread and globoid forms as *atypical*. In my opinion the so-called atypical forms occur when the organisms are growing under suboptimal conditions. This can be shown experimentally by inoculating a series of tubes containing broth and decreasing amounts of Fildes' solution containing the X and V growth factors, &c. In the tubes where there is an ample supply of the growth factors, films from the organisms show the coccobacillary or so-called typical forms to predominate but when one reaches about 1/10 or more below the normal supply there is a switch over to the bizarre forms which are normally called atypical.

Further confirmation of this can be obtained by filming the large and small colonies of influenza bacilli near to a colony of staphylococcus where satellitism is seen. Films from the large colonies nearest to the staphylococcus where the food supply is good are coccobacillary, and films from the small colonies some distance away where the organisms are struggling for existence show the bizarre forms. I have reason to believe that the production of bizarre forms is due to insufficient supply of the so-called V factor rather than other factors.

This phenomenon is also well demonstrated on a plate of Fildes' medium with a small disc of absorbent, containing about 10 units of penicillin. If it is a sensitive

Characteristics of Giant Colonies

Furthermore the bizarre forms are not infrequently found in mice after intraperitoneal inoculation; this again may be due to an insufficient supply of growth factors in that situation.

It seems to me that we have sufficient evidence to enable us to state *the only thing typical about the morphology of the influenza bacillus is its extreme pleomorphism and furthermore the pleomorphism can be produced at will if it is starved of its necessary food requirements.*

Certain strains are sometimes referred to as "atypical typicals" or "typical atypicals" when trying to describe their morphological appearances, but I think this nomenclature is absurd and it should be abandoned.

COLONIAL CHARACTERISTICS

In order to study the colonial characteristics of influenza bacilli in the present instance I have employed the method described by E. E. Atkin, 1923, for growing giant colonies of meningococci. By using double the ordinary quantity of culture medium in a Petri-dish and just pin-pointing out three or four inoculations on a plate and allowing the colonies to grow to maturity in six or seven days, he found colonial differences in the various types of meningococci and claimed to distinguish one serological type from another by this method. For the Hæmophilus group I have used Fildes' medium of the ordinary depth but have ringed the plate round with plasticine to prevent the medium becoming too dry.

When the influenza bacillus is inoculated in this manner very large colonies are formed and after incubation at 37° C. for twenty-four hours the colony has already grown to about 3 mm. in diameter. At seven days it is about 8 mm. It usually reaches maturity in twenty-one days by which time it has become 1 cm. or more in diameter. The Pittman strains and Pfeiffer strains form entirely different and characteristic colonies when studied by this method. The differences can usually be detected even after twenty-four hours when viewed through a hand lens and by transmitted light. The characteristics are also seen quite well when the colonies are viewed from above with oblique lighting.

FIG. 4.—CHARACTERISTICS OF GIANT COLONIES

	H. influenzæ (Pfeiffer)	*H. influenzæ* (Pittman)
Twenty-four hours at 37° C.	(*a*) The colony is about 3 mm. in diameter. It has an entire edge and is finely granular throughout. It is not iridescent.	(*e*) The colony is about 3 mm. in diameter. It has an entire edge and fine striations are seen by transmitted light radiating out from the centre which is raised. They somewhat resemble the spokes of a wheel. The colonies are very iridescent.
Three days at 37° C.	(*b*) Increase in size to 6 or 7 mm. in diameter and the edge is becoming undulate. Fine granules are still present.	(*f*) Increase in size to about 6 or 7 mm. The edge is becoming undulate and the striations and the iridescence are still present and the latter is very well marked at the periphery.
One week at 37° C.	(*c*) Increase in size to about 8 or 9 mm. The colony is raised with a lobate convex bevelled edge.	(*g*) Increase in size to about 8 or 9 mm. The edge is now lobate and the colony resembles a sunflower when viewed by transmitted light with a hand lens. Iridescence and rays have disappeared.
Three weeks at 37° C.	(*d*) No marked increase in size, but great alteration in structure. The colony bears a striking resemblance to the head of a daisy when viewed by transmitted light.	(*h*) No marked increase in size but the "sunflower" appearance is still present and the colony is covered with knob-like excrescences.

At this point growth usually ceases and the colonies can be regarded as being mature. Why these knob-like excrescences should be formed with the Pittman colonies I do not know but I am further investigating the matter.

However I think it is wonderful that a small organism about 1μ in length can give rise to structures of such beauty and size when properly nourished.

However I think it is wonderful that a small organism about 1μ in length can give rise to structures of such beauty and size when properly nourished.

GROWTH REQUIREMENTS

For the sake of convenience I have referred to requirements for growth as the X and V growth factors. In the past this has been the custom but the work of Fildes (1921) has shown that the X factor is hæmin and more recently the Lwoffs (1937) have shown that the V factor originally described by Thjötta and Avery (1921) is cozymase.

PATHOGENICITY TO ANIMALS

Previous to 1931 *H. influenzæ* was regarded as being comparatively non-pathogenic to laboratory animals but in that year I showed (Rosher, 1931) that by incorporating a trace of Fildes' (1920) peptic digest containing the X and V growth factors in the inoculum, certain strains of the organism could be rendered highly pathogenic for mice by intraperitoneal inoculation giving rise to septicæmic death in sixteen to thirty-six hours. The following experiments have some bearing on the matter:

INOCULATION EXPERIMENTS

EXPERIMENT 1.—*Showing the Effect of Fildes' Solution on the Pathogenicity of Living Influenza Bacilli.*

A dose of 2,000 million organisms which had been washed three times in saline to remove any exotoxic substances was injected into the peritoneal cavity of ten mice. They all survived the injection.

Another batch of ten mice was injected with a similar dose of influenza bacilli but 0·05 ml. of Fildes' solution was added to each dose. They were all dead in thirty-six hours.

The most likely explanation of this result seemed to be the presence of the X and V growth factors in the digest. These factors are not normally present in the peritoneal cavity of a mouse and therefore growth does not take place, but when they are supplied with the inoculum the organisms can reproduce and give rise to a fatal septicæmia.

To gain further evidence as to the validity of this assumption it was decided to see how small a dose of living bacilli could be rendered pathogenic with the digest and a pathogenic strain was titrated down in a series of mice. The result of this was to show that the approximate lethal dose is somewhere in the region of 1,000 million to 2,000 million bacilli and when the dosage gets down to 500 million the reaction does not take place. This result led me to reconsider whether the stimulation by the digest was due to growth-promoting properties or to some other factor, for the comparatively large dose of 500 million bacilli should become lethal when facilities for reproduction are provided. I then tried to find out if the digest could enhance the virulence of dead influenza bacilli.

EXPERIMENT 2.—*Showing the Effect of Fildes' Solution on the Toxicity of Dead Influenza Bacilli.*

A dose of 10,000 million organisms killed by heating for half-hour at 60° C. and twice washed in saline was used. Ten mice were injected without Fildes' solution and all survived, whereas another ten mice were injected with the same dose plus 0·05 ml. of the solution and all died within two or three days. Skin tests on rabbits were then tried and the above results were confirmed.

EXPERIMENT 3.—*Showing the Effect of Injecting Influenza Bacilli with and without Fildes' Solution Intradermally into Rabbits.*

The results in Table II show that the difference in reaction between living and dead bacilli is negligible. Furthermore when a large dose of 1,600 million organisms is injected the stimulating effect of the digest is not seen as the organisms alone in that quantity produce a marked reaction. However with smaller doses such as 200 million, 100 million and 50 million the stimulation becomes apparent.

About 40 Pfeiffer or respiratory strains have been examined by this method, and I am impressed by its reliability, for, with only one exception, they gave typical colonies (fig. 4 *a*, *b*, *c*, *d*). At the commencement I did not examine them all to maturity but those I have since done have given very reliable results.

I have also examined a similar number of Pittman strains chiefly type B and they have invariably given satisfactory and characteristic results (fig. 4 *e*, *f*, *g*, *h*). I am now using Atkin's method for the study of other organisms and I hope to make a communication about this later.

It has previously been the custom to describe colonial characteristics on the appearance of overcrowded and of ill-nourished colonies after a brief residence of forty hours or so in the incubator long before they have reached maturity.

The morphology of a colony developing under optimal conditions is due to a blend of processes which are characteristic of the organism in any metabolic or antigenic state it may be in. This is not the case when colonies are growing under overcrowded conditions. In these circumstances the characteristic processes cannot function and impress distinct features on the colony. Thus crowded colonies cannot indicate properly the differences in characters—whatever they may be—of a Pfeiffer or a Pittman strain of *H. influenzæ*.

Pittman rough strains are now being tested in this manner for purposes of comparison with Pfeiffer respiratory strains as it has been suggested that they are identical; but as far as I have gone it looks as if they will have quite different appearances.

Several strains of *H. influenzæ suis* from the National Type Culture Collection have been tested in this manner and give colonies almost identical with the Pittman strains. I thereupon tested them with Pittman sera and found that they come down readily with Pittman B serum and Edith Straker kindly confirmed this result for me. The strains were sent from America and it is possible they have been wrongly labelled, if not it will be a matter of great interest if Shope's bacillus is a Pittman B strain. However, Shope is sending me some strains he can vouch for and I hope the matter will be cleared up shortly.

BIOCHEMICAL REACTIONS

Most observers have found that the fermentation of carbohydrates is not a very satisfactory method for differentiating the various members of this group and I have therefore never been tempted to try this method.

Nevertheless, I have used the test for indole production as a routine measure and on the whole I find it fairly consistent and reliable. Pittman, 1931, stated that types A and B were indole-positive both smooth and rough strains but Mulder, 1939, quotes her as saying that some strains of the B type are indole-negative. I have tested the strains in the National Type Culture Collection and find that types A, B, C, and F are indole formers but D and E are indole-negative.

I have also tested about 50 Pfeiffer strains isolated from pneumonic conditions and find them almost invariably indole-positive. I have also recently been trying the bile solubility test: Pittman 1931 stated that all of her strains both rough and smooth are bile-soluble. I get the same results with the National Type Culture Collection Pittman strains.

However, I have tested six recently isolated Pfeiffer or respiratory strains and they are not bile-soluble so this is evidence against Pfeiffer strains being rough variants of Pittman strains, which has been suggested.

inducting swine influenza, should not have borne a similar relationship to each other in their preceding host''. He continues:

''Certainly of all the horde of bacteria occurring in pandemic influenza it would be most peculiar to have a non-essential one chosen to accompany the virus in transferring to a new host.'' He sums up as follows: ''For these reasons I believe the infectious unit in pandemic influenza is composed of a specific complex of virus plus Pfeiffer's bacillus.''

This seems to be common sense and a matter of fundamental importance to be settled one way or another. If the disease is due to a *complex* a question to be decided is whether the bacillus is in the respiratory passages beforehand, and the soil therefore ripe for invasion by the virus, or are both virus and bacillus introduced together? If the former is the case then we should get some information of this by a study of the carrier rate of influenza bacilli before and during epidemics.

I can here offer a little suggestive evidence in favour of this hypothesis from the work I did from 1929 to 1938 (Rosher and Cole, 1939). When endeavouring to plot the incidence of influenza bacilli in the trachea of post-mortem subjects not suffering from respiratory disease, *I found a distinct seasonal trend in the carrier rate of this organism.* In the first quarter of the year, when influenza is usually prevalent, the carrier rate is highest whereas in the third quarter, when influenza is rare, it is lowest.

Straker (1939) who was working on the carrier rate in the nose and nasopharynx during a similar period found a seasonal trend to occur in the nasal cavities but to a less extent than in the trachea. The carrier rate in the nasopharynx was maintained at a steady level of about 60% to 65% irrespective of seasonal influences.

TABLE III.—PERCENTAGE INCIDENCE OF *H. influenzæ* IN CASES SHOWING NO EVIDENCE OF RESPIRATORY DISEASE

Quarter	Nasopharynx	Trachea	Nose
1st	66·9	39	9·8
2nd	64·7	23	8·0
3rd	60·5	19	3·8
4th	61·3	24	4·3

The reason for this seasonal extension into the nose and trachea remains to be determined but it undoubtedly happens at the time of year when influenza is likely to occur, whether in epidemic form or not.

At the moment I think we should concentrate on Shope's bacillus as being the most likely partner in the complex and try to determine if any specific differences can be found between this and the other indole-negative strains of influenza bacilli.

The study of giant colonies may give some help in the matter and an attempt to detect serological differences might be further explored. If these are successful then it would be well worth while to determine more accurately the carrier rate of these indole-negative strains in the nasopharynx, nose and trachea in epidemic and non-epidemic times.

During the period when the tracheal carrier investigation was being carried out there were seven years when I paid particular attention to the indole reaction and I have records of the carriers of indole-positive and negative influenza bacilli during that period.

I was trying to find out if there was any difference in the incidence of indole-positive and negative strains in epidemic compared to non-epidemic times. During this period, there were three years, 1931, 1933 and 1937, which might be regarded as epidemic years from the recorded deaths from influenza, but the other four years were normal. In the first quarter of the epidemic years there was a distinct increase in the carrier rate of indole-negative strains whereas the carrier rate of indole-positive strains remained fairly stationary.

TABLE II.—SHOWING AN EXPERIMENT TITRATING DOWN THE DOSAGE OF LIVING AND DEAD INFLUENZA BACILLI WITH AND WITHOUT FILDES' SOLUTION

Dose (millions/ml.)	Living – Fildes'	Living + Fildes' (0·02 ml.)	Dead – Fildes'	Dead + Fildes' (0·02 ml.)
1,600	++++	++++	++++	++++
200	+	++	±	++
100	+	++	0	++
50	0	++	0	++
20	0	0	0	0

Intradermal injection of 0·2 ml. (bulk) to a rabbit. The reactions were observed for four days and marked accordingly.

EXPERIMENT 4.—*To Try to Determine Which of the Individual Components of the Digest is Responsible for the Stimulative Effect.*

For this purpose the V factor was obtained from yeast extract, hæmin was used for the X factor and as Fildes' solution contains some pepsin, this was also tried.

The quantities used roughly correspond to the amount normally present in Fildes' solution and I am indebted to Jocelyn Patterson for carrying out their estimation.

A dose of 4,000 million dead bacilli was injected intraperitoneally into mice and as a result of this experiment there is a suggestion that: (1) Fildes' solution gives the best stimulation. (2) The X and V factors combined give nearly as much. (3) The X and V factors alone give slight stimulation. (4) Pepsin gives none at all.

The mode of action of Fildes' solution is therefore difficult to explain. The possibility of it being an additive toxic effect is not likely as 100 times the amount of the solution used for the tests can be injected into the peritoneal cavity of mice without harmful effects. The small amount of Fildes' solution used for skin tests gives rise to no reaction when injected by itself.

Alteration of permeability such as occurs with testicular extract was considered and experiments were carried out to test this possibility but the results were negative.

The enhancement of virulence also occurs when living or dead staphylococci are injected intradermally into rabbits and therefore it is not a specific reaction and the mode of action is obscure. *Nevertheless it is a useful method for comparing the pathogenicity of various strains of these and possibly other organisms.*

In 1937 L. D. Fothergill, T. H. Dingle and C. A. Chandler found that virulence of influenza bacilli for mice could be enhanced by suspending the organism in mucin.

Increase in mucin virulence of a strain of *H. influenzæ* by repeated passage through mice was shown and it was put forward as a useful method for passive immunization studies.

Here again, as far as I am aware, the mechanism is obscure.

PATHOGENICITY IN THE HUMAN SUBJECT IN RELATION TO EPIDEMIC INFLUENZA

When dealing with pathogenicity in the human subject the problem of major importance to be dealt with is whether organisms of this group play any part in bringing about epidemics and pandemics of influenza. Prior to the discovery of the virus by Smith, Andrewes and Laidlaw (1933) it was generally agreed that influenza bacilli often, but not invariably, play a part in the disease. The subject is dealt with in Kristensen's (1922) valuable monograph. Since then the extensive literature has been carefully reviewed by Topley and Wilson (1945) and allusion is made to the curious absence of these bacilli in certain epidemics particularly in the summer of 1918 which raised doubts as to their being the primary cause. However, I see no reason why all epidemics of so-called "influenza" should have an identical ætiology, and I doubt if our knowledge of viruses is sufficient to warrant this assumption at present. Furthermore it must be remembered that in 1918 the culture medium in use was distinctly poor for the isolation of these fastidious organisms.

Shope (1944) has expressed the opinion that the pandemic virus has a specific avidity for the Pfeiffer bacillus and with it constitutes the infectious unit. He states "if as seems likely the pandemic virus transferred from man to swine in 1918 and if as also seems likely the Pfeiffer bacillus transferred with it, it would be rather illogical to suppose that two agents bearing such an intimate relationship to each other in

I should therefore recommend the following measures to be adopted during an epidemic: Nasopharyngeal swabs should be taken and specimens of sputum and blood sent for examination. Inoculations should be made on plates of rabbit's blood agar and Fildes' medium.

Giant colonies should be studied and the indole reaction and other tests applied for accurate investigation of the strains. The patient's serum should be tested for antibodies against various strains of influenza bacilli including *H. influenzæ suis.* In addition, the carrier rate of the various organisms of this group in the nose, throat and trachea should be determined before and during epidemics, paying particular attention to indole-negative strains and, furthermore, any unusual frequency during epidemic times of other pathogens should be noted, as it is within the bounds of possibility that the virus might link up with other organisms on some occasions.

The recent work of Dubos *et al.*, 1947, has shown that the course of pulmonary tuberculosis in the mouse appears to be accelerated as a result of concurrent infection of the lung with influenza A virus and the effect is obtained with virus inocula sufficiently small to induce little or no definite viral pneumonia. There may be further examples of this dual action to be discovered. At any rate the work of Orticoni and Barbié on guinea-pigs should be repeated.

If the methods of investigation I have suggested were to be carried out I think in the course of a few years the problem of dual ætiology might be solved.

Apart from academic interest it is a matter of great importance as regards prophylaxis, and possibly treatment. Already prophylactic vaccines of virus are on trial and if the disease is due to a partnership the question arises as to whether the bacillus should be included.

Shope finds that *H. influenzæ suis* vaccines alone give a certain amount of protection against swine influenza but the protection afforded by the virus vaccine alone is so good that he does not consider it worth incorporating a bacillary antigen as well.

However; it is not certain that the same would hold good in man. As regards treatment. the question of an antiserum would arise for already evidence is accumulating (Zinnemann, 1946) as to the value of antiserum in conjunction with antibiotics in meningitis due to Pittman B strains, so if this organism or another influenza bacillus was to be incriminated an antiserum might have some value in combating severe infections of respiratory influenza in times of epidemic.

Dr. H. C. Engbaek of the State Serum Institute in Copenhagen told me recently that he cured 17 out of 19 cases of influenzal meningitis by this method, which is most encouraging.

This brings me to the end of my remarks on the influenza group. At the moment it is a subject which, perhaps, is a little in the background as we have been spared another pandemic such as occurred in 1919 and proved to be more deadly than war. However, nobody can prophesy when a pandemic will occur again and we must be prepared for such an eventuality.

I hope these suggestions may be of some use in the future when dealing with epidemic influenza.

SUMMARY

(1) Some evidence is brought forward to show that the pleomorphism of *H. influenzæ* occurs when the organism is growing under suboptimal conditions. It is suggested that this may be due to an insufficient supply of the V factor.

(2) The bizarre forms also occur when penicillin comes into contact with the organism and therefore if the above suggestion is correct penicillin may have an antagonistic action on the V factor.

It will be noticed in Table IV that in the epidemic years the carrier rate of indole-positive strains was 18% compared to 22% in the non-epidemic years whereas the carrier rate of indole-negative strains was 26% as against 13%, representing +13% ±4·0 in favour of the epidemic years and *it must be remembered once again that Shope's bacillus is indole-negative.*

TABLE IV.—INCIDENCE OF INDOLE + AND − STRAINS OF *H. influenzæ* IN THE TRACHEA IN CASES SHOWING NO EVIDENCE OF RESPIRATORY DISEASE DURING THE FIRST QUARTER OF THREE EPIDEMIC AND FOUR NON-EPIDEMIC YEARS

	Epidemic years	Non-epidemic years	Diff. and S.E.
Indole + ..	18% (34/189)	22% (43/196)	−4±4·1
Indole − ..	26% (50/189)	13% (25/196)	+13±4·0

Let us assume that these indole-negative strains correspond to Shope's bacillus, then in the epidemic years there was an average of 26% of people not suffering from respiratory disease but carrying this organism in the trachea and therefore suitable subjects and soil for the reception of the virus, for, as Shope says, "the virus has specific avidity for the influenza bacillus and with it constitutes the infectious unit".

It must be remembered that these figures only represent the people who are carrying the indole-negative strains in the trachea and their frequency might be greater if these strains were looked for in the upper respiratory passages.

In my experience the Pfeiffer or so-called respiratory strains are usually indole-positive and from the figures I have shown their carrier rate does not alter appreciably in the epidemic years, whereas carriers of indole-negative strains certainly seem to increase.

It is a rather short run of years on which to base conclusions, but the result is sufficiently suggestive to warrant further investigation on these lines, the frequency of other pathogens in epidemic and non-epidemic times should also be plotted to act as a control.

As long ago as 1919 S. F. Dudley, in dealing with the subject of carriers, stated: "Perhaps this harmless organism (*B. influenzæ*) especially favours the spread of a filter passer which, though extremely virulent in its presence, cannot gain a footing in the human organism without the help of Pfeiffer's bacillus." He continues: "Since the above paragraph was first written A. Orticoni and Barbié have reported that *B. influenzæ* and filtered sputum from an influenza case are harmless to guinea-pigs separately, but together are extremely pathogenic." He concluded as follows: "Should this observation be confirmed it would go a long way towards proving the double ætiology of influenza as due to a filter passer plus Pfeiffer's bacillus."

This observation was made in 1919 and I wonder if the experiment has ever been repeated, if not, in my opinion, it is high time that it was.

W. J. Wilson *et al.* in 1924 reported the presence of agglutinins for the influenza bacillus in almost 100% of cases during the acute pyrexial period in the outbreaks of influenza in Ulster in 1922 and 1924.

Sometimes they were found as early as the first day of disease and in convalescence as a rule they rapidly disappeared. In a large number of control sera the vast majority gave negative results. In 1946 C. H. Andrewes kindly sent me a few sera to test from patients suffering from influenza and the results were of sufficient interest to warrant further investigation.

Transmeatal Attico-Antrotomy in Chronic Tympanomastoid Suppuration

By A. Tumarkin, F.R.C.S.Ed.

Introduction.—Ten years ago I became convinced that radical mastoidectomy could not give me the results I wanted. Seeing a reference to the work of Thies on the transmeatal route (Thies, 1912; Trampnau, 1935–36) I decided to investigate its possibilities. This paper gives an account of the technique I finally evolved and of the results.

Technique.—The operation is performed under general anæsthesia and the site of the incision is infiltrated with weak adrenaline solution. The incision starts at Shrapnell's membrane and ascends the outer attic wall to the roof of the external auditory canal (fig. 1). It then traverses the roof in the mid-line. At the junction of the osseous and cartilaginous canals it turns downwards and outwards. This marks out an elliptical flap which is easily elevated. The incision is made with a fine knife via a slotted aural speculum and it is easy, using one edge of the slot, to catch the flap and roll it into the floor of the meatus. A little hæmorrhage occurs and is easily controlled by pressure of the speculum. When it is mopped or sucked away, the whole bone of the outer attic wall and post-superior wall is clearly seen. This approach sacrifices no skin and is confined strictly to the osseous canal.

The bone removal should always commence at the tympanic ring. Fine labyrinth gouges 2 to 3 mm. in width are used to excise semilunes of bone as in fig. 2. This is the "mauvais pas" of the operation because the facial nerve is in the direct line of the gouge. It is, however, a good sixth of an inch away and, with reasonable care, it need never be damaged. The bone at the tympanic annulus is very thin and can be cut away with the gentlest of hammer blows. The aditus and the short process of the incus, the facial nerve, and the stapes come into view almost at once, giving perfect orientation. The cavity is extended by progressively flaking semilunes of bone from the cut margin. It is tempting—especially in deep narrow ears—to try and enter the antrum at a more superficial point T (fig. 2), but that is a very grave mistake for the following reasons: First, it is much more difficult to cut a hole than to flake off an edge of bone, and the operator is easily disorientated (incidentally, the dental drill has no place in this operation). Also, if the antrum is successfully entered at T there still remains the "bridge" between it and the annulus which has ultimately to be removed under the added disadvantage that it tends to be obscured by blood seeping down from the cut bone above it. By the flaking method the surgeon always has a clear view of the dry edge of bone which he has to remove.

It is useless to attempt this operation with punches. A punch delicate enough to permit of use under direct vision could not bite the bone away. A more powerful punch completely blocks the view and, being used blind, is dangerous; dislocation of the incus is almost certain to occur. The same objections apply to attempts to "protect" the facial nerve by passing a Stacke director into the aditus. This obscures the field, dislocates the incus and may indeed bruise the nerve. The only satisfactory method is to use sharp gouges as described above.

(3) Attention is drawn to the value of the giant colony method for differentiating organisms which are closely allied.

(4) The importance of the indole reaction and bile solubility test is emphasized for differentiating these organisms.

(5) A method is put forward for the study of the pathogenicity and toxicity of various strains of influenza bacilli for laboratory animals.

(6) Some literature is reviewed on the ætiology of epidemic influenza in relation to it possibly being due to a complex of virus plus influenza bacillus.

(7) Some experimental evidence is produced in favour of this theory.

(8) Some suggestions are made for investigations to be carried out before and during epidemics, the result of which might decide the question of dual ætiology.

In conclusion I wish to thank those who have helped me with this work, namely Sir Paul Fildes, O.B.E., F.R.S., and Professor G. S. Wilson, K.H.P., for criticisms, Professor A. Bradford-Hill for help with the statistics, Professor H. S. Barnard and Dr. A. B. Bratton and others for tracheal swabs. Mr. W. E. Crawley, Mr. W. F. Cole and Miss V. A. L. Brews for technical assistance, Mr. J. E. Andrews for the photographs and finally Miss S. Goldstein for clerical assistance.

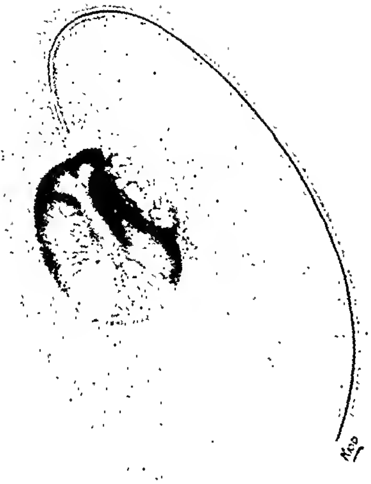

FIG. 1.—Transmeatal attico-antrotomy. The incision. Note the granulations on the post-superior quadrant of the tympanic ring. The tympanic membrane in that region has collapsed on to the inner tympanic wall.

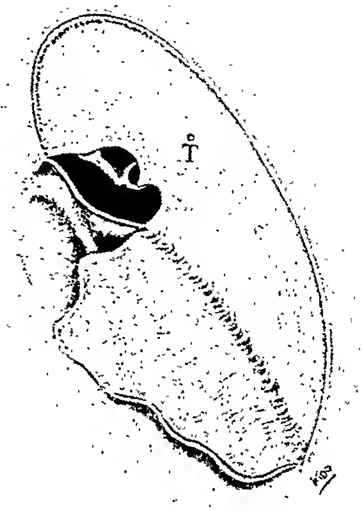

FIG. 2.—Transmeatal attico-antrotomy. The "mauvais pas". The flap has been elevated and is now thrust into the floor of the external auditory canal. The first two semilunes of bone have been chipped away, carrying the granulations with them. The long process of the incus comes into view and the crura of the stapes. The antrum could be reached by plunging a dental drill through the post-superior meatal wall at T. This is not recommended (*see* text).

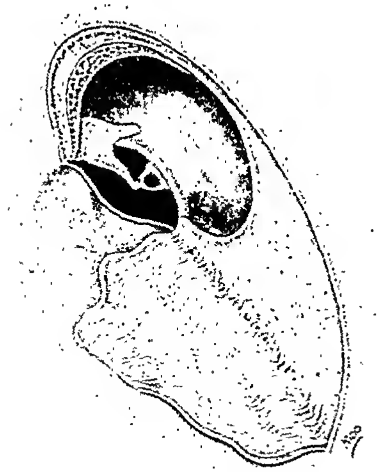

FIG. 3.—Transmeatal attico-antrotomy. The bone excision completed. Showing incus, semicircular canal, facial nerve and stapes. This shows a comparatively limited excision of bone. The exposure can easily be extended forwards, upwards or backwards. The strip of bone overlying the head of the malleus would normally be removed so as to gain access to Prussak's pouch.

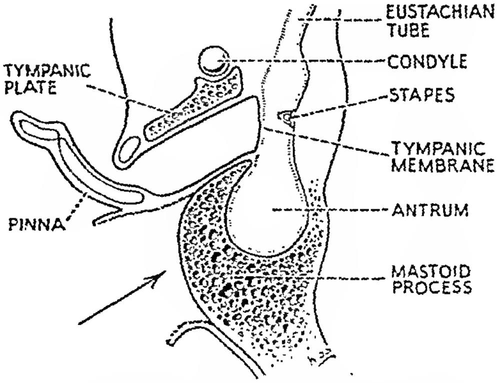

FIG. 4.—Classical radical mastoidectomy. Showing post-auricular incision and radical excision of mastoid process (shown by shaded area).

It might appear at first sight that three hands are needed: one to hold the retractor, one to hold the gouge and a third to hold the hammer. That apparently has been the practice on the Continent. Thies entrusted the hammer to his assistant—a laborious and precarious technique. Heermann constructed special self-retaining retractors so that he could do the hammering himself. The most valuable retractor is a slotted speculum. A set should be available rising in half millimetres from 4 to 8 mm. The largest possible speculum should be used so that the pressure is maintained on the cut flaps, thus ensuring hæmostasis.

The extent of the operation is determined by the findings. If necessary, the whole mastoid process can be explored by excising the intervening bone. The anterior pouch of the attic should be left till the last, when the surgeon is well orientated and has adequate space to manœuvre. The bone in that region is commonly rather thick but is readily removed by the same technique of progressively flaking off the cut margin. Thus the incudo-malleolar articulation is exposed and the decision finally made as to the fate of the incus (fig. 3). The ossicle is often submerged in granulations, but providing the incudo-stapedial articulation is intact it is justifiable to retain it. These cases commonly recover with excellent hearing. Even if suppuration persists, it is easy at a subsequent operation to pick out the diseased ossicle. The fate of the malleus depends on the incus. There is nothing to be gained functionally by leaving the malleus by itself, but the attached drum helps to protect the inner wall of the tympanum. Even so it is advisable to amputate the head of the malleus which is prone to necrosis.

The operation cavity is carefully irrigated and examined for loose spicules of bone and granulation tissue. Then the skin flap is rolled into place. It laps over the facial ridge and covers the raw edges right up to the semicircular canal. This is a most important feature of the operation (fig. 6). The functional results of mastoid surgery are greatly influenced by the rapidity with which epithelialization and healing of the aditus occur. In radical mastoidectomy, the surgeon is careful to sling the flap with sutures externally, but pays little attention to the state of affairs deep in. Consequently the aditus and facial ridge are only too often permanently covered with granulations. In attico-antrotomy the flap is gently smeared into position and then Zelex penicillin is squirted in (*see* page 771). No sutures or ligatures of any kind are necessary.

The first dressing is done about a week later and consists merely of syringing the Zelex out. The whole after-treatment is painless, a most important feature, especially when dealing with children. Nothing more than the simplest of aural toilets is necessary. In some cases the ear is dry within three weeks. Frequently, however, small granulations form in the roof at the site of the original incision. If neglected, these grow downwards and obstruct the atticostomy. They do not adhere to the facial ridge because the latter is protected by the skin flap. The granulations should be gently snared off under cocaine anæsthesia, after which the cavity usually heals rapidly. In general, one may confidently expect a healed cavity within four to six weeks. In those cases which prove resistant the trouble is usually in the tympanum and not in the mastoid cavity.

Rationale.—This underlines the rationale of atticotomy. In chronic otorrhœa the disease is in the middle ear, attic and aditus.The stress which has been laid on the idea of disease ramifying throughout the mastoid process has distorted the picture. Despite the exhortations of many authorities it is common practice to exenterate the mastoid process in search of outlying disease. Lempert (1938*a*), for instance, specifically states that a radical mastoidectomy should start with a complete exenteration of the process exactly as in a cortical mastoidectomy. We must condemn this attitude. From the practical point of view, it is shown to be unjustifiable by the fact that the limited excision of attico-antrotomy will produce better results by far. As to the theoretical point of view, let us remember that in the great majority of these cases there are no outlying cells—diseased or otherwise. The process is

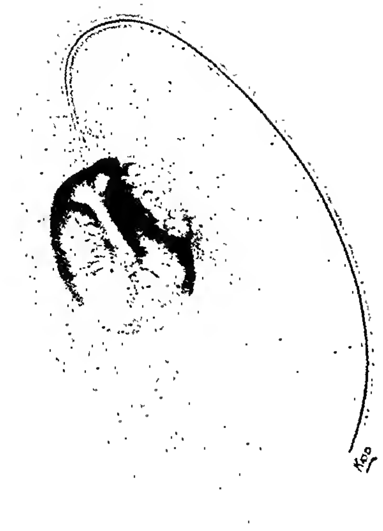

FIG. 1.—Transmeatal attico-antrotomy. The incision. Note the granulations on the post-superior quadrant of the tympanic ring. The tympanic membrane in that region has collapsed on to the inner tympanic wall.

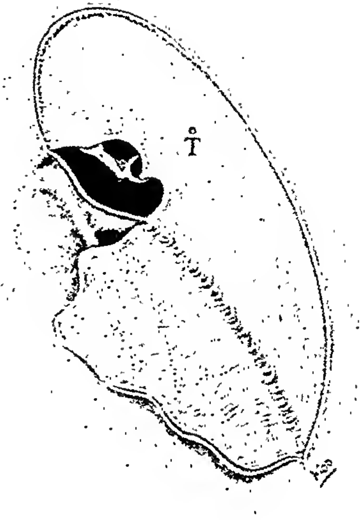

FIG. 2.—Transmeatal attico-antrotomy. The "mauvais pas". The flap has been elevated and is now thrust into the floor of the external auditory canal. The first two semilunes of bone have been chipped away, carrying the granulations with them. The long process of the incus comes into view and the crura of the stapes. The antrum could be reached by plunging a dental drill through the post-superior meatal wall at T. This is not recommended (*see* text).

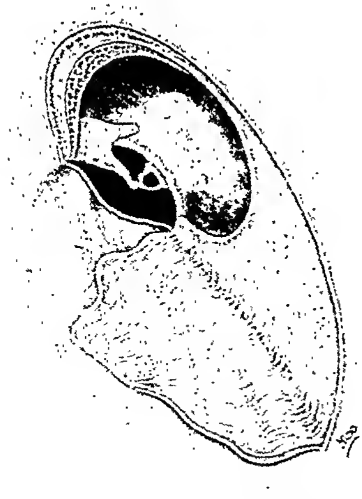

FIG. 3.—Transmeatal attico-antrotomy. The bone excision completed. Showing incus, semicircular canal, facial nerve and stapes. This shows a comparatively limited excision of bone. The exposure can easily be extended forwards, upwards or backwards. The strip of bone overlying the head of the malleus would normally be removed so as to gain access to Prussak's pouch.

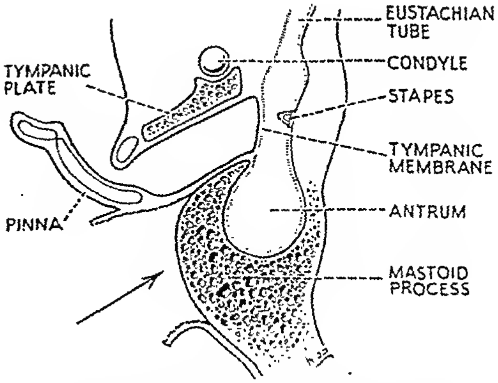

FIG. 4.—Classical radical mastoidectomy. Showing post-auricular incision and radical excision of mastoid process (shown by shaded area).

hypoplastic and is of the ivory or diploetic type. Again chronic middle-ear suppuration is a very benign condition. In 60% to 80% of cases it yields to simple hygiene of the outer ear. We deduce that in those cases there can be little or no involvement of bone, and that the disease must be confined to the accessible soft tissue adjacent to the tympanic ring. In the remaining intractable cases, why must we fly to the opposite extreme of very radical surgery? Surely there must be intermediate stages between the benign condition which we cure by simple hygiene and this desperate condition which demands complete mastoidectomy. Those intermediate stages will consist of a little caries of the tympanic ring—or of the ossicles and perhaps some accumulation of granulation and debris in the aditus or antrum. It follows that the operation of choice will *commence* at the tympanic ring and not *finish* there. In this way the main focus of the disease is immediately exposed and the surgeon can be guided by his findings. If the appearance suggests more extensive disease there is no difficulty whatsoever in following it up.

It seems to me that the heroic quality of the classical transmastoid approach (fig. 4) has crept in because of our obsession with the intracranial complications. These loom too largely in our minds and in our textbooks. Whatever may have been the case in the past, to-day they are interesting rarities. I will concede readily that where such complications are suspected, the widest possible exposure is necessary and can only be provided by extensive circum-aural incisions. But these cases are rare, and they will become even rarer if we begin to pay attention to the functional significance of chronic otorrhœa. I am the last person to advocate indiscriminate surgery. Nevertheless I submit that any suppurating ear which has resisted conservative treatment should be explored by the transmeatal route without delay. In that way we could abolish the group of intracranial complications which is caused by neglected chronic suppuration. More than that, we could give our patients some prospect of retaining, if not improving, their hearing. Is it an exaggeration to say that we are reluctant to do a radical mastoidectomy if hearing is good. We fear to make it worse. We prefer our patient to be deaf so that we can operate with impunity. Even if otorrhœa persists after the operation and deafness is as bad, or worse, we can claim to have saved him from the dreaded intracranial infections. The following extract expounds that viewpoint:—

> *Objects sought in operation.*—There are two principal reasons why the radical mastoid operation should be done: First, for the relief of an annoying and at times offensive otorrhœa; and second, the prevention of intracranial complications, which are always serious. This does not mean that the radical operation should be resorted to in all cases of chronic suppurative otitis media which do not wholly recover under conservative methods of treatment. Every case of chronic otorrhœa does not present the same degree of potentially serious complications and each must be dealt with on its own merits. When the suppuration continues as the result of carious erosion or a necrotic process, intracranial complications are threatened, but on the other hand, if the disease is confined to the mucosal lining of the tympanum, it is quite unlikely that intracranial complications will arise, thus contra-indicating a radical operation.—JACKSON, C., and COATES, G. M., 1929, The Nose, Throat and Ear and Their Diseases, pp. 537-8, London.

The writer of that article is led to the conclusion that mere persistence of discharge is not necessarily an indication for operation. That is an attitude which I most strongly oppose. Persistent otorrhœa *is* an indication for exploration of the attic and antrum. I will except the occasional cases of eustachian infection which resist treatment. They are rarities. Most eustachian infections are readily controlled by hygiene—ionization and attention to the nasopharynx. The vast majority of intractable cases have a post-superior or a Shrapnell perforation. In them pus is seeping over the floor of the aditus, filling Prussak's pouches and eroding the incus. If we think of such cases from a point of view of function, we shall regard them with the same urgency as the oculist regards chronic glaucoma.

Our aim must be to save the incus. It is generally held that the functional results of radical mastoidectomy are not improved by preservation of the incus, and that otorrhœa may persist if a diseased ossicle is retained. Those are the penalties we pay for the delayed operations. The position is quite different in atticotomy. I now have a number of patients on whom I have been able to preserve a functioning incus and in every case the hearing is excellent. This is particularly important in the children of the poorer classes, amongst whom bilateral middle-ear suppuration is so common.

How are we supposed to treat these cases? MacCuen Smith advises as follows:

> "It not infrequently happens that young children suffer from a bilateral chronic otorrhœa which resists persistently all non-operative measures for relief. It has been my custom with these children to perform first a simple mastoid operation on the ear in which the hearing is more impaired, on the theory that the principal pathology is located in the mastoid antrum and this procedure corrects the otorrhœa in a fair number of instances. If the disease is not eradicated by this means, then a modified radical mastoid operation, which completely exposes the antrum, should be tried. This failing, we should seriously consider the advisability of performing the radical mastoid operation, selecting the worse ear first and noting the effect on the hearing, and should still further postpone additional operative measures if audition has been seriously impaired unless further complications threaten."—S. MacCuen Smith: Jackson and Coates, The Nose, Throat and Ear and their Diseases, p. 542.

It is not difficult to detect an undertone of defeat in these recommendations, and the reasons are not far to seek. If the primary disease is in the aditus and attic, then exenteration of the mastoid process can do no good at all. This fallacious idea underlies Heath's operation and also Bárány's operation of mastoidectomy without a meatal plastic. Both these procedures are uniformly disappointing.

During the past year, I have operated on thirty-five school children. In no case was there the slightest complication. Nearly all of them left the hospital within a week and in most cases the ear was dry within a month to six weeks. Unfortunately these children are still not discovered soon enough—or the operation is postponed too long in the hope that conservative treatment may ultimately succeed. There is no real difficulty in recognizing the ear which is not doing well. It continues to seep a little foul pus—or it heals and then breaks down again. These cases should always be explored promptly.

Criticisms.—In the past this operation has been subjected to fierce criticisms. We may list them as follows: (1) Performed in the dark in a pool of blood. (2) Insufficient room for manipulation. (3) Danger to vital structures—stapes; facial nerve; dura and lateral sinus. (4) Cannot with certainty reach limits of disease.

(1) The operation is performed in the brilliant light of a bull's eye reflected by a head mirror down a large aural speculum. Hæmorrhage is reduced to a minimum—first because the incision is a minute one and secondly because the soft tissues are firmly compressed by the aural speculum. Thus, no blood seeps from above down to obscure the point of attack. A little blood may well up from the depths but is easily absorbed by a pledget of wool. By flaking the bone from below upwards (i.e. from within outwards) one keeps the point of attack well in sight all the time. It is always above the tide mark of the blood. It is of course necessary periodically to irrigate and suck out blood and pus so as to clarify the situation but I have never had to cut short any operation because the field was obscured with blood.

(2) It is true that the approach is constricted. The skin flap is perhaps half as big as a postage stamp and instruments have to be correspondingly delicate. The operation is admittedly difficult and demands meticulous care and precision.

(3) The danger to vital structures looms too largely in the imagination of the theoretical critic. Thies, Jnr., declares that his father operated on 1,500 cases without a death and with very few major complications. I have myself performed over 300 attico-antrotomies without a single death. In 3 cases I have caused a transient facial palsy (i.e. subsiding within two weeks); in one case a labyrinthitis supervened which was cured by penicillin. I have never injured the lateral sinus and although I have frequently exposed the dura of the middle fossa, I have never torn it or set up any intracranial complications.

(4) This criticism loses its force when we recall the pathological conceptions on which the operation is founded. In these cases we are dealing with localized disease

hypoplastic and is of the ivory or diploetic type. Again chronic middle-ear suppuration is a very benign condition. In 60% to 80% of cases it yields to simple hygiene of the outer ear. We deduce that in those cases there can be little or no involvement of bone, and that the disease must be confined to the accessible soft tissue adjacent to the tympanic ring. In the remaining intractable cases, why must we fly to the opposite extreme of very radical surgery? Surely there must be intermediate stages between the benign condition which we cure by simple hygiene and this desperate condition which demands complete mastoidectomy. Those intermediate stages will consist of a little caries of the tympanic ring—or of the ossicles and perhaps some accumulation of granulation and debris in the aditus or antrum. It follows that the operation of choice will *commence* at the tympanic ring and not *finish* there. In this way the main focus of the disease is immediately exposed and the surgeon can be guided by his findings. If the appearance suggests more extensive disease there is no difficulty whatsoever in following it up.

It seems to me that the heroic quality of the classical transmastoid approach (fig. 4) has crept in because of our obsession with the intracranial complications. These loom too largely in our minds and in our textbooks. Whatever may have been the case in the past, to-day they are interesting rarities. I will concede readily that where such complications are suspected, the widest possible exposure is necessary and can only be provided by extensive circum-aural incisions. But these cases are rare, and they will become even rarer if we begin to pay attention to the functional significance of chronic otorrhœa. I am the last person to advocate indiscriminate surgery. Nevertheless I submit that any suppurating ear which has resisted conservative treatment should be explored by the transmeatal route without delay. In that way we could abolish the group of intracranial complications which is caused by neglected chronic suppuration. More than that, we could give our patients some prospect of retaining, if not improving, their hearing. Is it an exaggeration to say that we are reluctant to do a radical mastoidectomy if hearing is good. We fear to make it worse. We prefer our patient to be deaf so that we can operate with impunity. Even if otorrhœa persists after the operation and deafness is as bad, or worse, we can claim to have saved him from the dreaded intracranial infections. The following extract expounds that viewpoint:—

> *Objects sought in operation.*—There are two principal reasons why the radical mastoid operation should be done: First, for the relief of an annoying and at times offensive otorrhœa; and second, the prevention of intracranial complications, which are always serious. This does not mean that the radical operation should be resorted to in all cases of chronic suppurative otitis media which do not wholly recover under conservative methods of treatment. Every case of chronic otorrhœa does not present the same degree of potentially serious complications and each must be dealt with on its own merits. When the suppuration continues as the result of carious erosion or a necrotic process, intracranial complications are threatened, but on the other hand, if the disease is confined to the mucosal lining of the tympanum, it is quite unlikely that intracranial complications will arise, thus contra-indicating a radical operation.—JACKSON, C., and COATES, G. M., 1929, The Nose, Throat and Ear and Their Diseases, pp. 537-8, London.

The writer of that article is led to the conclusion that mere persistence of discharge is not necessarily an indication for operation. That is an attitude which I most strongly oppose. Persistent otorrhœa *is* an indication for exploration of the attic and antrum. I will except the occasional cases of eustachian infection which resist treatment. They are rarities. Most eustachian infections are readily controlled by hygiene—ionization and attention to the nasopharynx. The vast majority of intractable cases have a post-superior or a Shrapnell perforation. In them pus is seeping over the floor of the aditus, filling Prussak's pouches and eroding the incus. If we think of such cases from a point of view of function, we shall regard them with the same urgency as the oculist regards chronic glaucoma.

Our aim must be to save the incus. It is generally held that the functional results of radical mastoidectomy are not improved by preservation of the incus, and that otorrhœa may persist if a diseased ossicle is retained. Those are the penalties we pay sloughing and post-aural fistulation, collapse of the pinna and so on. None of these complications ever occurs in atticotomy. Again the post-operative dressings and after-care of a mastoidectomy do still entail much pain and misery. After atticotomy there is practically no pain or discomfort. Healing is achieved much more rapidly and the discharge is never copious or offensive. The functional results of attico-antrotomy are in my opinion unquestionably superior to those of the radical operation. This I attribute to the following factors:

(1) Preservation, where possible, of the incus.

(2) Accurate positioning of skin flaps over the aditus floor. This prevents formation of granulations at that point and promotes rapid epithelialization of the cavity.

(3) Minimal excision of bone and minimal displacement of soft tissues. The radical operation leaves a comparatively large cavity which has to fill secondarily with granulations. These then contract down and are more or less covered with skin. It is agreed that one of the most important factors in preservation of function is the promotion of rapid healing. The atticotomy cavity has practically no raw area to heal, with the exception of the anterior edge of the incision to which I have already referred. Healing time is thus reduced to less than half of the time required by mastoidectomy with correspondingly good effect on hearing.

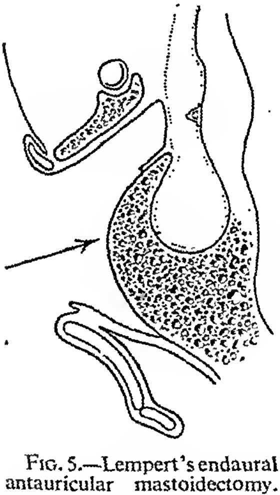

Fig. 5.—Lempert's endaural antauricular mastoidectomy. Showing endaural excision of skin, mobilization of concha and radical excision of bone as in fig. 4.

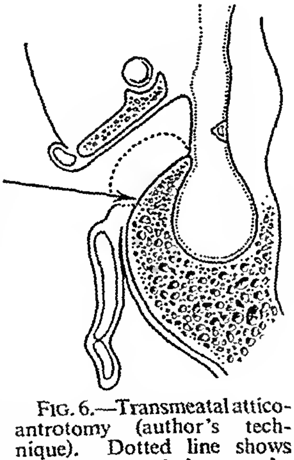

Fig. 6.—Transmeatal attico-antrotomy (author's technique). Dotted line shows skin flap turned downwards. Note limited excision of bone (shown by shaded area).

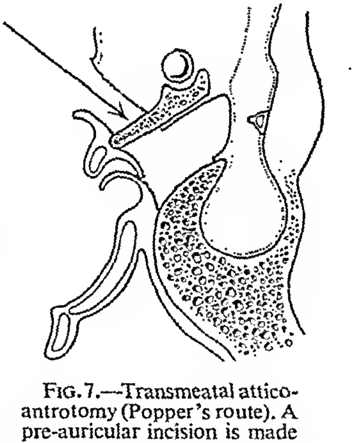

Fig. 7.—Transmeatal attico-antrotomy (Popper's route). A pre-auricular incision is made so as to expose the tympanic plate. This is excised and the external auditory canal is entered through its anterior wall. Bone excision as in fig. 6.

(4) In mastoidectomy the surgeon burrows from the surface downwards forming a conical cavity. The functioning tissues are reached towards the end of the operation, lying deep in the apex of the cone and liable to be obscured by blood seeping down from all sides. In the technique I have described the ossicles and aditus are exposed immediately and examined. The surgeon is always above the blood and cutting away from it rather than delving into it. He is thus able to preserve the functioning structures under direct vision all the time.

(5) The mastoidectomy cavity—even when apparently quite dry—can be a source of recurring trouble to the patient. Sometimes it is so widely open that draughts of cold air can set up caloric effects on the labyrinth. The wax-bearing area is displaced into the cavity and so waxy crusts are liable to accumulate. The lining membrane is of poor vitality and is readily ulcerated by this mass. By contrast the atticotomy flap does not encroach on the wax-bearing area, so that crusts do not accumulate. The

in attic and aditus. The antrum is usually involved in that its lining is unhealthy. Outlying cells are few and the whole tract recovers rapidly when it is adequately drained. It should not be thought that this limits attico-antrotomy to a small proportion of cases. Leaving out the rare cases in which intracranial complications are suspected the transmeatal route is applicable to at least 90% of all cases. The real refutation of these criticisms lies in the results. It is impossible to brush aside the statistics quoted by Thies, and an analysis of my own cases shows that the transmeatal operation can yield results which are in every way superior to the classical operation.

Advantages.—The intrinsic merits of the operation emerge when we compare it with alternative techniques. Although Shambaugh finds it identical with ossiculectomy the very names indicate the fundamental difference between ossiculectomy and atticotomy. In ossiculectomy the surgeon assumes the middle-ear structures are useless and proceeds to ablate them. In atticotomy the stress is on function. The surgeon is out to preserve. He explores the attic and antrum being guided entirely by the pathological findings. It is said that the end-result is the same, but this is incorrect. It is true that in atticotomy the incus frequently must be sacrificed. The fault lies not in the operation, but in the fact that we do it too late. The following account of ossiculectomy is extracted from Jackson and Coates' textbook:

> Ossiculectomy may be done under local anæsthesia but is quite painful. Membrana tympani circumcised from ring—cut away from malleus, and removed.
>
> TO EXTRACT MALLEUS
>
> (1) *American method.*—Insert angled tenotome behind malleus and scrape it down—thus dividing ligaments and tensor tympani. Body of bone seized by Sexton's upward grasping forceps and delivered. Traction on handle alone is usually disastrous resulting in fracture.
>
> (2) Delstanche-Brunschwig upward-cutting ring curette is slipped up the manubrium, &c., &c.
>
> REMOVAL OF INCUS
>
> A choice of methods: It may disappear altogether unless preliminary disarticulation from stapes has been done. *Continental School* uses right and left incus hooks. American operators prefer opposite rotation of the incus hook. Accidents are not infrequent. Sustained pressure by hook may damage facial nerve. Too strong backward pressure may lose ossicle in aditus, antrum, attic pouch, hypotympanum or eustachian tube mouth. Successful in 40% to 60%. Merits wider study and eventual employment of younger surgeons of special deftness.

One must be struck by the multiplicity of manœuvres described, the variety of instruments necessary to perform them and the many disasters which are liable to attend them. The removal of the malleus under direct vision during a radical operation commonly requires considerable force and it must be difficult, dangerous and painful to scrape it from under cover of the outer attic wall. This blind groping can surely not be compared with the simple precision of atticotomy in which the ossicles are clearly exposed and examined before disposal. Nor is ossiculectomy likely to succeed unless the carious annulus is removed and the aditus drained. Efforts are indeed made to utilize an attic punch for that purpose, but as I have already pointed out the bone punch is futile and dangerous in that situation. In brief, ossiculectomy abandons the ossicles without a struggle. In this it is too radical. On the other hand it is too conservative in dealing with the disease. It cannot be extended at will. Any effort to use punches merely scrapes away the skin of the attic wall.

The issue between attico-antrotomy and the various transmastoid operations has already been touched on but the main difference may be usefully summarized. First, although attico-antrotomy is perhaps the more difficult operation—it is from the patient's point of view much smaller in every way. It takes from twenty to forty minutes. No sutures or ligatures are *ever* used and the manipulation of the soft tissues is reduced to a minimum. With the advent of sulphonamides and penicillin the post-operative complications of mastoidectomy have become rare, nevertheless they do still occur. We may note hæmorrhage, stitch abscess, perichondritis, secondary

A thorough familiarity with the transmeatal technique is invaluable in dealing with many other conditions also. Despite injunctions to the contrary I have had no difficulty in removing osteomata of the osseous canal. Secondary ossiculectomy (when a previous conservative mastoidectomy or atticotomy has failed) is performed with the utmost ease and I have converted many Heath operations into radicals by the same technique. In the past I have also performed attico-antrotomy on a few cases of cortical mastoidectomy in which suppuration had persisted. It is noteworthy that Lempert's latest operation of tympanic sympathectomy is transmeatal and I believe with Popper (1946*b*) that functional surgery of the ear will in the future be more and more associated with this route.

Results.—In an effort to assess the value of atticotomy, a questionnaire was sent to fifty consecutive cases:

Forty-two replies were received, yielding the following figures:

All age-groups were represented from 5 to 65

Duration of disease	
Under one year	1
1 to 3 years	13
3 to 20 years	14
Over twenty years	14

Average stay in hospital after operation 7 days

Post-operative pain	
None	28
Slight	13
Severe	1

It is clear that we are very far from our ideal of "early operation".

Healing

The cases were then examined to check the condition of the cavity:

Completely dry tympanomastoid cleft	29	38 healed operation cavities
Dry mastoid cavity but slight discharge from middle ear	9	
Slight discharge from mastoid as well as middle ear	4	

In no case was there any gross purulent discharge.

Healing time	
1 to 3 weeks	14
3 to 6 weeks	11
6 to 12 weeks	2
Over 12 weeks	2

Effect on hearing	
Improved	21
Unaltered	19
Worsened	2

These figures were analysed as follows by the Department of Applied Mathematics, Liverpool University (Professor L. Rosenhead).

With data of this nature it is convenient to calculate two limits within which the true proportion (e.g. of moist mastoid cavities) may be expected to lie. More precisely, we give below an upper and lower limit such that, if the experiment were repeated many times under the same conditions and these limits calculated in the same way each time, then the true proportion would lie between these limits in 95% of cases, outside in only 5%.

We find: (1) *Mastoid cavity*. Proportion "moist" almost certain to lie between 2% and 24% (and therefore "dry" between 76% and 98%).

(2) *Middle-ear cavity*. Proportion "moist" almost certain to lie between 17% and 48% (and therefore "dry" between 52% and 83%).

(3) *Hearing*. With a probability of being correct lying between 92·5% and 97·5% we may assert that the proportion "improved" lies between 20% and 67%. "Unaffected" between 15% and 62%, while the proportion "impaired" is less than 18%.—(R. L. Plackett, 24.4.47.)

The following conclusions may justifiably be drawn from these figures:

(1) Since 38 operation cavities out of 42 healed completely and since the remaining four do not produce any gross purulent discharge, attico-antrotomy is quite adequate for dealing with the disease in the mastoid process. The fear of leaving outlying disease is without foundation.

(2) When healing occurs it does so far more rapidly than after a radical operation. The figures quoted are the patients' estimates and no doubt some reported a dry ear in the absence of overt discharge when in fact epithelialization was not quite complete. Several in fact reported a dry ear after the first dressing. Even allowing for this exaggeration it is clear that, in successful cases, healing takes place with gratifying rapidity. In six cases the patient was discharged as cured after the fourth dressing.

tiny cavity is lined by tough healthy skin and is tucked deep in out of harm's way. In favourable cases the patient is completely free of any further symptoms.

The endaural antauricular approach.—Many of my colleagues seem to confuse the approach described by Lempert (fig. 5) with the true transmeatal approach. Actually a comparison of the two techniques reveals that there is no resemblance whatsoever between them. Lempert (1938*b*) indeed specifically states in describing his approach:

> The endaural antauricular operation on the temporal bone is not performed through the external auditory canal, but through a widely-opened mobile window, which, together with the auricle, may be displaced in every direction over the temporal bone.

The differences may be summarized as follows:

(1) Lempert forms a window by excising a triangle in the soft tissues of the outer half of the canal.
The true transmeatal approach sacrifices no skin and is limited to the osseous canal.
(2) Lempert starts by plunging a dental drill down into the antrum.
In my opinion the dental drill is a bad instrument, especially when suppuration is present. This leaves the bridge to be dealt with later on. I have already discussed the disadvantage of this procedure.
(3) Above all, however, Lempert prescribes a radical excision of the whole mastoid process.

His operation is essentially a transcortical mastoidectomy. It only differs from the classical operation in that he approaches the cortex in front of the concha instead of behind it.

The following extract from his description shows how radical Lempert's endaural mastoidectomy is:

> The surgeon must expose tegmen, zygoma, base of the petrous—the sinus plate and the fallopian canal. He must venture posterior to the entire course of the lateral sinus and burrow down to the tip of the mastoid infero-anterior to the lower curve of the lateral sinus. He must expose the tympanic orifice of the eustachian tube, destroy the processus cochleariformis and avulse the tensor tympani.

It is not likely that this operation will leave much useful hearing.

Popper's route (1946*a*) (fig. 7).—Mention must also be made of Popper's route in which extra space is obtained by partial excision of the tympanic plate. The route is proposed really for fenestration and similar procedures for which indeed it may have real value. Popper has, however, suggested that his route might be useful in otorrhœa. This is unlikely for the following reasons: The surgeon will be reluctant to open up clean tissue spaces—especially close to the temporo-mandibular articulation in the presence of chronic sepsis. Furthermore there is no real need for the extra space thus obtained in view of the fact that ample exposure is already obtained by the technique herein described.

Indications.—The fundamental difference between atticotomy on the one hand and ossiculectomy and classical mastoidectomy on the other hand is most clearly brought out in considering the treatment of attic suppuration presenting via a small perforation in Shrapnell's membrane. The discharge is minimal but intractable. The hearing commonly remains excellent for many years. In these cases ossiculectomy is mischievous. It inevitably impairs hearing and may not cure the suppuration. Radical mastoidectomy has just as bad an effect on hearing and leaves a large cavity which may continue to discharge even more than before. Atticotomy achieves exactly what McKenzie proposed. I have performed the operation frequently in this sort of case and almost always preserved the incus. The tiny cavity heals remarkably quickly and the hearing remains excellent. It should, however, not be imagined that atticotomy is only indicated in this limited group of cases. On the contrary, I would say that once a surgeon has fully mastered the technique he will use it to the exclusion of all others. The only exceptions are: (1) Cases in which intracranial or other complications are definitely suspected. (2) Cases in which the soft tissues of the meatus have become chronically thickened and deny access to the deep meatus.

Acknowledgments.—I am happy to acknowledge my indebtedness to Mr. R. L. Plackett for the statistical analysis and to Mr. H. Zalin who has assisted me indefatigably, not only in the theatre, but also in the Out-Patient Department, where the vitally important after-treatment is given.

On the use of Zelex penicillin:

(1) The Zelex should be dry sterilized in small quantities in separate test tubes.
(2) Any moisture during sterilizing will denature it.
(3) Even at best there is always some impairment of the "gelling" quality. Therefore a batch should never be re-sterilized. Throw any surplus away.
(4) Mix the powder with penicillin solution of required strength. I use 5,000 units per c.c. The proportions required are easily determined by trial.
(5) When the mixture is still fluid suck it up into a Watson-Williams syringe using the straight sphenoidal cannula.
(6) Wait till the mixture has set to a gel, i.e. it just emerges from the cannula in a semi-solid consistency.
(7) Squirt it into the cavity under direct vision.
(8) Zelex must not be poured in whilst still fluid. It can seep under flaps or into the middle-ear cleft and act as a foreign body.
(9) Remove seven to fourteen days later by gentle syringing and if necessary morcellement.

Mr. F. W. Watkyn-Thomas said that transmeatal methods had been practised for some eighty years, and although they had achieved success in the hands of gifted surgeons, they had never been generally accepted. The reason for this was that the difficulties of the operation made the methods unsuitable for general application. Mr. Tumarkin had mentioned and condemned removal of the outer attic wall by a punch with the transmeatal method. This was described by West and Scott in their "Operations of Aural Surgery", London, 1909. When he was their house surgeon five years later—in 1914—he was forbidden ever to try anything of the sort. He could not see that the results were in any way superior to the modified radical, or, say, the transmastoid atticotomy. Here in his experience, and, he thought, in that of many of his colleagues, there was no danger to the hearing. The hearing was usually improved. The access was much easier, and he could not agree that it was so necessary to remove the incus. If the incus was absolutely loose, lying in a mass of granulation, so that it came out of the end of a sucker, then he thought it was useless to leave it, but otherwise the incus could always be left intact. In fact one's guide for the operation should be to see the crus of the incus lying on the external canal.

Then came the question of accessibility. The majority of cases of attic disease were due to cholesteatoma, and he knew of no method by which one could tell, except by full exposure, how far that cholesteatoma extended. If there was cholesteatoma one could not remove it except by removing the matrix, and if the matrix extended far back into the antrum he failed to see how a surgeon, even of Mr. Tumarkin's ability, could reach it and eliminate it.

The second question of accessibility was in cases in which there was a mastoid structure where one had compact bone with a central chain of cells which had been destroyed by suppuration and had left a cavity—an empyema—in the mastoid. He knew of no way of detecting that except by exposing it. Therefore, although he was impressed by Mr. Tumarkin's skill and his excellent results, he must regard his procedure as retrograde so far as mastoid suppuration was concerned.

Mr. R. L. Flett desired to support Mr. Tumarkin as against Mr. Watkyn-Thomas. Mr. Tumarkin generally tried by previous X-rays to find the limitations of work on the mastoid. He himself was very well satisfied with the transmeatal operation. He was also doing fenestrations through that route. He wished to pay a tribute to Mr. Tumarkin's method.

Mr. Terence Cawthorne said that he thought that some form of meatal approach was becoming more popular in operations for chronic suppurative otitis media. He had been accustomed for some years to using the endaural approach, and he could see that there might be some advantages for what Mr. Tumarkin described, but that it required suitable practice and considerable skill. Those who had seen large numbers of school children suffering from chronic suppurative otitis media would welcome the possibilities presented by this operation.

Mr. I. Simson Hall had found a great many points of interest in Mr. Tumarkin's paper, but he could not help feeling that if discharge continued in one of these cases, as discharge will in a small

(3) The effect on function is also gratifying. The following audiograms appertaining to four children (shown at the Otological Section of the Royal Society of Medicine on February 7, 1947) demonstrate what can be achieved in suitable cases. In each case there had been bilateral chronic suppurative otitis media for many years. Conservative treatment cured one ear but failed in the other. Atticotomy was then performed on the infected ear. In each case there was a substantial improvement in hearing although in no case was the operated side as good as the opposite side.

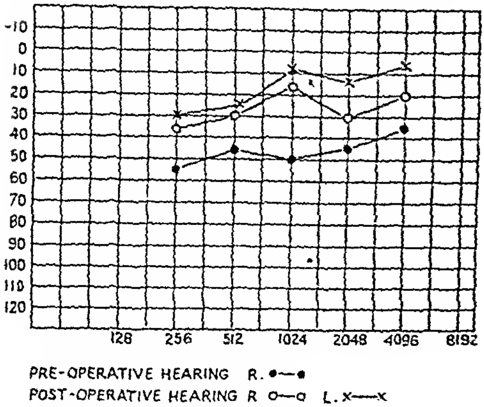

FIG. 8.—Audiogram of R. L., *aged 11*. History: Bilateral chronic suppurative *otitis media*, three years. Left ear recovered with conservative treatment. Right ear resisted treatment. Right ear—post-superior perforation with purulent otorrhœa. Operation: Right transmeatal atticotomy, 21.1.46. In hospital seven days. Ear healed in seven weeks. Incus preserved. Average hearing gain 21 db.

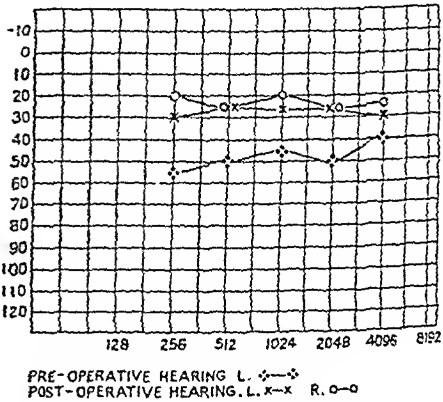

FIG. 9.—Audiogram of E. P., aged 13. History: Bilateral chronic suppurative otitis media, three years. Right ear recovered with conservative treatment. Left ear resisted treatment. Left ear—post-superior perforation with purulent otorrhœa. Operation: Left transmeatal atticotomy, 21.1.46. In hospital seven days. Ear healed in seven weeks. Incus preserved. Average hearing gain 21 db.

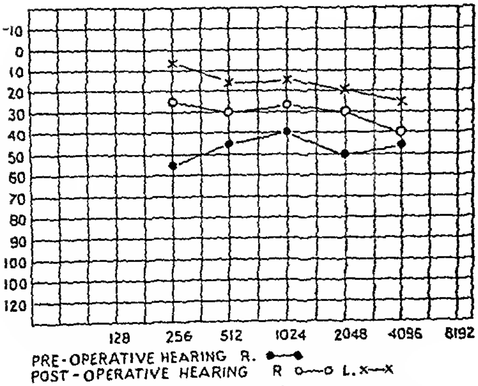

FIG. 10.—Audiogram of I. G., aged 10. History: Bilateral otorrhœa when teething, condition subsided but recurred when she entered school. Intermittent otorrhœa five years. Conservative treatment cured left ear, but failed to cure the right. Right post-superior perforation with purulent otorrhœa. Operation: Right transmeatal atticotomy. In hospital five days. Ear dry in seven weeks. Incus preserved. Average hearing gain 17 db.

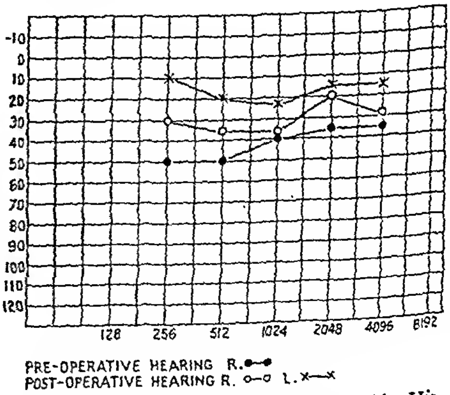

FIG. 11.—Audiogram of P. S., aged 11. History: Bilateral otorrhœa two years ago (also otorrhœa in infancy). Intensive conservative treatment for two months cured the left otorrhœa but not the right. Right ear—post-superior perforation with purulent otorrhœa. Operation: Right transmeatal atticotomy, 25.3.46. In hospital five days. Ear dry in six weeks. Incus preserved. Average hearing gain 12 db.

To sum up.—(1) Transmeatal attico-antrotomy is described and proposed as the method of choice for dealing with intractable non-complicated otorrhœa. (2) It is a minor operation from the patient's point of view. (3) It is possibly more difficult than transmastoid operations. (4) It is *not* a dangerous operation. (5) Its results are extremely satisfactory.

Acknowledgments.—I am happy to acknowledge my indebtedness to Mr. R. L. Plackett for the statistical analysis and to Mr. H. Zalin who has assisted me indefatigably, not only in the theatre, but also in the Out-Patient Department, where the vitally important after-treatment is given.

On the use of Zelex penicillin:

(1) The Zelex should be dry sterilized in small quantities in separate test tubes.
(2) Any moisture during sterilizing will denature it.
(3) Even at best there is always some impairment of the "gelling" quality. Therefore a batch should never be re-sterilized. Throw any surplus away.
(4) Mix the powder with penicillin solution of required strength. I use 5,000 units per c.c. The proportions required are easily determined by trial.
(5) When the mixture is still fluid suck it up into a Watson-Williams syringe using the straight sphenoidal cannula.
(6) Wait till the mixture has set to a gel, i.e. it just emerges from the cannula in a semi-solid consistency.
(7) Squirt it into the cavity under direct vision.
(8) Zelex must not be poured in whilst still fluid. It can seep under flaps or into the middle-ear cleft and act as a foreign body.
(9) Remove seven to fourteen days later by gentle syringing and if necessary morcellement.

Mr. F. W. Watkyn-Thomas said that transmeatal methods had been practised for some eighty years, and although they had achieved success in the hands of gifted surgeons, they had never been generally accepted. The reason for this was that the difficulties of the operation made the methods unsuitable for general application. Mr. Tumarkin had mentioned and condemned removal of the outer attic wall by a punch with the transmeatal method. This was described by West and Scott in their "Operations of Aural Surgery", London, 1909. When he was their house surgeon five years later—in 1914—he was forbidden ever to try anything of the sort. He could not see that the results were in any way superior to the modified radical, or, say, the transmastoid atticotomy. Here in his experience, and, he thought, in that of many of his colleagues, there was no danger to the hearing. The hearing was usually improved. The access was much easier, and he could not agree that it was so necessary to remove the incus. If the incus was absolutely loose, lying in a mass of granulation, so that it came out of the end of a sucker, then he thought it was useless to leave it, but otherwise the incus could always be left intact. In fact one's guide for the operation should be to see the crus of the incus lying on the external canal.

Then came the question of accessibility. The majority of cases of attic disease were due to cholesteatoma, and he knew of no method by which one could tell, except by full exposure, how far that cholesteatoma extended. If there was cholesteatoma one could not remove it except by removing the matrix, and if the matrix extended far back into the antrum he failed to see how a surgeon, even of Mr. Tumarkin's ability, could reach it and eliminate it.

The second question of accessibility was in cases in which there was a mastoid structure where one had compact bone with a central chain of cells which had been destroyed by suppuration and had left a cavity—an empyema—in the mastoid. He knew of no way of detecting that except by exposing it. Therefore, although he was impressed by Mr. Tumarkin's skill and his excellent results, he must regard his procedure as retrograde so far as mastoid suppuration was concerned.

Mr. R. L. Flett desired to support Mr. Tumarkin as against Mr. Watkyn-Thomas. Mr. Tumarkin generally tried by previous X-rays to find the limitations of work on the mastoid. He himself was very well satisfied with the transmeatal operation. He was also doing fenestrations through that route. He wished to pay a tribute to Mr. Tumarkin's method.

Mr. Terence Cawthorne said that he thought that some form of meatal approach was becoming more popular in operations for chronic suppurative otitis media. He had been accustomed for some years to using the endaural approach, and he could see that there might be some advantages for what Mr. Tumarkin described, but that it required suitable practice and considerable skill. Those who had seen large numbers of school children suffering from chronic suppurative otitis media would welcome the possibilities presented by this operation.

Mr. I. Simson Hall had found a great many points of interest in Mr. Tumarkin's paper, but he could not help feeling that if discharge continued in one of these cases, as discharge will in a small proportion of all operations, it would be very difficult for him to satisfy himself that some diseased cells had not been overlooked, but as Mr. Tumarkin had not quoted any figures he assumed that Mr. Tumarkin was satisfied that in his hands this operation gave better results than any other form of radical mastoidectomy in suitable cases.

Mr. W. Ogilvy Reid spoke of the unfortunate tendency to recurrence of mastoid infection in children. Children seemed to be liable to acute reinfection of the mastoid cavity subsequent to operation. Some time before the late Mr. G. J. Jenkins died he was working with him on a periosteal-flap operation which he (Mr. Reid) later published in 1942 (*J. Laryng.*, 57, 405), the aim being to try to prevent the spread of any subsequent infection of the middle ear to the mastoid cavity formed by the operation. That flap operation had been very effective in limiting the spread, confining it to the middle ear. He wished to ask Mr. Tumarkin whether he had found the recurrence rate diminished in any way by his particular technique. He wondered whether the provision of drainage from the attic cut short any subsequent attack of otitis media.

Mr. A. Tumarkin, in reply, said that Mr. Watkyn-Thomas had raised what were, after all, the standard objections to the operation, and short of repeating what he had already said in the paper he could not say any more in answer to his objections. He believed that no particular difficulty would stand in the way of any competent surgeon carrying out what he had advised.

Mr. Cawthorne had spoken of skill in the operation and in the after-treatment. One of the essential features of attico-antrotomy was that the after-treatment was simplicity itself. Members must have been struck by the rapidity of healing in many of the cases he had shown. Of course, cases did come along which involved special difficulty; nevertheless, when he did an attico-antrotomy he expected to syringe the Zelex out a week or ten days later and to see the patient thereafter once a week for a month and, at the end of that time, no more trouble.

Mr. Simson Hall had asked for statistics, but he did not know how his own figures could be quoted with any real significance against somebody else's. Attico-antrotomy was an operation based on a definite conception of pathology. It set out to do certain things and it did them. Actually he would say quite definitely that he could get better results than he ever got with any other operation. He expected the operation cavity to dry and he was disappointed if it did not.

When the ear continued to discharge it discharged from the middle ear. His case No. 1 was a man who had a radical operation in childhood. His other ear became infected, and he came to him after eighteen months obviously very deaf. He treated him for three months before he finally operated. He operated and preserved the incus. The middle ear was still moist, but instead of a gross purulent discharge, there was a slight mucoid discharge which came from the middle ear. Ears which did not dry after an attico-antrotomy failed to do so because of discharge seeping from the middle ear and not from the mastoid. In the cases of partial cure the partiality of the cure was not due to disease in the mastoid, and those cases which did persist were reduced in number if operated earlier. Early operation was a necessity. He was thinking not so much about adults, but about children. Many children of the working classes had bilateral otitis media, and were going to be crippled if surgeons did not save them. He had brought 4 of them to that meeting, and he had done 35 cases during the year; every one of those 35 had a dry cavity.

Complications did occur after radical operation, but they should not be common. He did not suggest that these occurrences were a grave disadvantage of the radical, but still they did occur.

On the question raised by Mr. Reid as to whether attico-antrotomy was effective when the child got an acute ear, it was essential to distinguish quite clearly between acute otitis media and the chronic infection for which he did this transmeatal attico-antrotomy. Most of these children did not have a properly developed pneumatic system of their mastoid, and they were not liable to typical acute mastoiditis. Cases were seen in which the ear continued to seep discharge from the eustachian orifice, but not from the attic if an attico-antrotomy had been done. The child was not liable to acute mastoiditis because the mastoid was not pneumatized.

As to how one managed a procedure which was sometimes said to demand three hands, there was no difficulty in putting in the speculum, but it must fit tightly.

The President, in closing the discussion, said that he was familiar with Mr. Tumarkin's work and the good results which, in chronic middle-ear suppuration, followed his operations by the external meatal route, but as Mr. Watkyn-Thomas had remarked, many of us, accustomed to operate from behind the auricle, found it easier to do so and further cholesteatomatous invasion at times was remarkably extensive, filling the cells of the mastoid apex even in young children.

The more slender standard gouges appeared too thick in the shaft for these operations though Mr. Tumarkin had had some improved in the workshop. He had also spoken of the use of "the third hand". He (the President) made use of this regularly in the intranasal approach to the bone overlying the lacrimal sac and in "taking down" the crest in operations on the nasal septum.

Perhaps an assistant in the role of "Blacksmith's striker" might also be helpful to those deciding to operate upon the tympanic attic and antrum by the meatal route. Regulation of the force applied had not been at all difficult in intranasal work.

Section of Medicine

President—MAURICE DAVIDSON, M.D.

[*April* 22, 1947]

DISCUSSION: THE MANAGEMENT OF PATIENTS WITH ESSENTIAL HYPERTENSION

Dr. Geoffrey Evans, in opening the discussion, referred to the differential diagnosis between symptomatic and essential hypertension. In discussing the ætiology of essential hypertension Dr. Evans referred in the first place to the constitutional factor, that is to say, inheritance, which may determine not only the development of hypertension in a person, but also its location (in terms, for instance, of cerebral vascular disease or hypertensive heart disease) and the age of onset of symptoms. Although the predisposition to hypertension may be inherited, family influence and environment may be the factors which determine its development. Continued over-fatigue and exhaustion undoubtedly aggravate hypertension and, perhaps, on occasion, cause it. The background, therefore, of the patient's life, as well as the outlook and emotional state, need to be taken into account in advising a patient with essential hypertension, and Dr. Evans emphasized the importance of a sanguine outlook in the management of such a case. In discussing the detail of treatment, living within the limits of the individual's strength and the prescription of extra rest was the general rule. The most intensive form of conservative treatment consists of a preliminary period of rest in bed with sedatives, such as phenobarbitone, bromide or chloral; a diet of limited calorie value should be prescribed for all those who are over-weight, and in some cases it seemed that a restricted fluid intake, restriction of salt, alcohol, tea, coffee or tobacco, might do good; but a little alcohol taken with meals acted as a sedative and probably did no harm, and the same comment probably applied to tea, coffee and tobacco in moderation. In those with peripheral congestion venesection might do good, and for those with circulatory failure small doses of digitalis were given as a routine. For obesity Dr. Evans advised the fruit, vegetable and meat diet of Dr. Gardiner-Hill or the high protein diet of the late Dr. Dennis Embleton. Dr. Evans spoke at some length on the value of potassium thiocyanate, especially in respect of relief of headache and giddiness in hypertensive subjects, and the fall of blood-pressure in some cases. Dr. Evans remarked that in spite of eleven years' experience of the intensive treatment of essential hypertension with potassium thiocyanate therapy in the hands of physicians, and an equally long history of lumbar and dorsilumbar sympathectomy in the hands of surgeons, the value of these forms of treatment is not yet fully agreed. The reason for this he believed to be due to the association of hypertension with arteriosclerotic disease, and especially due to the fact that in some patients the arteriosclerotic process of disease might be continually active and progressive, whereas in others there were phases of activity with long periods of quiescence. The disease, in fact, consists of functional and structural components. The functional components are a generalized hypertonia of the systemic circulation which is responsible for the hypertension, and localized vascular spasm which is especially responsible for many of the clinical manifestations of the disease, including retinal exudates and hæmorrhages, cerebral vascular accidents, hypertensive heart disease (he thought), and renal complications in some cases. It seemed to him that disorders of vascular tone might cause such symptoms as headache and giddiness from time to time, or for a number of years, without necessarily causing a coincident change in vascular structure. Such a case might be stationary in spite of symptoms. On the other hand patients with hypertension and a more stable vasomotor control would be symptom-free. But in another group of cases, coincident with alteration in vessel tone, structural changes in the blood-vessels took place, and a condition of active arteriosclerotic disease was present. This state of activity could be recognized by the presence of hæmorrhages in various parts of the body, including retinal hæmorrhages and microscopic hæmaturia, epistaxis, menorrhagia, hæmoptysis, hæmatemesis and melæna. In other cases thrombotic phenomena registered the activity of arteriosclerotic disease. Evidence of active disease was also to be looked for in alterations in the electrocardiogram, in the urine, in the peripheral circulation in the lower extremities, and it was generally present in patients whose diastolic pressure was over 120 mm.Hg. In fact the difficulty of assessing the value of either intensive medical or surgical treatment was due to the impossibility at present of forecasting the natural course of arteriosclerotic disease in a hypertensive subject. No method of treatment at present available could be relied on to prevent the recurrence of active phases of arteriosclerotic disease in some subjects or prevent the continued progress of the disease in others.

Mr. A. Dickson Wright said that the surgical management of the case of hypertension was by no means standardized, and it was very difficult to be dogmatic in a disease so variable in its course and effects. The ineffectiveness of medical treatment and the lethal character of the disease brought surgery into the picture possibly only as a stop-gap until an effective medical treatment or prophylaxis based on sound physiology was evolved, but, nevertheless, in selected cases a valuable way out of an awkward position lay with surgery for the unfortunate patient afflicted with this distressing complaint.

Selection was the most important step in the surgical handling of these cases. If hopelessly advanced cases were submitted to operation the method would be discredited, the surgeon's time wasted and the patient and relatives bitterly disappointed. In the selection of cases many factors had to be considered and sometimes surprisingly good results were obtained in patients with rather poor prospects. It was unusual to operate on patients over 50 years old although some patients over 60, generally in the upper social classes, were being treated surgically in the United States of America. Females did better than males surgically just as they did medically, and especially hopeful were those cases in which the high blood-pressure of pregnancy toxæmia became established permanently. The patient with a ruddy complexion did better than his pallid counterpart with the same blood-pressure. Patients with hopelessly damaged kidneys were avoided although nephritis was not an absolute contra-indication, it being felt that the reduction of the filtration pressure would help the damaged renal tissue and reduce the albumin loss. A renal function of at least 65% of normal was essential for cases for surgery, but there were great fallacies in these renal tests, and they should be repeated and checked to eliminate error.

A severely damaged heart was another definite contra-indication and pulsus alternans, cardiac asthma and Cheyne-Stokes' breathing should put operation out of question. Angina and lesser degrees of myocardial damage were not contra-indications, and the inverted T wave had returned to normal in some cases as recorded by White of Boston. In certain cases of angina a left cervical sympathectomy added to the pressure-reducing operation might turn a partial cure into a complete one as far as the angina was concerned.

Severe cerebral damage from thrombosis or hæmorrhage was a complete contra-indication but cases with minor residual damage had been done with fair results.

Blindness or near blindness were also contra-indications, and many regarded established papillœdema and the "tiger skin" fundus as indications of the unsuitable case. Early retinal damage was an indication of urgency, and there was little doubt that the surgical reduction of blood-pressure often saved the eyes from irretrievable damage.

Severe encephalopathy was unfavourable as regards prognosis but provided the surgeon with his greatest incentive to operate. To rid the patient of blinding headaches, vertigo and mental obfuscation and, most important of all, transient hemiplegias and hemianæsthesiæ was indeed a cause for gratification. One felt little patience for those who criticize successes in this respect saying that encephalopathy manifestations are functional even though they afflicted the most stolid types and children before they had ever learnt to be "functional".

A high pulse-pressure was very unfavourable, gross thickening of the arteries also and a high sleeping blood-pressure. A lumbar puncture pressure of over 300 was regarded by others as an unfavourable prognostic sign.

The sedation tests were very valuable for estimating the lability of the blood-pressure, this could be quickly done with pentothal intravenously provided a full dose was used and the deepest anæsthesia produced. Another way was the sodium amytal test, 3 grains being given hourly till the patient was unrousable and pressures taken at regular intervals while the drug was effective. A substantial fall obtained by either method was a direct encouragement to operate.

Intravenous pyelography disclosed cases of renal disease which could be remedied by surgery, such as atrophic pyelonephritis, calculus, tuberculosis, pyonephrosis, &c., but as operations for unilateral disease only produced a cure in 30% of cases it was wise, when dealing with the kidney condition, to supplement it with a sympathectomy so that if the case was a failure from the unilateral kidney point of view only one more operation was necessary to give him the *full* benefit of sympathetic surgery.

Coarctation of the aorta was eliminated by observing the femoral pulses and if found the coarctation should be excised.

Adrenal neoplasms caused hyperpietic crises due to adrenaline release and were dealt with appropriately. More difficult was high tension due to basophilic adenoma of the pituitary. Uterine myomata, prostatic or urethral obstruction and lead poisoning were all dealt with before regarding a case as one of essential hypertension. Addiction to benzedrine or ephedrine must be thought of in these high-pressure days.

The first suggestion that high blood-pressure could be reduced by cutting the sympathetic nerves came from Kraus of Berlin. The first series operated upon were done at the Mayo Clinic by Adson and his confrères who cut the anterior nerve roots of the lower six dorsal nerves through an extensive laminectomy. This was a great mutilation and did not last although some good results were obtained. Adson then simplified his operation to a renal incision of each side at a ten-day interval and removed all three splanchnic nerves and the first two lumbar ganglia with removal of half the adrenal (optional) and biopsy of the kidney. He claimed remarkably good results from this operation, and it was noticed that many of the patients with a maintained blood-pressure after operation had nevertheless a great mitigation of symptoms. This operation of Adson's is very simple, disturbs the patient very little, has practically no complications or death-rate and is followed by only minor discomfort.

Peet has done a single-stage operation on a very large series and operates through the posterior mediastinum, removing the eleventh and twelfth ribs on both sides and extracting as many of the lower dorsal ganglia as possible and the splanchnics before they pierce the diaphragm.

Smithwick combined the two operations and extended the operation in an upward direction by means of special illuminated retractors claiming a much more radical removal including certain small contributions to the aortic plexus missed by both the other operations. Both Peet's and Smithwick's operations can be followed by troublesome intercostal neuralgia, abdominal wall palsies, pleural and mediastinal exudates and this price as well as a higher mortality rate must be paid for the more extensive sympathectomies.

Poppen has endeavoured to make the Smithwick operation easier in its upper extension by making another window into the posterior mediastinum by removing the seventh or eighth rib through a separate incision.

Grimson has opened the chest widely through two rib spaces, fourth and eighth, and removed the whole dorsal ganglionic chain by the transpleural route. Then if this did not suffice the abdominal sympathetic chains were removed at a third operation and if the blood-pressure still remained undiminished it could be safely described as humoral. This large operation carried a considerable death-rate (15%) and had not been widely adopted although it was *the* only radical sympathectomy, the others having varying degrees of partiality. Equally good figures of benefit have been reported for all the operations but all figures have to be received with great caution. It is possible to get varying blood-pressure (and even E.C.G.) in the same patient according to the depth of respiration, posture, mental state and so on. The price paid for the more extensive sympathectomies in the way of pain, complications and death-rate might be rather too much to pay in contrast with the small degree of discomfort and quite good results obtained by a thorough Adson sympathectomy done under spinal anæsthesia.

An attempt had been made recently to treat the very severe cases of malignant hypertension with papillœdema by resecting so much adrenal that a near-Addison's disease was produced (some patients even becoming pigmented). There seemed to be some hope for the hopeless by this procedure especially when combined with a sympathectomy, but the reactions after subtotal adrenalectomy were very severe, and there was a considerable death-rate. In a few very severe cases artificial arteriovenous fistula had been made in the neck. These staved off the evil day of blindness or cerebral hæmorrhage and could be closed quite easily when the heart grew tired of feeding the fistula. A remarkable fall in blood urea occurred in these cases, the reason for it might repay investigation.

Dr. C. H. Wyndham: *Sympathectomy in hypertension.*—Dr. Wyndham said that in spite of the present enthusiasm for the surgical treatment of hypertension, we were in the inevitable time-lag during which evidence, in a sufficiently large series of cases over a sufficient number of years, was accumulated and would or would not indicate the clinical justification of the procedure. It was of interest to re-examine, therefore, the original aims of the authors of the procedure in the light of evidence that had accumulated on the effects of sympathetic deprivation.

Adson and Brown were early in the field—first case of sympathectomy for hypertension was done in 1925—and they began a series in 1930. They based their expectancy of a fall of blood-pressure to follow on a "maintained vasodilatation of arteries in the sympathectomized area". That this result would follow sympathectomy was concluded from a series of acute observations on the skin temperature increase, extending over not more than nineteen days, in local sympathectomy. The observation of a fall in blood-pressure after spinal anæsthesia was attributed to the same mechanism and the fall of blood-pressure was used as an argument in favour of an anticipated drop of blood-pressure on surgical sympathectomy.

Their emphasis on the fact that the new blood-pressure adjustment was due to "maintained vasodilatation of the arteries in sympathectomized area" and solely to the drop of the total peripheral resistance offered to the outflow of blood from the arterial circuit has been accepted and has obscured thought on the mechanism of sympathectomy in hypertension.

Recent work on circulatory dynamics has thrown into relief the constant interplay of both the central and the peripheral factors at work in cardiodynamic adjustments.

Dr. Wyndham continued: The blood-pressure in the arterial circuit is dependent largely on both the amount of blood pumped into the circuit and the resistance offered by the *total tone of the arterioles* to the outflow of blood from the circuit:

$$\text{B.P.} = \text{C.O.} \times \text{T.P.R.}$$

The litre volume per minute pumped into the circuit was shown to be related to two main factors: (*a*) The venous filling pressure; (*b*) the rate of the heart; and probably hormonal factors which have a direct effect on cardiac muscle action. An increase of either (*a*) or (*b*) causes an increase of cardiac output in a direct linear relationship.

At the other end of the circuit the resistance offered to the outflow of blood depends on the tone of arterioles of the three major vascular beds—skin, muscle and splanchnic areas. The flow through these areas is influenced, and in no constant manner, from one to the other by: (*a*) Metabolic state; (*b*) temperature; (*c*) hormonal content of perfusing blood; (*d*) sympathetic nervous control.

The manner in which these factors operate had been demonstrated when normal volunteers were bled up to 1,500 c.c. of blood, the following results being observed:

(i) Right auricular pressure, reflecting the venous filling pressure, falls. Since there is a steady fall of the right auric. pressure during bleeding it suggests that there is no immediate increase of venous tone (McMichael and Sharpey-Schafer, 1944).

(ii) The fall of right auric. pressure usually leads to a fall in the cardiac output, in spite of some acceleration of the heart rate.

(iii) The arterial pressure is maintained up to a point in each subject when it falls suddenly and the heart slows, the vasovagal faint.

(iv) This sudden fall in the arterial pressure is not due to a further drop of the cardiac output but is due to a sudden vasodilatation in muscle arterioles (Barcroft *et al.*, 1944).

Effect of Sympathectomy on Circulatory Dynamics

It had been demonstrated that a local and immediate decrease in arteriolar tone occurs in the sympathectomized area (Grant and Holling, 1938). In view of the fact that the uninvolved area is capable of full vasoconstrictor activity, the effect on total arteriole tone is not known in the type of sympathectomy performed for hypertension.

It had been suggested that sympathetic denervation decreases venomotor tone (Smith *et al.*, 1939). A decrease in venomotor tone would, probably, lower the venous filling pressure of the right auricle. A fall in right auricular pressure led usually to a decrease in cardiac output. The length of time and the degree to which venomotor paralysis persisted after sympathectomy was conjectural. Clinical observation suggested that it was not enduring. It was important to establish, therefore, the part played by each of the factors, the loss of venomotor tone, and the loss of arteriolar tone in the mechanism of the arterial blood-pressure fall of sympathectomy.

If (*a*) % change of the "mean" blood-pressure and (*b*) % change of the cardiac output can be calculated then the direction of change of the third factor, the "total peripheral resistance", can be assessed and compared with normal subjects.

It was now a practical procedure by the method of right auricular catheterization, to measure the alteration of the filling pressure of the right auricle and the change in cardiac output caused by sympathetic denervation in hypertensives.

Finally, evidence was accumulating on the relative efficacy of sympathectomy in producing vasodilatation and in its capacity to maintain this effect on arterioles. The following observations were made by Barcroft *et al.* (1943, 1944):—

Blood Flow through Muscle in c.c./100 c.c. tissue/min.

At 35° C.	After local heat 45° C. 1943	After acute sympathectomy 1944
4·0 c.c.	18 c.c.	7–8 c.c.

This suggests that in one of the major vascular beds, sympathectomy is not as effective a vasodilator as local heat. Local exercise apparently has an even greater vasodilator effect. That this twofold increase is not maintained even at this level was shown by Grant and Holling (1938).

We were now in a position to comment on Adson and Brown's original claim and to suggest that:

(*a*) Sympathectomy might act in reducing arterial pressure, both by the effect on arteriole tone, thereby decreasing total peripheral resistance, and possibly by an effect on venomotor tone, thereby decreasing cardiac output.

(*b*) That it produces less effect on the total capacity of arterioles in muscle to vasodilate than local heat or local exercise. It is highly improbable that this initial decrease in tone is maintained.

Mr. H. J. B. Atkins pointed out that in Mr. Dickson Wright's large series there was a remarkably low mortality, but that in one case cerebral thrombosis had developed. In his very much smaller series he had had a case of retinal thrombosis on the third day after operation with the development of a permanent blindness in that eye. As the consequences of thrombosis in the heart, the brain and the eye were so much more serious than thrombosis elsewhere, and as it was in these sites that thrombosis was likely to follow the operation for hypertension, Mr. Atkins inquired whether the incidence was sufficiently high in Mr. Dickson Wright's experience to merit the injection of heparin as a routine after this operation.

Dr. Evan Bedford said that by far the commonest cause of death in essential hypertension was heart failure, which occurred in 60 to 70% of all cases, compared with about 20% dying of cerebral vascular accidents and less than 10% of renal failure. Therefore, the management of patients with hypertension should be directed especially to the care of the heart.

The natural course of the disease was one of gradually progressive cardiac enlargement extending over a period of ten to thirty years and terminating in heart failure, either congestive or anginal. Coronary disease was frequently associated with hypertension, and angina pectoris or coronary occlusion occurred in 30 to 40% of cases. The rate at which the heart enlarged was almost imperceptible from year to year, in the absence of failure, and by measuring serial orthodiagrams over periods up to fourteen years he had found the average increase in transverse diameter to be less than 2 mm. per year. Once the stage of left heart failure was reached, rapid cardiac enlargement often occurred.

He quoted Dr. Paul White as stating that the crux of the treatment of hypertensive heart disease was not the imposition of an invalid life or the support of the heart with digitalis, &c., but the control of the hypertension itself. However, as yet we had no medical means of accomplishing this. Evans and Loughnan (1939) had made a systematic and painstaking investigation of 33 drugs, including thiocyanates, which had been advocated in treating hypertension, testing each remedy against a placebo as control, over a reasonable period of time, and they had shown conclusively that none of these drugs was hypotensive.

Thiocyanate had been in use for over twenty years without convincing the majority of physicians that it could effectively control hypertension. Admitting that thiocyanate was sometimes successful in relieving symptoms, as in cases which Dr. Geoffrey Evans had cited, it was usually too toxic or too disappointing to offer any serious solution to the problem of preventing hypertensive heart disease.

If we had no means of removing the burden on the heart, we could at least minimize it by prescribing suitable restrictions, and prevent the superimposition of additional burdens in the form of obesity, alcoholism, overeating, excessive smoking, and the stresses of a high-pressure life. Patients with hypertension must learn to live slowly and, in accordance with modern ideas, the heart required *a forty-hour week*. He was confident that regular medical supervision and the imposition of a suitable régime could slow the progress of the heart disease and thus prolong life. Each patient needed his mode of life carefully planned, and a timetable should be worked out which allowed adequate time for sleep and rest in bed, and which excluded all unessential physical and psychological stresses.

When the hypertensive heart failed, the ordinary treatment for heart failure was indicated, namely an adequate period of complete rest in bed, restriction of fluids and salt, digitalization, and mercurial diuretics. Albuminuria and a slightly raised blood-urea were not contra-indications to mercurial diuretics in hypertensive heart failure. In the majority of cases, a stage of isolated left heart failure preceded signs of systemic venous congestion, and it was important to recognize and treat heart failure at this stage.

A triad of important signs of cardiac weakness gave warning of impending failure, namely gallop rhythm, pulsus alternans, and inversion of the T wave in lead I of the electrocardiogram, and in such cases attention should be focused on the lung bases and not the legs for the first appearance of œdema. Aminophylline was often of value in treating Cheyne-Stokes' respiration which was a common complication of hypertensive heart failure.

Finally, the indications for surgical treatment of hypertension had to be considered. Sympathectomy for hypertension had been introduced by Adson and Rowntree twenty years ago, and had been practised ever since, without becoming accepted as a reasonably effective method of treatment for general use. Great claims had recently been made for the more radical surgical procedure introduced by Smithwick of Boston, but, even in America, opinion as to its value and indications was by no means unanimous. It was already clear that this operation did not cure hypertension. It produced a significant reduction in blood-pressure in a proportion of selected cases, possibly about half. The question of when to employ surgical treatment was most important. It would seem rational to do so in the early stages of the disease, before the heart became involved, and no less a surgical authority than De Takats expressed the view that the only clear-cut indication for surgery in hypertension was a pressure constantly exceeding 140/90 mm. in subjects aged 18 to 25 years. He regarded surgery as debatable in the middle-aged hypertensive and as contra-indicated in malignant hypertension. Because the outlook seemed hopeless was not a proper reason for submitting a patient to surgical treatment unless it offered a reasonable chance of proving effective. Dr. Paul White believed that the cardiac changes in hypertension were in some measure reversible, and advocated surgical treatment for hypertensive heart disease.

Two quite distinct problems required solution, first the value of surgery in the early stages of the disease with a view to preventing heart disease, and secondly its value in the later or cardiac stages of the disease. The time has not yet arrived when surgical treatment could be regarded as generally applicable to patients with hypertension. The method required careful testing under controlled conditions, both in the early and the later stages of hypertension, before its indications could be decided, and the results needed to be carefully assessed by those with special experience of the disease.

REFERENCE

Evans, W., and Loughnan, O. (1939) *Brit. Heart J.*, 1, 199.

Dr. T. H. Whittington, speaking as an ophthalmologist, said that many cases of hypertension were first seen, and the diagnosis made, because of visual symptoms. The retina might be considered the extracranial part of the cerebral hemispheres, and the optic nerve homologous with the association tracts, and the retinal artery as a terminal branch of the intracranial circulation. Therefore, the ability to see these structures during life under a magnification of 15 to 20 times should be of importance in assessing the case. He suggested that careful observation of the signs in the fundus oculi, which had not been mentioned by speakers, should be made in all cases, and be added to the other clinical controls, in assessing the effects of medical and surgical treatment. The tragic loss of sight in one eye, due to a vascular catastrophe in it, and the danger of a similar occurrence in the other eye, might be considered, in the younger patients, as an indication for sympathectomy, but the results of treatment on the circulation in the eye could only be assessed if careful observation of the fundi was made in all cases having operation. For the same reason physician and ophthalmologist should collaborate in judging effects on retinal circulation when thiocyanate or other treatment was used.

Mr. A. Dickson Wright, in reply to Mr. Atkins, said that heparin had not been used to counteract these post-operative thromboses because the incidence was not sufficiently high; on the slightest sign of their appearance heparin treatment to the full extent would be indicated.

DISCUSSION: THE PRESENT POSITION IN REGARD TO THE PNEUMOCONIOSES

Dr. E. R. A. Merewether (*H.M. Senior Medical Inspector of Factories*): That over 500 deaths a year from pneumoconiosis should still occur in this country is something of a challenge—a challenge not only to us doctors but to all who have a specific contribution to make to the prevention and control of this, so venerable a disease.

Naturally enough, each of us will first look at so complex a problem from the angle of his own particular activities, and for me this resolves itself into the salutary and somewhat chastening task of trying to assess what knowledge is lacking for the solution of the social problems which have been associated with this disease throughout the ages, that is problems of prevention, control, disablement and rehabilitation.

Section (1), Subsection (2) of the Workmen's Compensation Act, 1943, states "In this Act, the expression 'pneumoconiosis' means fibrosis of the lungs due to silica dust, asbestos dust or other dust, and includes the condition of the lungs known as dust reticulation," and Section 57, Subsection (3) of the National Insurance (Industrial Injuries) Act, 1946, defines "pneumoconiosis" in the same words.

From the legal point of view, therefore, *for purposes of compensation*, the essential feature of pneumoconiosis is the presence of fibrosis of the lungs.

Many medical men and laymen generally take a more comprehensive, if less precise, view, and if asked what they understood by this expression will say, "Any affection of the lungs produced by dust."

Clearly, therefore, we must make plain our meaning when we use this word, and particularly so in a medical certificate or a radiological report, or difficulties and disappointments will arise if we raise possibilities of compensation where none exist.

I propose therefore to use the legal meaning of the term, and this leads us directly to the question of diagnostic criteria. We depend, of course, on the triad of occupational history, clinical examination, and X-ray appearances; of these, the results of the clinical and radiographic examination may be of doubtful significance, particularly the radiographic, but the occupational history, if accurately taken and thoroughly investigated, is always significant and may carry conclusive weight in conjunction with the other examinations.

The interpretation of the radiographic appearances is becoming exceedingly difficult.

Here definitely, I feel, is an aspect which urgently requires reassessment in the light of recent knowledge with the view of relating much more accurately cause and effect, of standardizing techniques and laying down scientific criteria for interpretation. How this can be achieved I am not competent to say, but evidently such research includes not only consideration of pure radiological technique, but the determination of the limits of normality in the X-ray picture of industrial lungs and differentiation between abnormal markings representing presence of dust with no disease and those representing dust with disease present or in the offing.

The X-ray appearances resulting from the reaction of the lungs to the stimuli of dusts in mixtures in different degrees of concentration and particle size, some of the constituents being inert, some fibrosis producers, some inhibitors of fibrosis, and some believed to be accelerators, but all diffractors of X-rays in varying degrees present a pretty problem for research and analysis.

In addition, further research into the correlation of morbid histology with the X-ray appearances, if done on a considerable scale, might produce invaluable data.

This both by close follow-up of human cases and by animal experiment. Hitherto radiography in this field has been as an indispensable aid to diagnosis; now we would like it also to serve as an aid to the assessment of disablement and as a real guide to prognosis. Both these aspects are of increased importance in connexion with the improved basis of compensation provided by the Industrial Injuries Act and in respect of new rehabilitation measures provided for by the Disabled Persons (Employment) Act of 1944, and the new factories provided by the Board of Trade for the suitable employment of pneumoconiotics.

The assessment of disablement in pneumoconiotics is a most difficult matter to set on a scientific basis since at present so much depends, at least in the earlier stages, on the reactions of the individual, both involuntary and voluntary, to exercise.

There are many other aspects on which the lack of fundamental data is hampering progress of which I shall mention only a few.

We do need a great deal more knowledge of incidence rates and morbidity rates for pneumoconiosis in the relevant occupations. Incidence rates should provide, over a period of time, a sensitive index of the efficiency of preventive measures. The risk of silicosis, for example, varies very much in different occupations, as also does the average severity of the cases.

An average of 6·6 deaths a year during the six years 1940–45 from silicosis in sandblasters is no measure of the risk unless we know the population of sandblasters. Actually it is small, and therefore a few deaths represent a high mortality rate. A number of years ago I estimated that 5·4% of a population of sandblasters died from silicosis or silicosis with tuberculosis in the space of three and a half years.

A very rough calculation, but sufficient to give an indication of the importance of this point, shows that while the number of deaths from silicosis in coalminers each year is over 38 times that of sandblasters, the mortality rate from silicosis per 1,000 sandblasters is some 18 times that of coalminers and probably higher.

We can get an idea of the comparative risk and severity in certain occupations by comparison of the average duration of employment in fatal cases of silicosis: these range from 8·4 years to 39·1 years, the overall average duration of employment of 902 fatal cases of silicosis being 34·1 years, that of 54 sandblasters being 12 years, and that of 154 fatal cases of asbestosis being 14·9 years.

Apart from susceptibility to tuberculosis, personal idiosyncrasy appears to loom large, but here again much more information is required.

More data on the effects of massive exposures of man to so-called inert dusts like pure french chalk are necessary. That much-loved and much-missed Leroy Gardiner, who so greatly advanced our knowledge in this field, used to refer to exposure to "insulting" concentrations of dust—a very apposite expression.

Another point of importance is that not everybody who contracts pneumoconiosis to a diagnosable degree dies of the disease: here again we need to know much more of such cases, for they have a great bearing on preventive measures. Moreover, a person can contract more than one type of pneumoconiosis. I have a specimen of a lung from a man who contracted silicosis which was diagnosable but unlikely to kill him; he subsequently contracted asbestosis which was the cause of his death, and the lung shows both conditions.

I have touched only on a few aspects which serve to illustrate the need for more and yet more knowledge in this great field of work if the relevant preventive and social legislation is going to be completely successful in attaining its aims. They are practical problems of applied research and the solutions to them are, I suggest, matters of urgency.

I have not discussed the possible role of inhibitors such as alumina in helping the prevention and treatment of pneumoconioses, nor such questions as the effects of silica in the form of fume, the so-called nascent action of freshly fractured quartz and flint, the differences between the effect of diatomaceous earth and flint, and the great field of research still unexplored in dust counting and analysis.

Dr. C. M. Fletcher commented on the complete absence of any instruction on the subject of pneumoconiosis in the medical student's training. He referred to figures and certification from coalminers' pneumoconiosis to show that the disease is of great importance and is crippling the industry in South Wales at present. He then referred to some findings of Dr. Alice Stewart in a survey of men certified from pneumoconiosis in South Wales, showing that after certification, the disease is commonly progressive, despite cessation of dust exposure. The finding of a raised sedimentation rate in most progressive cases suggests that this progression may be due to infection, possibly tuberculous, but the results of cultures of sputum have not so far lent support to this hypothesis.

Dr. Fletcher then referred to the many problems at present outstanding in this field to which the Pneumoconiosis Research Unit were directing their attention.

Professor Matthew J. Stewart (*Leeds*): I shall confine my remarks to two aspects of this subject, namely (1) what I propose to term subclinical silicosis and (2) certain pathological considerations in relation to asbestosis.

SUBCLINICAL SILICOSIS

That the healthy lung is capable of dealing effectively with even large quantities of silicious dust is a fact which is still insufficiently recognized. Everyone is familiar with the coal-black discoloration and enlargement of the hilar and tracheobronchial lymph glands of the middle-aged and elderly town-dweller and the blue-black mottling, often confluent, of the pleural surface of the lungs which result from the long-continued inhalation of coal dust and soot, but the fact that such dust invariably contains traces or even considerable quantities of silica is less generally appreciated. So long as the parenchyma of the lung is otherwise healthy, its power of clearance, by lymphatic drainage, of silicious dust is very great. This is clearly shown by the not infrequent discovery of silicotic lesions in the hilar and tracheobronchial lymph glands, and in the immediately subpleural pulmonary tissue, while the rest of the pulmonary parenchyma is completely free from any suggestion of silicosis. Occasionally even the upper abdominal lymph glands may be grossly silicotic without any recognizable lesion being present in the substance of the lungs. The affected lymph glands are usually greyish-black on section, instead of jet black as in the more purely anthracotic lesion. They are also harder in consistency and drier on section. For many years in the post-mortem room I have made use of a simple test for determining the extent to which an enlarged and blackened lymphatic gland is silicotic. If the freshly cut surface of such a gland is dried by dabbing it momentarily on a dry cloth (e.g. one's P.M. room coat), it will remain dry afterwards if the lesion is in any appreciable degree silicotic. In a purely (or almost purely) anthracotic lymph gland, on the other hand, the cut surface will again become moist and glistening as soon as it is removed from contact with the dry cloth. I have confirmed the value of this test on many occasions by subsequent histological examination.

Now these lymph-gland and subpleural lesions are, in general, mere casual findings at autopsy in persons dying from other and quite unrelated diseases. Women are

This both by close follow-up of human cases and by animal experiment. Hitherto radiography in this field has been as an indispensable aid to diagnosis; now we would like it also to serve as an aid to the assessment of disablement and as a real guide to prognosis. Both these aspects are of increased importance in connexion with the improved basis of compensation provided by the Industrial Injuries Act and in respect of new rehabilitation measures provided for by the Disabled Persons (Employment) Act of 1944, and the new factories provided by the Board of Trade for the suitable employment of pneumoconiotics.

The assessment of disablement in pneumoconiotics is a most difficult matter to set on a scientific basis since at present so much depends, at least in the earlier stages, on the reactions of the individual, both involuntary and voluntary, to exercise.

There are many other aspects on which the lack of fundamental data is hampering progress of which I shall mention only a few.

We do need a great deal more knowledge of incidence rates and morbidity rates for pneumoconiosis in the relevant occupations. Incidence rates should provide, over a period of time, a sensitive index of the efficiency of preventive measures. The risk of silicosis, for example, varies very much in different occupations, as also does the average severity of the cases.

An average of 6·6 deaths a year during the six years 1940–45 from silicosis in sandblasters is no measure of the risk unless we know the population of sandblasters. Actually it is small, and therefore a few deaths represent a high mortality rate. A number of years ago I estimated that 5·4% of a population of sandblasters died from silicosis or silicosis with tuberculosis in the space of three and a half years.

A very rough calculation, but sufficient to give an indication of the importance of this point, shows that while the number of deaths from silicosis in coalminers each year is over 38 times that of sandblasters, the mortality rate from silicosis per 1,000 sandblasters is some 18 times that of coalminers and probably higher.

We can get an idea of the comparative risk and severity in certain occupations by comparison of the average duration of employment in fatal cases of silicosis: these range from 8·4 years to 39·1 years, the overall average duration of employment of 902 fatal cases of silicosis being 34·1 years, that of 54 sandblasters being 12 years, and that of 154 fatal cases of asbestosis being 14·9 years.

Apart from susceptibility to tuberculosis, personal idiosyncrasy appears to loom large, but here again much more information is required.

More data on the effects of massive exposures of man to so-called inert dusts like pure french chalk are necessary. That much-loved and much-missed Leroy Gardiner, who so greatly advanced our knowledge in this field, used to refer to exposure to "insulting" concentrations of dust—a very apposite expression.

Another point of importance is that not everybody who contracts pneumoconiosis to a diagnosable degree dies of the disease: here again we need to know much more of such cases, for they have a great bearing on preventive measures. Moreover, a person can contract more than one type of pneumoconiosis. I have a specimen of a lung from a man who contracted silicosis which was diagnosable but unlikely to kill him; he subsequently contracted asbestosis which was the cause of his death, and the lung shows both conditions.

I have touched only on a few aspects which serve to illustrate the need for more and yet more knowledge in this great field of work if the relevant preventive and social legislation is going to be completely successful in attaining its aims. They are practical problems of applied research and the solutions to them are, I suggest, matters of urgency.

silicosis in both mediastinum and upper abdomen, but the lungs were hardly affected. The cause of death was congestive heart failure with great cardiac hypertrophy, apparently due to intense indurative mediastinitis with complete obliteration of the pericardium and both pleural sacs. To this the glandular silicosis may well have contributed, but there was evidence also of old rheumatic valvular disease, although without serious mechanical defect.

PULMONARY ASBESTOSIS

The contrast between silicosis and asbestosis in respect of the character and distribution of the lesions is now well established. In asbestosis the fibrosis is diffuse or patchy but never nodular, and it is always more marked towards the bases of the lungs than elsewhere. In silicosis the upper portions of both upper and lower lobes are most frequently affected. In asbestosis, when a long interval of time has elapsed since exposure to the dust, the affected portions of the lung become sharply demarcated from adjacent comparatively healthy portions, but they never assume a nodular character. Bronchiectasis, often advanced and complicated by suppuration, is frequent in long-standing and severe cases of asbestosis: it is rare in silicosis, even when advanced. I attribute the difference in distribution of the lesions to the very different physical characters of the two dusts. The finely particulate silicious dusts are capable of being inhaled right into the bronchioles and no doubt some of the dust reaches the lung alveoli themselves. Asbestos dust is composed of sharp-pointed fibres of varying and often very considerable length—up to 100μ or more. They are much more likely to become stuck in the lumen of the bronchioles, or even to engage, by their sharp-pointed ends, in bronchi of larger size. Ultimately such fibres are likely to gravitate downwards to the bases, especially of the lower lobes, while far fewer are carried, by inhalation, into the apical regions, especially of the upper lobes.

Mechanical transportation by phagocytes is also very different in the two cases. It is easy for alveolar phagocytes to take up a charge of silicious particles, to transport it into the lung substance, and then to carry it, via the lymphatic channels, to the regional and even more distant lymph glands. The result in many cases, as already mentioned, is the development of a true silicotic lesion within the lymphatic glands themselves, most frequently the hilar and tracheobronchial, occasionally those of the upper abdomen. Transportation of asbestos fibres is a very different matter. While short fibres and short asbestos bodies are often engulfed in mononuclear phagocytes capable of movement and migration, it is much more usual to see large multinucleated giant cells, probably non-motile, with these structures in their interior. Yet in spite of the enormous number of asbestos fibres and bodies present within the lungs, it is only very exceptionally and in very small numbers that one sees them in the hilar or other lymph glands, and I am not aware that any lesion resulting from their presence has ever been described outside the lungs and pleura.

The diagnostic significance of asbestos bodies in the sputum.—Asbestos bodies probably make their appearance sooner or later in the sputum of all persons exposed for any length of time (weeks to months) to an atmosphere containing asbestos dust. In a case reported by Simson and Strachan (1931) they were present after only five months' exposure and I have found them in the sputum of persons whose occupation entailed only their occasional presence in the asbestos factory. It would seem that the sputum must come from the lung itself, or from the bronchioles at least, and usually the bodies are only demonstrable after the use of a concentration method and when the patient has a bronchitic attack or "chest cold". The presence of bodies as such in the sputum merely indicates that asbestos dust has been inhaled and has remained *in situ* for at least two or three months. It does as frequently affected as men and there is usually no history of the person having been engaged in an industry with a recognized silicosis risk. They have inhaled the dust from their "normal" environment and it has done them little harm. As a rule they are advanced in years. In persons employed (or who have formerly been employed) in "silicosis" industries, similar "subclinical" lesions are not infrequently encountered at autopsy and it is undesirable that undue significance should be attached to these findings in assessing claims for compensation. Naturally there are all intermediate grades between this strictly localized type of lesion and a full-blown silicosis with nodular or confluent lesions scattered throughout the parenchyma of the lungs.

In compensation cases, more importance should, however, be assigned to the presence of minimal (subclinical) silicotic lesions if these are accompanied by pulmonary tuberculosis, but in my experience this association is an infrequent one.

The silicotic apical scar.—For years it has been generally accepted (and supported by high authority) that virtually all apical scars are the result of old tuberculous disease. This view has always been challenged by a small number of observers, but it has remained for Davson and Susman (1937) and Davson (1939) to produce the final proof that the vast majority of these scars are silicotic and not tuberculous. In a series of 94 consecutive autopsies at all ages (excluding cases of gross pulmonary disease) there were 40 cases with apical scars which showed no histological evidence of healed tuberculosis and only 6 which did. A definite relationship was shown to exist between silicious dust accumulation in the upper part of the lungs and the presence of these non-tuberculous scars. Moreover frank silicotic nodules in various stages of development were demonstrated in 13 of these 40 cases, all of them belonging to the later age-groups in whom there was a high silica content in the lungs generally. The chief feature of the morbid histology of these non-tuberculous (silicotic) scars was the existence of an unbroken network of proliferated elastic fibres corresponding to the original pattern of the lung alveoli. The tuberculous scars, on the other hand, presented definite evidence of healed or quiescent tuberculosis, with one or more necrotic areas showing varying amounts of calcification, in all cases surrounded by a well-defined fibrous capsule. These caseous or calcified areas were devoid of any elastic network, indicating that there had been a breakdown of lung structure of a kind not seen in the purely silicotic type of scar. Davson has produced additional histological evidence for the non-tuberculous character of the vast majority of apical scars.

In fact, it is usually quite easy to distinguish the two types of scar by the naked eye. Purely silicotic scars are nearly always flat and superficial, but may be, superficially, quite extensive, and they are often covered by a plaque of hyaloserositis. On section they are black, grey-black or blue-black in colour, with a sharply-defined deeper margin. They range from 1 or 2 mm. to about 1 cm. in thickness and the cut surface is usually homogeneous. There are no contained foci of caseation or calcification. Pleural adhesions are usually lacking, and when present are by no means dense. These silicotic scars start at quite an early age and continue to enlarge with the passage of time. Like the other subclinical forms of silicosis already described they are no doubt due to the inhalation of road dust and silicious ash from domestic and industrial fires.

Silicosis of the spleen.—Classical nodular silicosis of the spleen is rare. It is probably due in most cases to a silicotic gland or glands ulcerating through into a branch of the pulmonary artery or vein (cf. Heggie, 1946). It can therefore occur in cases of glandular (subclinical) silicosis as well as in cases of gross pulmonary disease. Indeed the only case which I have seen was of this kind. There was gross glandular silicosis in both mediastinum and upper abdomen, but the lungs were hardly affected. The cause of death was congestive heart failure with great cardiac hypertrophy, apparently due to intense indurative mediastinitis with complete obliteration of the pericardium and both pleural sacs. To this the glandular silicosis may well have contributed, but there was evidence also of old rheumatic valvular disease, although without serious mechanical defect.

PULMONARY ASBESTOSIS

The contrast between silicosis and asbestosis in respect of the character and distribution of the lesions is now well established. In asbestosis the fibrosis is diffuse or patchy but never nodular, and it is always more marked towards the bases of the lungs than elsewhere. In silicosis the upper portions of both upper and lower lobes are most frequently affected. In asbestosis, when a long interval of time has elapsed since exposure to the dust, the affected portions of the lung become sharply demarcated from adjacent comparatively healthy portions, but they never assume a nodular character. Bronchiectasis, often advanced and complicated by suppuration, is frequent in long-standing and severe cases of asbestosis: it is rare in silicosis, even when advanced. I attribute the difference in distribution of the lesions to the very different physical characters of the two dusts. The finely particulate silicious dusts are capable of being inhaled right into the bronchioles and no doubt some of the dust reaches the lung alveoli themselves. Asbestos dust is composed of sharp-pointed fibres of varying and often very considerable length—up to 100μ or more. They are much more likely to become stuck in the lumen of the bronchioles, or even to engage, by their sharp-pointed ends, in bronchi of larger size. Ultimately such fibres are likely to gravitate downwards to the bases, especially of the lower lobes, while far fewer are carried, by inhalation, into the apical regions, especially of the upper lobes.

Mechanical transportation by phagocytes is also very different in the two cases. It is easy for alveolar phagocytes to take up a charge of silicious particles, to transport it into the lung substance, and then to carry it, via the lymphatic channels, to the regional and even more distant lymph glands. The result in many cases, as already mentioned, is the development of a true silicotic lesion within the lymphatic glands themselves, most frequently the hilar and tracheobronchial, occasionally those of the upper abdomen. Transportation of asbestos fibres is a very different matter. While short fibres and short asbestos bodies are often engulfed in mononuclear phagocytes capable of movement and migration, it is much more usual to see large multinucleated giant cells, probably non-motile, with these structures in their interior. Yet in spite of the enormous number of asbestos fibres and bodies present within the lungs, it is only very exceptionally and in very small numbers that one sees them in the hilar or other lymph glands, and I am not aware that any lesion resulting from their presence has ever been described outside the lungs and pleura.

The diagnostic significance of asbestos bodies in the sputum.—Asbestos bodies probably make their appearance sooner or later in the sputum of all persons exposed for any length of time (weeks to months) to an atmosphere containing asbestos dust. In a case reported by Simson and Strachan (1931) they were present after only five months' exposure and I have found them in the sputum of persons whose occupation entailed only their occasional presence in the asbestos factory. It would seem that the sputum must come from the lung itself, or from the bronchioles at least, and usually the bodies are only demonstrable after the use of a concentration method and when the patient has a bronchitic attack or "chest cold". The presence of bodies as such in the sputum merely indicates that asbestos dust has been inhaled and has remained *in situ* for at least two or three months. It does not necessarily mean that a fibrotic process is already in existence or that asbestosis will ultimately develop. Concentration of dust as well as length of exposure must be taken into account: probably it is the more important. It remains to be seen just how effective are the elaborate preventive measures now in use in the factories, but I must point out that all the fatal cases I have seen were those of persons who had been employed in asbestos manufacture for at least part of their working time prior to the introduction of these modern preventive measures.

The finding of "clumps" of asbestos bodies in the sputum is a very different matter (Stewart, Tattersall and Haddow, 1932; Page, 1935). In order that such clumps may escape from the parenchyma of the lung it is necessary that the alveolar walls should be broken down, either by a simple suppurative (bronchopneumonic) process or by tubercle. The former is the more likely, as tuberculous caseation not only causes the clumps to disintegrate but also leads to absorptive changes in the bodies themselves. Clumps must be searched for with care and a concentration method should be used (Stewart, 1929, 1934), but not too vigorously lest the clumps be broken down. I have now found clumps in the sputum in nearly a dozen cases and am satisfied that their presence is tantamount to a diagnosis of asbestosis. By this time, it must be admitted, it is probable that the clinical and radiological picture is already diagnostic, and the search for clumps a work of supererogation. The presence of single bodies in large numbers, especially if they are large, deeply pigmented and much "weathered", is at least suggestive and confirmatory.

Finally I would record the opinion that asbestosis is a more serious disease than silicosis. Even a short period of exposure (six months for example) to a dust of sufficient concentration may lead to a progressive fibrotic process which will ultimately kill the patient, it may be after an interval of many years. There can be no doubt, however, that modern protective methods are very effective in minimizing the occupational risk, and much credit is due to Dr. Merewether for his pioneer investigations into this sinister and insidious disease and its prevention.

Some Experiences with Bone Tumours. [*Abridged*]

By JAMES F. BRAILSFORD, M.D., PH.D., F.R.C.P., F.I.C.S.

Radiologist, The Royal Cripples and The Queen Elizabeth Hospitals, Birmingham

THERE is probably no more interesting or varied study in pathology than the study of bone tumours. Throughout the years there has been a constant search by clinicians, pathologists and more recently radiologists to find evidence which would reveal the nature of these lesions. Much has been learnt which permits us to classify the majority of bone tumours; but with one's experience limited to a little less than forty years—which includes the macroscopic and microscopic study of pathological conditions in the food animals at the Birmingham Public Abattoir for over nine years—I have to admit that we have not yet discovered one sign on which we can entirely depend for a solution of our difficulties. We have learnt that the clinical features can be indistinguishable, though the tumours are essentially different, even as regards their simplicity and malignancy; they may appear to be grave yet the lesion simple; they may appear insignificant yet the lesion may be deadly.

Because it was felt that early diagnosis and prompt amputation gave the best chance to eradicate malignant disease, undue significance and reliance have been placed upon the interpretation of the histological appearances of the tumour tissue, and biopsy became, and in some centres still is, the recognized initial measure in treatment. Alas, because pathology was taught from well-established lesions which presented certain well-defined characters, the impression was conveyed to surgeons that biopsy afforded the best evidence. But those who have had a wide experience know that the most simple lesions can contain cellular tissues which are indistinguishable from some considered as characteristic of malignancy; though in some highly malignant tumours those characters may not be found. Hence, from a given tumour, material has been submitted to a number of expert pathologists and as many different opinions have been obtained, ranging from simplicity to high malignancy. The more extensive the histological investigations throughout the course of a bone tumour, the more varied and confusing the opinions of the different observers appear to be. On the other hand, individual histologists have seen the same cellular structures in groups of tumours which they have classified accordingly, though these tumours have been proved clinically and radiologically to be of essentially different pathology. No better examples of this can be seen than those two cases illustrated on pages 192 (fig. 125) and 193 (fig. 126) in Geschickter and Copeland's "Tumors of Bone" 1936 [1]. Both tumours are recorded as being chondroblastic sarcoma from their histological appearances, yet the radiographic definition of the tumour tissue in fig. 125 suggests simplicity which is borne out by the subsequent cure, whereas fig. 126 shows that the bone structure has been reduced to a "mush", as one would expect from the irregular destruction by invasion of malignant cells and this is borne out by the subsequent fatal issue.

To-day with the ubiquity of X-ray units the radiograph has become the first court of reference. This court also has its great limitations and difficulties which are all too little appreciated. As in pathology, so in radiology, the teaching of clinicians has been from spectacular and well-established radiographic appearances while the more common slight and insidious changes, because more difficult to appreciate by any but the experienced observers, have been avoided.

Because the radiographs of lesions show spectacular localized irregularities in calcification and ossification such lesions are thoughtlessly dubbed sarcomata, and sometimes it is not until irrevocable and unnecessary amputation has been performed, and the subsequent history has indicated the useless disaster, that the cases have been published as "—— simulating sarcoma". The literature contains records of many such cases. Amputations have been performed because of a mass of callus at the site of an unrecognized fracture, localized myositis ossificans, subperiosteal hæmatomata, and hæmatomata associated with neurotropic lesions, scurvy, osteogenesis imperfecta, hæmophilia, &c.

The admonishing words of John Hunter, "It is astonishing to see what little curiosity people have to observe the operations of nature and how very curious they are about the operations of art", deserve to be especially emphasized in the diagnosis and treatment of bone tumours. Radiology has given the clinician a further means of observing the not necessarily mean that a fibrotic process is already in existence or that asbestosis will ultimately develop. Concentration of dust as well as length of exposure must be taken into account: probably it is the more important. It remains to be seen just how effective are the elaborate preventive measures now in use in the factories, but I must point out that all the fatal cases I have seen were those of persons who had been employed in asbestos manufacture for at least part of their working time prior to the introduction of these modern preventive measures.

The finding of "clumps" of asbestos bodies in the sputum is a very different matter (Stewart, Tattersall and Haddow, 1932; Page, 1935). In order that such clumps may escape from the parenchyma of the lung it is necessary that the alveolar walls should be broken down, either by a simple suppurative (bronchopneumonic) process or by tubercle. The former is the more likely, as tuberculous caseation not only causes the clumps to disintegrate but also leads to absorptive changes in the bodies themselves. Clumps must be searched for with care and a concentration method should be used (Stewart, 1929, 1934), but not too vigorously lest the clumps be broken down. I have now found clumps in the sputum in nearly a dozen cases and am satisfied that their presence is tantamount to a diagnosis of asbestosis. By this time, it must be admitted, it is probable that the clinical and radiological picture is already diagnostic, and the search for clumps a work of supererogation. The presence of single bodies in large numbers, especially if they are large, deeply pigmented and much "weathered", is at least suggestive and confirmatory.

Finally I would record the opinion that asbestosis is a more serious disease than silicosis. Even a short period of exposure (six months for example) to a dust of sufficient concentration may lead to a progressive fibrotic process which will ultimately kill the patient, it may be after an interval of many years. There can be no doubt, however, that modern protective methods are very effective in minimizing the occupational risk, and much credit is due to Dr. Merewether for his pioneer investigations into this sinister and insidious disease and its prevention.

behaviour of bone tumours, and though it has the advantage recognized by the lay and medical press of 1896, immediately Roentgen's discovery was made known, i.e. that the examination can be made without causing the patient any additional pain, it has been neglected. One radiographic examination may give the required evidence for diagnosis, but in many cases it is insufficient for this purpose, and, like the clinical examination, must be repeated, sometimes frequently, over a course of months, before we can determine the nature of the lesion.

In previous papers [2] I have drawn attention to the importance of the latent negative radiographic period which elapses between the onset of clinical signs and symptoms and the development of sufficient changes for radiographic demonstration, and the positive radiographic symptomless period during which there may be spectacular radiographic evidence of healed lesions which are of no clinical significance. As an instance of the significance of the former we may take metastatic carcinoma where the clinical signs and symptoms may be present at a site months before radiographs indicate characteristic changes in the bone. As an instance of the latter—the positive radiographic symptomless period—we have no better example than the aseptic infarct in bone which occurs without recognition and is not discovered until a radiograph of the part is taken because of some other factor, i.e. trauma, arthritis; then undue significance may be placed upon the spectacular radiographic appearances, and biopsy with its erroneous histological interpretation is sometimes followed by unnecessary amputation. Failure to seek the co-operation of the radiologist is responsible for many errors and any registry of bone tumours which fails to recognize that expert radiographic evidence is an essential complement to that obtained by the clinician and pathologist will fail to achieve the best results; indeed, it may give rise to erroneous impressions.

There is perhaps no better instance of the confusion which can arise from interpretations of extensive histological examinations in the case of a simple lesion with prominent clinical signs and ill-understood spectacular radiographic appearances than that recorded by S. L. Baker [3]. In this case of osteogenesis imperfecta, the child sustained a fracture and at the site an extensive hæmorrhage occurred which produced clinical and radiographic signs interpreted as those of a rapidly growing sarcoma. A biopsy was performed five weeks after the fracture and "disarticulation of the hip was considered but regarded as too risky and of doubtful value and palliative X-ray treatment was decided on". A course of deep X-radiation was given. The first biopsy yielded material which "I considered showed a chondrosarcoma but later had expressed doubt upon, considering that the extreme rarity of a sarcoma developing on fracture indicated further investigation of the biopsy material". A second biopsy yielded material which favoured a better outlook, and clinical and

Fig. 1a.—Radiograph, December 28, 1944, of arm of girl, M. W., aged 14 years, with the history of an injury seven weeks previously, showing multiple linear accretions on upper third of the humerus with some alteration in the internal structure, surrounded by a massive fusiform swelling of the soft tissues. Clinically diagnosed as a Ewing's sarcoma. Found to have a positive Wassermann.

Fig. 1b.—Radiograph of M.W., October 1, 1946, after sulphathiazole and antisyphilitic medication —complete resolution.

It is very rare for trauma to be followed at once by the development of sarcomatous metaplasia. The history of trauma is often given in cases of sarcoma, but radiographs taken immediately after the alleged trauma indicate that the lesion was well developed at the time of the trauma, which, because of abnormal tenderness, drew the patient's attention to the site. A knowledge of the time taken for the sequence of radiographic changes to have developed supported the view that the trauma was the cause of the lesion.

In some cases sarcomatous metaplasia occurs at the site of a known old fracture or lesion in the bone. The radiographs will indicate, however, to the trained observer that the bone lesion is old, but it may not, in the early stages, show any evidence that malignancy has developed. It is the clinical evidence in these cases which should guide us.

Fig. 2a.—Radiograph of fusiform swelling of upper arm of B.W., aged 6 years, November 1944, showing disintegration of the upper half of the humeral shaft periosteal cuff and multiple lesions in the lungs.

Fig. 2b.—Radiograph of B. W., January 4, 1945, showing marked increase in the lung lesions. Diagnosed as sarcoma with multiple secondaries in the lungs. All lesions completely resolved within a few months and patient now quite fit. The only medication—a course of sulphathiazole.

The nature of the condition must be one of conjecture. Even for an osteomyelitis (of which she gave no clinical or laboratory evidence) with multiple pulmonary infarcts, the cure is very remarkable, for neither the bone nor the lung, which were both seriously affected, showed any residual lesion—a rarity with such disintegration. It is possible that the condition was related to that group of bone pathology, the granulomata of reticulo-endotheliosis which includes xanthomatosis, lipoid granuloma, eosinophil granuloma, or possibly to some such infection as parathyroid, for lesions in this group may heal without leaving any scars. As I have indicated elsewhere [8] aborted osteomyelitis from any cause may be associated with radiographic appearances liable to be mistaken for sarcoma. A remarkable and complete cure resulted in this case without any surgical intervention.

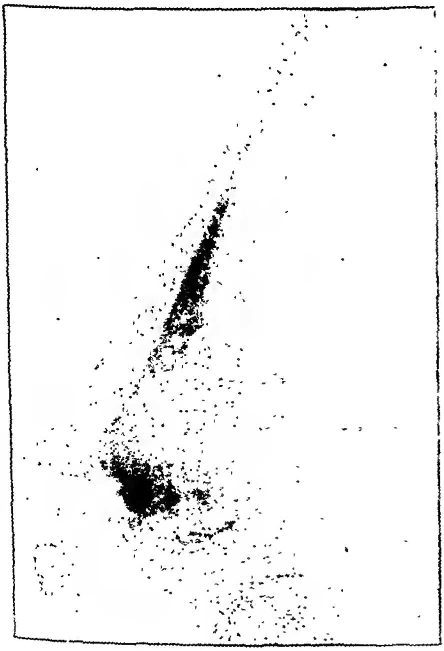

FIG. 4A

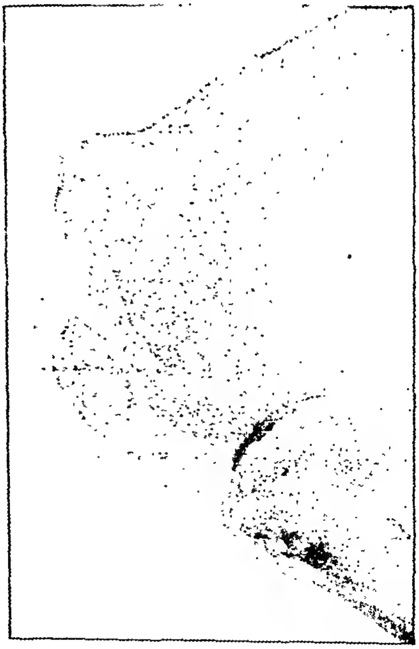

FIG. 4B

radiographic observations over three years confirmed this. But as I had indicated in a previous paper [4], to which S. L. Baker referred, the nature of such lesions, their development, and even their essential histological features may be determined by serial radiographic examinations which cause the patient no pain and do not involve the risk of the erroneous interpretation which might have cost this patient useless pain and risk of losing the affected limb. As I recorded, such a lesion in a patient with osteogenesis imperfecta did eventually develop malignant metaplasia, with the spread of metastases and death; but this event has been seen to occur in isolated cases with localized or generalized osseous dysplasia but is not the common sequence.

When we consider the answer to the question, What is a bone tumour? we must use some classification of the lesions which appear clinically, histologically and radiographically to fall under that heading. As I have indicated in a previous paper [5] classification of bone tumours on clinical signs and symptoms alone is impossible. Classification on clinical and histological grounds together is likely to be erroneous as already indicated, and must be based essentially on post-mortem and histological appearances rather than on living tissue. Modern classification is being made principally on radiographic findings, though, as indicated, this must be made with recognition of possible shortcomings. By radiography alone can we study the living structure of the tumour, watch its development, life-history and the reaction of the adjacent tissues; but in our interpretation we must always keep a careful scrutiny of the clinical course. The radiography must always be first-class showing the intimate osseous structure in sharp definition with the lesion in the middle of the radiograph so that its extension and changes can be compared with subsequent radiographs. Anything less than this is unsatisfactory and may seriously affect the interpretation.

By radiography we can separate the bone tumours into the following seven sections: (1) Congenital and developmental irregularities of the skeleton. (2) Dysplasias and dystrophies of bones. (3) The deficiency and blood diseases affecting the skeleton. (4) The secondary effects of trauma to bone. (5) Granulomata of bones. (6) Simple tumours of bones. (7) Malignant tumours of bones.

Briefly summarized, the essential features of lesions in these sections are as follows:

(1) *The Congenital and Developmental irregularities of the skeleton* can be recognized from the maturity of the osseous structure of the affected bones.

(2) *Dysplasias and dystrophies of the skeleton.*—The skeletal changes associated with these irregularities of mesoblastic growth may affect

(*a*) the whole skeleton as in: Osteogenesis imperfecta; Albers-Schönberg's disease; achondroplasia; chondro-osteo-dystrophy,

or

(*b*) while in isolated cases the dysplasia may be generalized throughout the skeleton, it is more frequently found to involve mainly one side of the skeleton; every bone on that side being completely involved, or bearing but single or multiple foci; the bones on the other side being free or exhibiting one or two small lesions.

The degree of the dysplasia may be such as is incompatible with life; it may permit of childbirth, the infant may come to adolescence or maturity; again, it may be so trivial that it is only discovered by radiography during examination following trauma, disease, &c. The recognition of such lesions may be of great significance.

Such dysplasias may be associated with:

(*a*) Proliferation of myxomatous tissue (polycystic dysplasia or osteitis fibrosa cystica).
(*b*) Proliferation of fibrous tissue (fibrosis of bone; polycystic fibrous dysplasia).
(*c*) Proliferation of angiomatous tissue (Kast's disease, &c.).
(*d*) Proliferation of chondrous tissue. (Ollier's disease, &c.).
(*e*) Proliferation of osseous tissue (multiple exostoses; Keith's diaphyseal aclasia).
(*f*) Proliferation of abnormal osseous tissue (Léri's melorheostosis).

These dysplasias may be associated with the deficiency diseases, &c., their appearances being accordingly changed.

The differential diagnosis includes such diseases as rickets, scurvy, hæmophilia, osteo-myelo-sclerosis (associated with polycythemia and subsequently anæmia and leukæmia), fluorosis, carcinomatosis, myelomatosis, hyperparathyroidism, Paget's disease.

FIG. 4A.—Radiograph, November 28, 1944, of painless and much swollen leg of a boy aged 14 years, showing a fracture dislocation through the femoral diaphysio-epiphyseal junction and multiple linear accretions on the lower half of the diaphysis, detached bony fragments and calcium deposits in the soft tissues. Amputation avoided because of paralysis of extremities associated with spina bifida.

FIG. 4B.—Radiograph, May 24, 1946, showing complete resolution of the lesion. No treatment of any description in the interval.

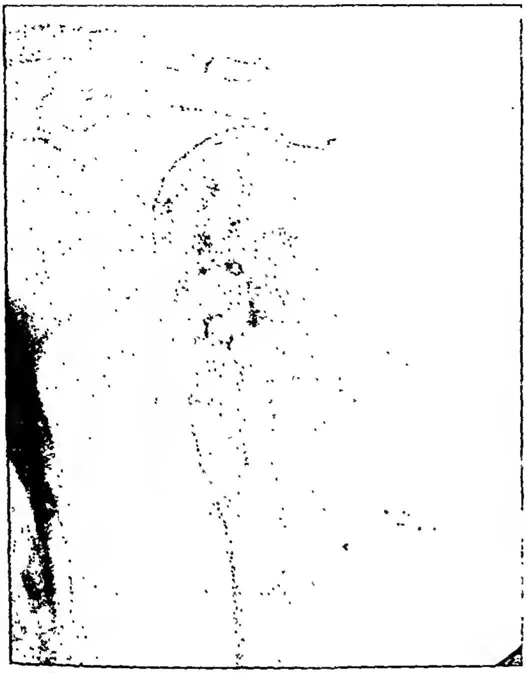

FIG. 3A

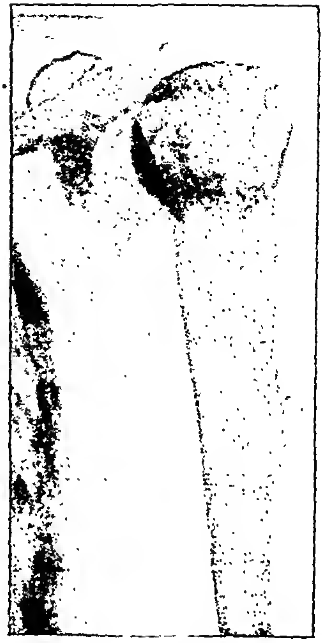

FIG. 3B

FIG. 3A.—Radiograph October 27, 1938, of fusiform swelling of arm of girl aged 18 years showing disintegration of upper third of the humerus.

FIG. 3B.—Radiograph of same case, fig. 3A, October 4, 1940 (1,274 r had been given in the interval), showing complete resolution, which has persisted.

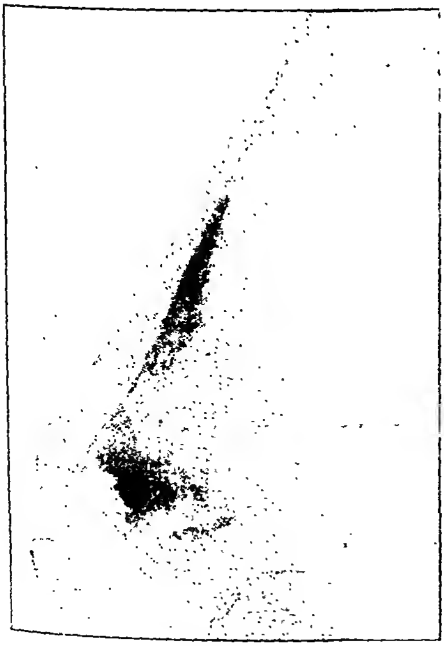

FIG. 4A

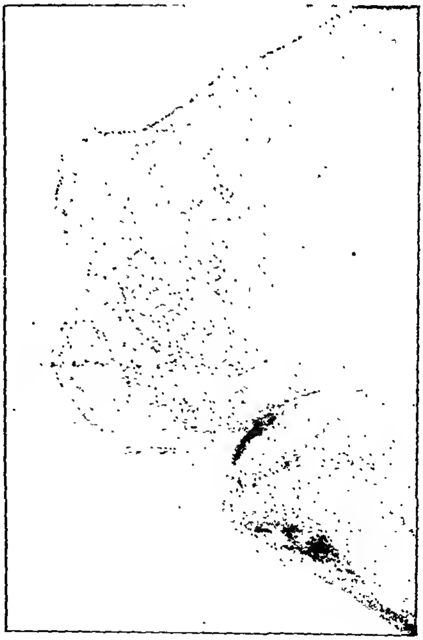

FIG. 4B

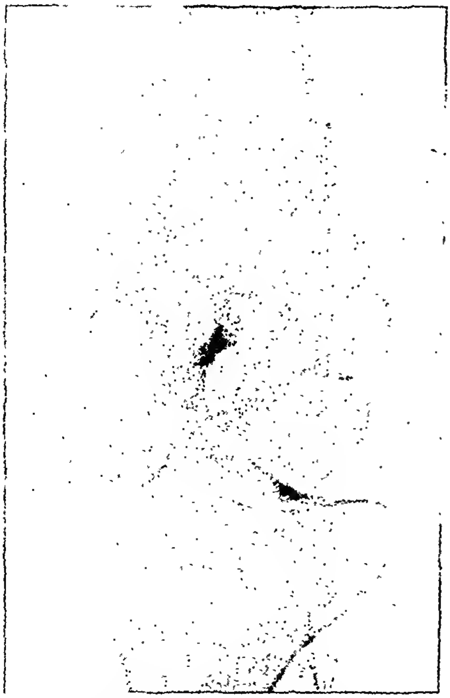

FIG. 5A.—Radiograph of M. H., aged 20 years, August 15, 1945. Osteoclastoma.

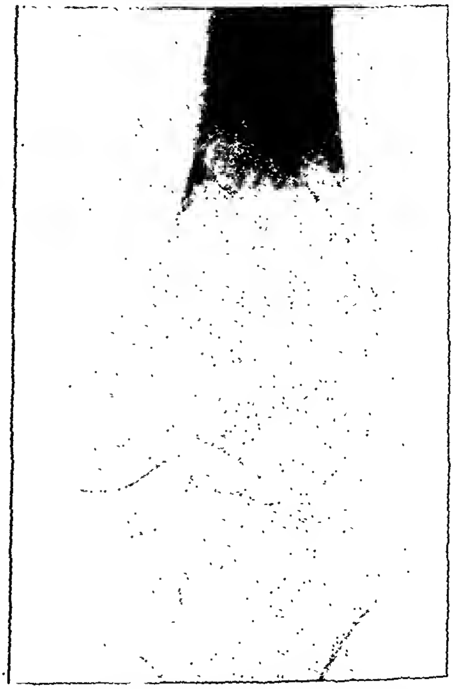

FIG. 5B.—Radiograph of M. H., September 23, 1946, after X-radiation therapy.

FIG. 5A and 5B.—This case illustrates an osteoclastoma which responded with the known sequence of changes following X-radiation therapy, i.e. for a month or so progressive decalcification, destruction of bone in and around the tumour site, followed by gradual recalcification and consolidation, and—if the limb has been carefully immobilized during the osteolytic phase—without any deformity. No biopsy was performed, there has been no sign of secondaries and the limb is sufficiently consolidated to permit of normal function.

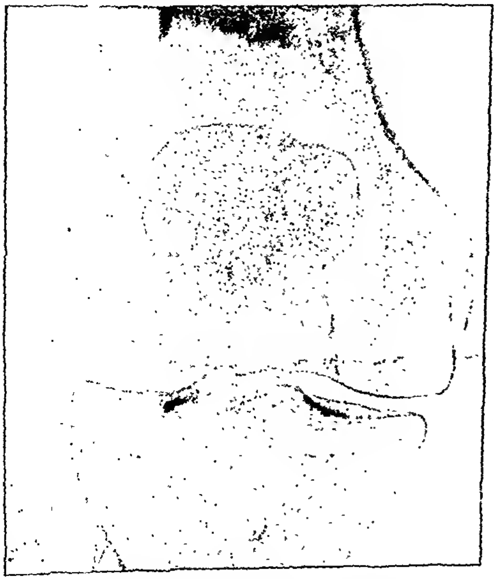

FIG. 6A

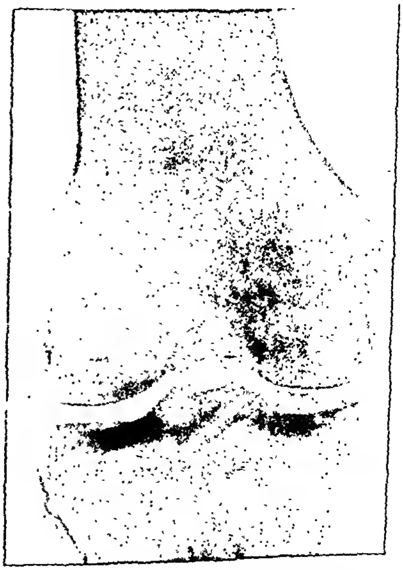

FIG. 6B

FIG. 6A.—Radiograph of R. M., aged 31 years. July 1944. Diagnosed osteoclastoma on radiographic appearances. FIG. 6B.—Radiograph, January 1, 1945. Failure to respond to repeated courses of deep X-radiation—amputation because of hæmorrhage—histology typical osteoclastoma. No recurrence to this date (November 1947) and patient in good health.

(3) *The deficiency and blood diseases affecting the skeleton.*—The characteristic clinical and radiographic features of fœtal, infantile, resistant or late rickets, renal rickets, osteomalacia, idiopathic steatorrhœa. Dislocations, fractures, healing deformities.

Scurvy: Subperiosteal hæmorrhages. Dislocations. Tumours associated with osteogenesis imperfecta.

Hæmophilia: Tumours simulating sarcoma. Joint changes.

Polycythemia, Anæmias and Leukæmias: General skeletal changes. Osteo-myelosclerosis. Localized foci.

(4) *The secondary effects of trauma on bone* in which we must consider: (*a*) the time factor in production of changes, (*b*) the latent negative radiographic period and the positive radiographic symptomless period, (*c*) overlap of these periods.

Acute atrophy of bone: Myositis ossificans. Conflicting histology. Treatment.

Avascular necrosis: Time factor very important for detection. Secondary effects. Joint changes. Plasticity of bones. Secondary inflammatory and neoplastic changes. Frequency.

(5) *Granulomata of bone.*—Time factor in the production of clinical and radiographic signs. The latent negative and positive radiographic periods. Changes produced in bones by different organisms—the rate of change at different ages—the degree of resolution at different ages.

Pyogenic organisms: The typhoid group.

Brodie's abscess: Differential diagnosis.

Osteoid osteoma: A granuloma with much surrounding reaction.

Tuberculosis of bones and joints: Characters of rate of development and healing. Abscess features. Frequency of pulmonary tuberculosis—type.

Syphilis of bone: Characters at different ages. Resemblance to other lesions—sarcoma, &c.

Eosinophilic granuloma: Characters—response to treatment.

Lipoidgranulomatosis: Hand-Schüller-Christian syndrome. Result of treatment. Letterer-Siwe's disease.

Lymphogranulomatosis: Bone changes in.

(6) *Simple tumours of bone and adjacent tissues.*—Lipoma, myxoma, fibroma, angioma, chondroma, osteoma and osteoclastoma, have characteristic radiographic appearances. Localized resection offers the best cure. Secondary malignant metaplasia may develop. Effect of radiation.

(7) *Malignant tumours of bone.*—The clinical features and the time factor show considerable variation.

Consideration of the 10 radiographic features [6] which are associated with malignancy. The importance of the clinical history and the value of biopsy.

Within the limits of this paper it is impossible to illustrate examples of lesions in all these sections. That has been done elsewhere [6], but the following figures illustrate a few of the many cases which were watched throughout their course, during which they exhibited features liable to be misinterpreted as indicating malignancy, yet which resolved without any surgical intervention. In some (as in the case described by S. L. Baker) major surgical measures would undoubtedly have been performed, but for other features in the cases which indicated the futility of such actions.

CONCLUSION

For the diagnosis of tumours of bones we are dependent on the clinical and radiographical evidence. This can be obtained without causing the patient any pain and without disturbing the lesion. Such evidence permits of the most accurate diagnosis. In many cases the radiographic evidence in itself is distinctive and permits accurate diagnosis at a time when the clinical examination yields little or no contribution. The values of the two methods are reversed when the lesion does not involve the bone. In some cases neither the clinical nor the radiographical evidence is sufficiently characteristic at the first examination. We may have to make repeated observations over several weeks or months before we can decide. Because it was thought that prompt amputation of the affected limb offered the best and only cure and that the waiting period could be eliminated by histological examination of the tumour tissue, a resort to biopsy was often made. I regret to say that in my experience when the clinical and the radiographic evidence is indefinite the histological appearances are at least equally indefinite—in fact may only add confusion or errors to the judgment. The cases of two young women under 20 years of age occur to me. Both of them had lesions in the lower third of the humerus. The one appeared radiographically as a localized rounded sequestrum within a cyst; it appeared to be a simple lesion. The sequestrum was enucleated and some sections were histologically examined and reported as showing evidence of a rapidly growing sarcoma. The limb was amputated but on careful examination of the specimen it had all the aspects of simplicity, though one section had the suspicious cells. The patient is now alive and fit ten years later. The second patient had an ill-defined change in the shaft, the appearance of which suggested an early Ewing's tumour, but clinically it appeared to be a localized inflammatory lesion. Some pus-like material was evacuated by the surgeon but histological examination of small pieces of tissue from the site were reported as having the characters of a highly malignant endothelial myeloma, and as at that time prompt amputation was regarded as the only chance of cure, I urged that this should be done. Fortunately the parents refused, for the lesion completely resolved, and now, ten years after, she is fit and well.

I have not been fortunate enough to see cure resulting from prompt amputation of a limb showing the typical radiographic evidence of an osteogenic sarcoma. To amputate a limb when the radiographic and clinical evidence is not conclusive, even though the histology suggests malignant disease, is to take an unjustifiable risk. If biopsy is excusable, it is so when it provides material which supports the clinical and radiographic evidence of simplicity, rather than malignancy, and prevents amputation. This raises the question as to who shall interpret the radiographic appearances. My answer is, the person who by learning and practice has fitted himself to do so. There is a growing tendency for the clinician to use his own interpretation of radiographs rather than that of his colleague, the radiologist. This is unfortunately the cause of much dissatisfaction. The clinician by co-operation can bring forth evidence which permits of great improvement in the value of the radiologist's report. Much of my own radiological interpretation I have learnt with the help of co-operating clinicians, for in certain specialized fields the clinician has the better chance of correlating the clinical and surgical findings with the radiographic appearances; but he cannot do this to the best advantage unless he has made himself acquainted with all the radiographic features likely to influence the decisions. Unless the radiologist seeks the information which the clinician can give he will be unable to give that additional help which the clinician has a reasonable right to expect. The radiologist's opinion is sometimes ignored. The clinician may well excuse himself for being wrong in such cases, but he may not forgive the radiologist for being right, until he has learnt that the practice is consistent.

May I suggest to those concerned with the education and training of radiologists that the student be taught more extensive radiology in its application to clinical methods at the expense of the practically useless physics, which at present engages far too much of his time. Some of the responsible elders in radiology appear to believe that there is no need to give the student for his diploma examination more than a general outline of the common conditions met with in radiology. To-day the medical student is taught that, but I consider that the radiologist ought to make himself so familiar with all the radiological features which are met with in all specialities, that he can give expert advice to the consultant specialist seeking it. It should be his job to find out in what way radiology can help. He will only be able to do this if he is not compelled to acquire non-essential facts. A better knowledge of clinical medicine is far more important than a smattering of physics which he can safely leave to the physicist. The more radiographs I see the more significance I place on clinical findings.

A number of cases have reported at hospital complaining of pain, unusual tumour, tenderness, pulsation, or fracture of relatively short duration; radiographs of the affected area have shown evidence of osteogenic sarcoma, and radiographs of the chest have shown, even at the first examination, evidence of secondaries in the lung. Some patients without the latter evidence have been subjected to prompt amputation but metastases have subsequently developed with fatal issue.

Experience with these cases, and with those amputations of limbs for lesions which are subsequently found to be simple, indicates that there is nothing to be gained by undue haste and precipitate amputation but something can be gained by observation of the clinical features and serial radiographs; it supports the conclusions included in the final chapter of my book.

Injuries to the Bladder

By Richard A. Mogg, F.R.C.S.

The subject matter of this paper is the result of observations on a small series of cases treated at Naval Hospitals during the recent war.

Bladder injuries are seen more frequently during wartime, even then the incidence of these injuries is not high and in the 1914–18 war, Fullerton estimated that the incidence of bladder injuries in the B.E.F. casualties evacuated from France were not more than 1 : 3–4,000. On the other hand it is quite probable that the incidence of this injury, was higher than this, as the majority of bladder injuries are complicated by severe associated injuries from which the patients may die before they reach hospital or perhaps before a diagnosis can be made while in hospital.

There are two main types of bladder injury. The first is rupture, due to sudden increase of the internal hydrostatic pressure, and the second due to puncture or perforation from some foreign body or adjacent bone. With the exception of injuries sustained in wartime, rupture of the bladder is the more frequent of the major injuries of the bladder; occurring more often in males because of the greater hazard of exposure of the male to trauma. The injury is more frequently seen in the adult, but recent statistics from American surgeons have shown that the incidence in children is increasing, due, mainly, to the increased number of automobile accidents.

These injuries are nearly always complicated because the bladder is a well-protected viscus being entirely surrounded by bones, muscles and ligaments which constitute the pelvic girdle and it is only when it becomes distended that the apex of the bladder rises into the abdomen. It is then more vulnerable, not only because it lacks the protection of the pelvis, but because it now presents a larger target to the trauma-producing agent. Rupture of the distended bladder can result from comparatively slight trauma to the anterior abdominal bladder wall; this is especially seen in conditions that allow the bladder to become over-distended and the foremost of these is alcoholic intoxication. The diuretic effect of the alcohol fills the bladder allowing it to become overfilled and, combined with impairment of cerebration which prevents the anticipation of trauma, there is a lack of the normal protective function of the abdominal wall muscles for the bladder.

The anatomy of the pelvic fascia is the key to the subsequent pathological processes which occur following bladder injuries (figs. 1 and 2). Below the peritoneal attachments of the bladder, the vesical part of the visceral layer of the pelvic fascia completely invests the bladder, being loosely attached to it at the front and sides. It is the loose attachment of the fascia that allows the bladder to distend during the filling phase. This perivesical fascia can be definitely divided into two compartments, an anterior and a posterolateral, there being a free connexion between the two. The anterior or prevesical space can be readily

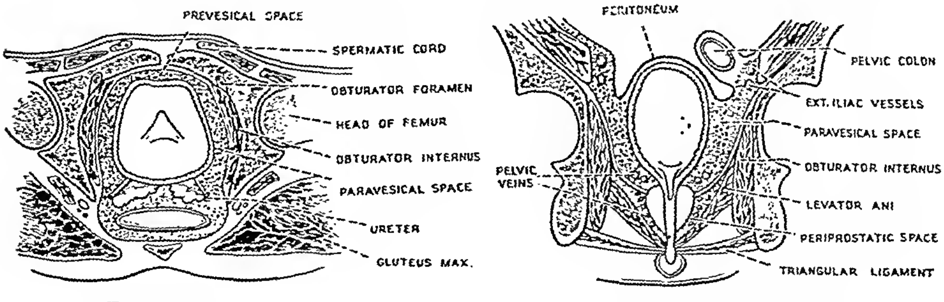

Fig. 1.—Transverse section

Fig. 2.—Vertical section.

Figs. 1 and 2.—Diagrams of perivesical cellular spaces at level of hip-joint. (From Sandrey and Mogg, *Lancet*, 1944 (i), 717.)

approached by the suprapubic route, by stripping the bladder from the front of the pubis. An effusion in this space presents in the suprapubic region and may be drained in this region, or it may track along the vas deferens and present in the inguinal region. If there is also damage to the pelvic girdle, the effusion may extend inferiorly along the obturator vessels and nerves deep to the origins of the adductor groups of muscles into the tissues of the thigh and counter-incisions in the inguinal and femoral regions may be needed to provide free drainage.

The posterolateral, or paravesical space, extends behind the bladder in front of the rectum communicating anteriorly with the prevesical space. It is immediately below the rectovesical pouch of the peritoneum and any effusion in it will gravitate between the bladder and the rectum and can be recognized on rectal examination as a diffuse boggy mass above the prostate gland. When the abdomen is opened in such a case, the rectovesical pouch in the male will be found to be diminished in depth by the underlying effusion. The posterolateral or paravesical space is best drained by the perineal route, which route provides dependent drainage.

The fascia in the perivesical spaces has very poor resistance to infection and any effusion into it, whether it be blood or urine, if allowed to remain, will rapidly suppurate. Records of the 1914-18 war showed that pelvic cellulitis was responsible for more deaths than any other single cause in patients who had suffered a bladder wound. It also plays a major part in the morbidity rate following bladder injuries and the late complications such as persistent cystitis, calculus formation, osteomyelitis of the pelvic girdle, infective arthritis of the hip-joint and ascending renal infection, result from a chronic perivesical cellulitis. Osteitis of the symphysis pubis is a common sequel of chronic perivesical cellulitis. Therefore, the most important factor in the treatment of any bladder wound is the prevention of perivesical cellulitis. This is achieved ideally by immediate suture of the wound or wounds of the bladder wall thereby preventing extravasation of urine and blood into the perivesical cellular tissue, and by adequate drainage of this cellular tissue. It is just as important to suture a bladder wound as it is to suture a wound of the gut. At the same time a diversion of the urine by suprapubic cystostomy will put the bladder at rest, prevent leakage of urine through the suture line and allow healing.

The types of injury to the bladder are varied in character and may range from extensive laceration with destruction of large areas of the bladder to contusions of the bladder wall. When the anterior abdominal wall is injured, the bladder may herniate through the wound, giving a condition described by Legueu as "L'extrophie traumatique". Small incisions or puncture wounds of the bladder are often difficult to find on operation, due to the fact that they seal themselves off quite readily but they can be seen on cystoscopy. A common type of wound is a through-and-through wound and a careful search should be made for the exit wound when the missile is not retained in the bladder. The most extensive injuries to the bladder are due to shell or bomb fragments which are low-velocity missiles and readily give rise to infection. Bullet wounds and bayonet stabs are usually clean perforations with little infection. Any missile which strikes the bony pelvis first will cause much soft tissue damage. The pubis, being compact bone, tends to splinter into small fragments when injured by missiles, these splinters being driven into the surrounding tissues ("Blessure à grand fracas", described by Legueu). As the sacrum and ilium are composed largely of cancellous bone, clear-cut perforations or fractures are produced when these are injured and bony fragmentation is far less than when the anterior part of the pelvic girdle is injured.

The track of the missile injuring the bladder is usually an oblique one and it was found by Fullerton that 75% of his cases had wounds in the buttock. Therefore any wound of the buttock should be regarded with suspicion and carefully investigated as soon as possible. Anteroposterior wounds are much less common. Other routes are via the thigh, the groin and the perineum.

Injuries of the bladder may be intra- or extraperitoneal or combined. The peritoneal surface may be damaged even when the viscus is empty when the missile enters via the perineum and ascends vertically. The intraperitoneal wounds are likely to be complicated by injury to the small intestine, for one or more loops of small gut are usually in contact with the peritoneal surface of the bladder. Very often it is the associated lesion which completely overshadows the bladder injury and not only may it take precedence over the bladder wounds as regards treatment, but the bladder wound is very likely to be overlooked. The pelvic girdle is damaged in about 50% of cases, the rectum is also damaged in about 20% to 30%.

Extraperitoneal injury of the bladder is more common in wartime whereas, in civilian life, intraperitoneal injury is the more common injury.

CLINICAL FEATURES

Shock varies greatly and it is usually due to associated injury or to hæmorrhage. Perforation of the bladder *per se* gives rise to comparatively little shock and an uncomplicated closed rupture, especially if it is intraperitoneal, is notoriously difficult to diagnose in the early stage. Hæmorrhage may be intra- or extravesical. Extravesical hæmorrhage may be intra- or extraperitoneal, depending on the site of the bladder wound. It is frequently difficult to diagnose the type of case that has a concealed hæmorrhage in the form of a large perivesical hæmatoma, tracking retroperitoneally up along the psoas muscles.

Leakage of urine from an external wound is not invariable, because there is a tendency for some bladder wounds to close. The appearance of urine from a buttock wound may be delayed for some hours or even days, especially when there is a long narrow track through the gluteal muscles. Rectovesical wounds give rise to an internal urinary fistula and it is usual for urine to flow into the rectum rather than fæces into the bladder. When any doubt arises as to the nature of a clear effusion from a surface wound, estimation of the urea content should be made. Any figure higher than 0·1% of urea identifies the effusion as urine. Retention of urine after bladder wounds is usual but not invariable, and at the same time urine may be passed without difficulty when the wound is sealed off. Dysuria may occur when a projectile or foreign body is in contact with the bladder neck, though this is not reliable evidence of a retained foreign body. Tenderness and rigidity are unreliable signs and may only indicate a contusion of the abdominal muscle, but these signs must not be confused with those that occur following an intraperitoneal injury when the signs of peritonism are present.

DIAGNOSIS

Various ancillary aids in the diagnosis of bladder injuries have been suggested, such as pneumocystography, cystography using an opaque medium such as sodium iodide, and catheterization of the bladder with the injection and withdrawal of a measured quantity of fluid. These methods are not conclusive or reliable and not always helpful; it is possible to pass the catheter through an intraperitoneal tear in the bladder and withdraw urine from the peritoneal cavity, thus jeopardizing the early diagnosis of a bladder injury.

If a cystogram is required and the time and condition of the patient permit, far more reliable information can be obtained by an intravenous injection of pyelectan. This will show the state of renal function, evidence of any wound of the ureters, whether any foreign body is retained in the bladder, evidence of injuries to the pelvis and lastly evidence of injury to the bladder. If any instrumentation is to be performed, it is far better to perform a cystoscopy. Cystoscopy will give definite evidence of missiles and foreign bodies retained in the bladder and also reveal the sites of wounds, except in gross laceration where it is impossible to fill the bladder to permit of its visualization.

The following routine examination is useful in establishing a diagnosis of bladder injury:

(1) Examine the entrance wound and the wound of exit, if any; a urinary fistula may thus be discovered.

(2) X-ray of the abdomen and pelvis, either straight X-ray in conjunction with an intravenous pyelogram, will locate and show evidence of associated bony damage.

(3) An attempt should be made to reconstruct the pathway of the missile by joining entrance to exit wound or to the site of the retained missile.

(4) Rectal examination should always be undertaken because it will reveal evidence of a perivesical effusion or a rectovesical injury to the pelvic girdle.

The bladder should always be explored in doubtful cases and this was justifiable especially during the war years when through lack of special equipment a full investigation could not be carried out in those patients with a suspected bladder injury. Suprapubic cystostomy with exploration of the perivesical spaces is equivalent to exploratory laparotomy, where the principle of "it is better to look and see rather than to wait and see" applies.

TREATMENT

Each case presents its own peculiar problems and this was very marked in wartime injuries because the majority of these cases were complicated by other injuries and these in themselves were often severe. McAlpine outlined four cardinal principles of treatment as: (1) Excision of the wound in the bladder; (2) suture of the wound; (3) drainage of the bladder; (4) drainage of the pelvic cellular tissue.

Operation should be undertaken at a properly equipped centre at the earliest possible moment to prevent extravasation of blood and urine, to remove any source of infection and to control hæmorrhage.

(1) Formal exploration of the bladder by a suprapubic route. The peritoneum should be opened and the peritoneal surface of the bladder and adjacent pelvic organs carefully inspected and any intraperitoneal lesion should be dealt with then and the rectovesical pouch drained. The bladder should be opened either through a separate incision or by enlarging the existing wound if that is accessible, foreign bodies within the bladder should be removed and all wounds of the wall located and the edges excised.

(2) Perforations are closed by interrupted catgut sutures, including the whole thickness

approached by the suprapubic route, by stripping the bladder from the front of the pubis. An effusion in this space presents in the suprapubic region and may be drained in this region, or it may track along the vas deferens and present in the inguinal region. If there is also damage to the pelvic girdle, the effusion may extend inferiorly along the obturator vessels and nerves deep to the origins of the adductor groups of muscles into the tissues of the thigh and counter-incisions in the inguinal and femoral regions may be needed to provide free drainage.

The posterolateral, or paravesical space, extends behind the bladder in front of the rectum communicating anteriorly with the prevesical space. It is immediately below the rectovesical pouch of the peritoneum and any effusion in it will gravitate between the bladder and the rectum and can be recognized on rectal examination as a diffuse boggy mass above the prostate gland. When the abdomen is opened in such a case, the rectovesical pouch in the male will be found to be diminished in depth by the underlying effusion. The posterolateral or paravesical space is best drained by the perineal route, which route provides dependent drainage.

The fascia in the perivesical spaces has very poor resistance to infection and any effusion into it, whether it be blood or urine, if allowed to remain, will rapidly suppurate. Records of the *1914-18* war showed that pelvic cellulitis was responsible for more deaths than any other single cause in patients who had suffered a bladder wound. It also plays a major part in the morbidity rate following bladder injuries and the late complications such as persistent cystitis, calculus formation, osteomyelitis of the pelvic girdle, infective arthritis of the hip-joint and ascending renal infection, result from a chronic perivesical cellulitis. Osteitis of the symphysis pubis is a common sequel of chronic perivesical cellulitis. Therefore, the most important factor in the treatment of any bladder wound is the prevention of perivesical cellulitis. This is achieved ideally by immediate suture of the wound or wounds of the bladder wall thereby preventing extravasation of urine and blood into the perivesical cellular tissue, and by adequate drainage of this cellular tissue. It is just as important to suture a bladder wound as it is to suture a wound of the gut. At the same time a diversion of the urine by suprapubic cystostomy will put the bladder at rest, prevent leakage of urine through the suture line and allow healing.

The types of injury to the bladder are varied in character and may range from extensive laceration with destruction of large areas of the bladder to contusions of the bladder wall. When the anterior abdominal wall is injured, the bladder may herniate through the wound, giving a condition described by Legueu as "L'extrophie traumatique". Small incisions or puncture wounds of the bladder are often difficult to find on operation, due to the fact that they seal themselves off quite readily but they can be seen on cystoscopy. A common type of wound is a through-and-through wound and a careful search should be made for the exit wound when the missile is not retained in the bladder. The most extensive injuries to the bladder are due to shell or bomb fragments which are low-velocity missiles and readily give rise to infection. Bullet wounds and bayonet stabs are usually clean perforations with little infection. Any missile which strikes the bony pelvis first will cause much soft tissue damage. The pubis, being compact bone, tends to splinter into small fragments when injured by missiles, these splinters being driven into the surrounding tissues ("Blessure à grand fracas", described by Legueu). As the sacrum and ilium are composed largely of cancellous bone, clear-cut perforations or fractures are produced when these are injured and bony fragmentation is far less than when the anterior part of the pelvic girdle is injured.

The track of the missile injuring the bladder is usually an oblique one and it was found by Fullerton that 75% of his cases had wounds in the buttock. Therefore any wound of the buttock should be regarded with suspicion and carefully investigated as soon as possible. Anteroposterior wounds are much less common. Other routes are via the thigh, the groin and the perineum.

Injuries of the bladder may be intra- or extraperitoneal or combined. The peritoneal surface may be damaged even when the viscus is empty when the missile enters via the perineum and ascends vertically. The intraperitoneal wounds are likely to be complicated by injury to the small intestine, for one or more loops of small gut are usually in contact with the peritoneal surface of the bladder. Very often it is the associated lesion which completely overshadows the bladder injury and not only may it take precedence over the bladder wounds as regards treatment, but the bladder wound is very likely to be overlooked. The pelvic girdle is damaged in about 50% of cases, the rectum is also damaged in about 20% to 30%.

Extraperitoneal injury of the bladder is more common in wartime whereas, in civilian life, intraperitoneal injury is the more common injury.

CLINICAL FEATURES

Shock varies greatly and it is usually due to associated injury or to hæmorrhage. Perforation of the bladder *per se* gives rise to comparatively little shock and an uncomplicated

Few cases of true extravasation of urine were seen and they were not of a very serious nature. Three factors probably account for this satisfactory position: (1) Retention of urine follows an injury to the urethra. The patient is unable to micturate. It is usually only when the bladder, if unrelieved, finally overflows that extravasation occurs. (2) A suprapubic cystostomy has usually been carried out long before this critical point is reached. (3) The administration of sulphanilamide drugs and penicillin has helped to keep the tissues sterile.

MISSILE RUPTURES OF THE URETHRA

Fifty-three patients suffering from rupture of the urethra due to penetrating missiles have been treated. The distribution of the lesions is shown in the following table:

55 lesions in 53 patients	Penile urethra ..	14
	Bulbous urethra ..	25
	Posterior urethra ..	16

In two patients double ruptures of the urethra occurred. In the former the bulbous and posterior urethra were separately damaged; in the latter the penile and posterior urethra were injured. The bladder was also injured on three occasions. One patient sustained a double rupture of the urethra and a perforation of the bladder.

The urethra has been wounded by almost every type of missile. It is uncommon to find shell or mortar fragments larger than one inch in length and half an inch in breadth and depth penetrating the pelvis. The larger fragments usually cause such severe injuries that death rapidly supervenes.

Ruptures of the Penile Urethra

Fourteen patients sustained injuries to the penile urethra. The following table shows the types of lesions encountered:

Partial ruptures (8 cases)	Glans penis ..	2	Complete ruptures (6 cases)	Traumatic amputation	2
	Glans and body of penis ..	1		Others	4
	Body of penis ..	5			

In all but three patients the missile traversed the penis in a transverse or slightly oblique direction causing a tangential or through-and-through wound. On two occasions it entered the penis in the region of the glans, passed down the length of the body of the penis injuring the urethra in its course and then travelled on into the perineum or pelvis. In only one instance did a foreign body lodge in the penis.

Partial ruptures.—The partial ruptures of the penile urethra were mainly caused by small missiles. With one exception all had a suprapubic cystostomy performed to divert the urine from the urethra.

Two of the three cases of injury to the glans and adjacent body of the penis required plastic repairs. One healed completely ; in the other a minute urinary fistula persisted on the under-surface of the penis.

Of the five patients suffering from wounds of the shaft of the penis it had been found impossible to catheterize two at Forward Units. With careful manipulation, however, it was later found possible to pass a catheter and the partial continuity of the urethra was thus proven. One of the earliest of these patients was treated with an indwelling catheter as a splint. This treatment was, however, later abandoned and once continuity of the urethra had been demonstrated no catheter was left in position and no further treatment was given except the occasional passage of a sound. In no case was the urethra sutured. Secondary suture of the skin wounds was carried out in three patients.

Complete ruptures.—In two patients traumatic amputation of the penis had occurred. In each instance the penis had been cut across about one inch distal to the pubis and the skin torn away from the remaining stump up to the level of the pubis. Both cases were complicated by severe adjoining wounds of the left groin and in one the posterior urethra and bladder were also injured. It was evident in each case that if the remaining stump was not covered with skin gross fibrosis and retraction would occur and render the organ practically useless. In both patients the adjoining injuries rendered immediate grafting impossible and it was several weeks before they were fit for treatment. By this time considerable retraction had occurred and the stump of the penis in each instance required mobilization from a bed of granulation tissue. The stump of the penis was then covered by a pedicle skin flap cut from the scrotum. One case was completely successful and before returning to the United Kingdom was able to use his penis to micturate through the fly of the trousers. This patient has since informed me that he has full control of micturition. In addition erections of the penile stump occur and intercourse is possible. In the second patient the scrotal flap was cut a little too narrow at its base and some terminal necrosis occurred. He, however, of the wall. It is often seen that small punctures or incised wounds of the bladder, particularly those affecting the peritoneal surface, may have a tendency to come together and seal themselves off. Too much reliance should not be placed on this as a safeguard against subsequent leakage of urine and it is better to suture a wound however small it may be.

(3) Suprapubic drainage of the bladder should always be undertaken however small the perforation or wound may be. This method of drainage, though it has many critics, does put the bladder at rest and by diverting the flow of urine prevents leakage through the suture line.

An indwelling urethral catheter, except as an emergency method of treatment to get a patient to hospital at a distance, has no place in the treatment of bladder wounds, however slight they may be. Drainage is uncertain, and it is not possible to drain a bladder *per urethram* for a sufficient length of time to allow the bladder to heal and to correct any urinary infection, also the small eye of the catheter is very likely to become blocked with mucus or blood clot converting the catheter into a plug instead of a drain.

There appears to be great reluctance on the part of some general surgeons to do a suprapubic cystostomy in order to drain the bladder with the mistaken belief that a persistent suprapubic fistula is likely to result. If a persistent fistula occurs, it is due to infection resulting either from an overlooked foreign body in the bladder or from a perivesical cellulitis. In the absence of infection and obstruction to the normal passage of urine, a suprapubic sinus will always close quite rapidly after the tube has been removed.

(4) Careful exploration of perivesical tissues adjacent to any extraperitoneal wound of the bladder should be carried out. The extravesical hæmorrhage is controlled and any foreign body removed. Free drainage of the perivesical tissues adjacent to the bladder wound is most essential and in this respect it may be necessary to use counter-incisions in the groins, medial aspect of the thigh or the perineum where perivesical cellulitis is widespread.

Before laparotomy, wounds of the buttock should be explored from behind, a tube should be inserted into the depths of the wound to drain the pelvic cellular tissues, as adequate drainage from the abdomen is often impossible. Associated wounds of the rectum should be treated by diversion of the flow of fæces by a left iliac or transverse colostomy. An attempt should be made to suture the rectal wall and drain the perirectal tissue. This often involves removal of the coccyx or often part of the sacrum as was suggested by Sir Charles Gordon-Watson. Any associated injury of the lower end of the ureter should be treated by reimplantation into the bladder in such a position that the site of anastomosis is free from tension.

Injuries of the Urethra [*Abridged*][1]

By D. S. Poole-Wilson, F.R.C.S.

In outlining a policy for the treatment of urethral injuries by Forward Units in the Field it had to be recognized that operative facilities were sometimes not too good, that the patient's general condition frequently did not warrant a prolonged operation and that the after-care might not be entirely satisfactory. Under these circumstances surgeons were advised to avoid carrying out complicated urethral repairs and to be content with performing a toilet of the wounds, a suprapubic cystostomy to relieve retention and divert the urine from the injured area, and when necessary incision and drainage to relieve extravasation or very large hæmatomata.

Following this primary treatment patients were, whenever possible, evacuated back to the G.U. Centre for definitive treatment. It is thus evident that the work which I am submitting in this communication has been contributed to by almost every surgeon serving in a Forward Unit in the Central Mediterranean Force.

A total of 81 patients suffering from ruptures of the urethra were observed. 53 of these patients had missile injuries of the urethra; the remaining 28 were accidental ruptures.

In the majority of patients primary surgical operations had been carried out at Field Surgical Units or Casualty Clearing Stations and the patients reached the G.U. Centre at varying periods from twenty-four hours after injury. The standard of diagnosis was high and in the vast majority of patients the urethral lesion had been noticed shortly after wounding or injury. Suprapubic cystostomy was almost invariably used to divert the urine from the urethra. These patients travelled extremely well. In a few instances perurethral catheter drainage was used but all subsequently required a suprapubic cystotomy. These patients travelled badly as the urethral catheters usually became either blocked or lost in transit. Relatively few attempts were made at the primary operation to repair the urethra. When the posterior urethra was damaged, however, an indwelling catheter was frequently fixed in position to act as a splint and prevent any loss of urethral alignment.

---

[1] The material used in this Paper regarding missile injuries of the urethra is condensed from a Hunterian Lecture on Missile Injuries of the Urethra delivered in 1946 and which it is hoped will be published shortly.

Few cases of true extravasation of urine were seen and they were not of a very serious nature. Three factors probably account for this satisfactory position: (1) Retention of urine follows an injury to the urethra. The patient is unable to micturate. It is usually only when the bladder, if unrelieved, finally overflows that extravasation occurs. (2) A suprapubic cystostomy has usually been carried out long before this critical point is reached. (3) The administration of sulphanilamide drugs and penicillin has helped to keep the tissues sterile.

MISSILE RUPTURES OF THE URETHRA

Fifty-three patients suffering from rupture of the urethra due to penetrating missiles have been treated. The distribution of the lesions is shown in the following table:

55 lesions in 53 patients	Penile urethra ..	14
	Bulbous urethra ..	25
	Posterior urethra ..	16

In two patients double ruptures of the urethra occurred. In the former the bulbous and posterior urethra were separately damaged; in the latter the penile and posterior urethra were injured. The bladder was also injured on three occasions. One patient sustained a double rupture of the urethra and a perforation of the bladder.

The urethra has been wounded by almost every type of missile. It is uncommon to find shell or mortar fragments larger than one inch in length and half an inch in breadth and depth penetrating the pelvis. The larger fragments usually cause such severe injuries that death rapidly supervenes.

Ruptures of the Penile Urethra

Fourteen patients sustained injuries to the penile urethra. The following table shows the types of lesions encountered:

Partial ruptures (8 cases)	Glans penis ..	2	Complete ruptures (6 cases)	Traumatic amputation	2
	Glans and body of penis ..	1		Others	4
	Body of penis ..	5			

In all but three patients the missile traversed the penis in a transverse or slightly oblique direction causing a tangential or through-and-through wound. On two occasions it entered the penis in the region of the glans, passed down the length of the body of the penis injuring the urethra in its course and then travelled on into the perineum or pelvis. In only one instance did a foreign body lodge in the penis.

Partial ruptures.—The partial ruptures of the penile urethra were mainly caused by small missiles. With one exception all had a suprapubic cystostomy performed to divert the urine from the urethra.

Two of the three cases of injury to the glans and adjacent body of the penis required plastic repairs. One healed completely; in the other a minute urinary fistula persisted on the under-surface of the penis.

Of the five patients suffering from wounds of the shaft of the penis it had been found impossible to catheterize two at Forward Units. With careful manipulation, however, it was later found possible to pass a catheter and the partial continuity of the urethra was thus proven. One of the earliest of these patients was treated with an indwelling catheter as a splint. This treatment was, however, later abandoned and once continuity of the urethra had been demonstrated no catheter was left in position and no further treatment was given except the occasional passage of a sound. In no case was the urethra sutured. Secondary suture of the skin wounds was carried out in three patients.

Complete ruptures.—In two patients traumatic amputation of the penis had occurred. In each instance the penis had been cut across about one inch distal to the pubis and the skin torn away from the remaining stump up to the level of the pubis. Both cases were complicated by severe adjoining wounds of the left groin and in one the posterior urethra and bladder were also injured. It was evident in each case that if the remaining stump was not covered with skin gross fibrosis and retraction would occur and render the organ practically useless. In both patients the adjoining injuries rendered immediate grafting impossible and it was several weeks before they were fit for treatment. By this time considerable retraction had occurred and the stump of the penis in each instance required mobilization from a bed of granulation tissue. The stump of the penis was then covered by a pedicle skin flap cut from the scrotum. One case was completely successful and before returning to the United Kingdom was able to use his penis to micturate through the fly of the trousers. This patient has since informed me that he has full control of micturition. In addition erections of the penile stump occur and intercourse is possible. In the second patient the scrotal flap was cut a little too narrow at its base and some terminal necrosis occurred. He, however, now has full control of micturition from the stump. Erections occur but owing to the severe injuries in the left groin the penile stump becomes drawn over to the left side.

Two of the remaining four cases of complete rupture of the penile urethra were complicated by gross penile damage. In one patient it was possible to pass a finger completely through the penis. At the Field Surgical Unit it was felt that the distal portion would inevitably become gangrenous but it was wisely decided to leave it attached. This soldier was seen on the fourth day after injury. His wound was clean. The ends of the urethra were found and mobilized and a complete suture performed around a catheter arranged for penicillin irrigation. The corpora cavernosa penis were repaired as far as possible and the subcutaneous tissue and skin sutured. Complete healing, except for a minute sinus leaking about five drops of urine per act of micturition, was obtained. The other case of complete rupture was also treated by suture of the urethra and delayed primary suture of the cutaneous wounds with complete success.

The two remaining instances of complete rupture were fairly old injuries in two Jugo-Slav Partisans. One patient, a boy of 15 years, had sustained a wound of the penis resulting in complete occlusion of the urethra. He had been draining by the suprapubic route for over a year. Complete excision of the fibrous occluded section was carried out and full normal micturition restored. The second Jugo-Slav patient had also sustained a through-and-through wound of the penis, which had resulted in occlusion of the urethra. Attempts had been made to restore continuity but had resulted in a peno-scrotal fistula. It was evident that to close the fistula and restore continuity a large block of fibrous tissue would have to be excised and the cut ends of the urethra united. The operation was difficult but proved successful.

Ruptures of the Bulbous Urethra

Twenty-five patients suffering from rupture of the bulbous urethra have been treated and are classified as follows: Contusion urethra 3; partial rupture 16; complete rupture 6.

Contusion of the urethra was diagnosed when, following a wound in the region of the urethra, retention or urethral bleeding occurred but no difficulty was experienced in passing a catheter and no perforation of the urethra was demonstrated in the adjacent wound. In two of the three cases there were extensive groin and perineal wounds, which required extensive plastic repairs.

Partial ruptures.—Sixteen partial ruptures of the urethra were treated and were mainly caused by projectiles passing anteroposteriorly across the perineum. A few were due to mine and shell wounds, which entered the perineum from below. Apart from the passage of a catheter to demonstrate the continuity of the urethra eleven patients required no operative treatment on the urethra. Removal of foreign bodies and delayed primary suture of perineal wounds were, however, carried out. In five instances repairs of the urethra were performed. It is noteworthy that in eight of these sixteen partial ruptures it had been found impossible to pass a catheter at the original operation carried out at a Forward Unit and that in five of these patients no further urethral operation was eventually found necessary.

Complete ruptures.—Six cases of complete rupture of the bulbous urethra have been treated. One patient, who was suffering from multiple injuries and a complete occlusion of the urethra, died from infective jaundice before any repair was attempted. Of the remaining five two had undergone unsuccessful repairs before admission to the Centre and required further operative treatment; the other three had complete repairs of the urethra carried out. It has always been possible to mobilize the ends of the urethra after the manner of Marion sufficiently to bring them together and to obtain complete suture over a catheter, which has then been withdrawn. The technique of bridging a gap with an indwelling catheter, or suturing the roof and leaving the perineal wound to granulate over, has never been resorted to. The perineal wounds have all been closed but a penicillin irrigation tube has frequently been left in position. Young's technique of closing large flaps in the bulbous urethra by liberating the attachments of the penis within the scrotum and drawing the corpora cavernosa and spongiosum backwards has never been employed. It is, however, noteworthy that Young claims that gaps of even four inches can be closed by this means. Likewise the method of Pasteur and Iselin has not been used.

The use of penicillin, both intramuscularly and by local and urethral irrigation, allowed closure of perineal wounds, which would otherwise have been left to granulate. Healing has thus been accelerated and there can be little doubt that the resulting decrease in scar tissue meant less tendency to stricture formation.

Ruptures of the Prostato-Membranous Urethra

Sixteen missile ruptures of the posterior urethra have been treated. The injury may involve any portion of the posterior urethra.

A catheter can seldom be passed in these patients and it is therefore impossible to divide them satisfactorily into partial and complete ruptures. There is, however, little doubt that in many the continuity of the urethra is not completely broken. The wounds of the membranous urethra seem to be the most dangerous from the point of view of stricture formation. Complete ruptures at the junction of the prostatic and membranous urethra with posterior dislocation of the prostate on the urogenital diaphragm, such as occur in severe traumatic fractures of the pelvis in civil life, were not seen.

The rectum has been injured on six occasions but only two prostato-rectal fistulæ have failed to close spontaneously and have required separation and closure.

The danger of stricture formation in the region of the membranous urethra, and the great difficulty of treating this condition satisfactorily at a later date, have led me invariably to use an indwelling urethral catheter as a splint. It is probable that this is unnecessary in many wounds involving the bladder-neck or body of the prostate, and that the rigidity of the remaining prostatic wall is sufficient to prevent the ends of the urethra getting out of alignment. Nevertheless the difficulty of estimating the exact extent of the wound and the seriousness of an unsuccessful outcome seem to make an indwelling catheter imperative.

Two methods have been used to introduce the indwelling catheter: (1) In the first method a finger is passed down into the posterior urethra and it is then frequently possible to guide the tip of a Lister's sound, which has been passed down the anterior urethra, into the bladder. The distal end of a small rubber catheter is then slipped over the tip of the sound so that it grips firmly and the catheter is drawn through the urethra by withdrawing the sound.

(2) In the more difficult cases, where the rupture is in the region of the membranous urethra, two Lister's sounds are used, the tip of one of which has been slightly hollowed out so as to form a cup in which the tip of the other may engage. The female sound is passed through the internal urethral orifice and the plain one down the anterior urethra. The two sounds are gently manipulated until the points engage. These are then held firmly together, whilst the distal sound is carried forwards into the bladder. The distal end of a rubber catheter is then slipped over its tip and drawn back down the urethra. These two methods have always been successful and no perineal explorations have been necessary. In addition the operation can frequently be carried out by slipping a finger down the suprapubic track and it is seldom necessary to reopen the suprapubic wound entirely.

The indwelling catheter is held in position by a stitch through its tip, which is brought out alongside the suprapubic Malecot catheter and tied to a piece of rubber tubing on the abdominal wall. This technique also ensures that subsequent catheters can, if necessary, be drawn through the urethra. The catheter is not really for use as a drain but as a urethral splint. Prior to introduction a piece of thread is tied around the catheter immediately distal to the eye. This prevents drainage down the catheter and allows of one tube the less to be attached to a bottle. If the catheter is not draining, it is also easier to keep the catheter and urethra sterile as the whole of the perineum and penis can be covered over with sterile dressings. This catheter is also frequently used for penicillin irrigation of the urethra by cutting an eye distal to the ligature mentioned above (*see* fig. 1).

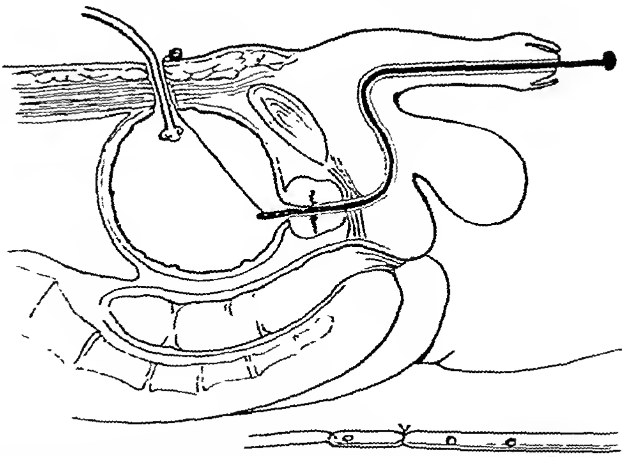

FIG. 1.—Illustrating method of fixing a urethral catheter as a urethral splint. The inset shows a catheter arranged for penicillin irrigation.

The urethral catheter is left in position for at least two weeks so as to ensure firm fixation of the ends of the urethra.

In two patients prostato-rectal fistulæ required operation. An inverted V perineal incision was made and separation of the rectum and prostate carried out to a level well above that of the fistula. The fistula in the posterior margin of the prostate was then sutured and the rectal opening invaginated and oversewn with two layers of sutures. The perineum was closed with a small penicillin irrigation tube in position.

ACCIDENTAL RUPTURES OF THE URETHRA

Twenty-eight cases of accidental rupture of the urethra came into the Genito-Urinary Centre. These were divided as follows:

Rupture of bulbous urethra	8	*Rupture of posterior urethra*	20
Contusion	1	Complete	9
Partial rupture ..	7	Partial	11
Complete rupture ..	0		

Ruptures of the Bulbous Urethra

With one exception all the ruptures of the bulbous urethra resulted from various types of blows in the perineum. The exception was a patient in whom a Tobruk plaster had been applied too tightly. An area in the perineum about two and a half inches in diameter became necrotic and finally sloughed away leaving the two open ends of the urethra exposed in a bed of granulation tissue and joined by a thin strand of the roof of the urethra.

At the primary operation one patient appeared to have sustained little more than a contusion of the urethra. He was catheterized with ease and as the urethral bleeding had been slight and as no perineal hæmatoma was present no further operative treatment was carried out. He had a little trouble in starting micturition and then passed urine very satisfactorily.

The patient suffering from the necrosis of the perineum had a suprapubic cystostomy performed to divert his urine. At a later date a very extensive plastic repair was carried out and the ends of the urethra were mobilized, brought together and sutured. The scrotum was brought back to cover the perineum. Complete healing occurred and normal micturition was restored.

Of the remaining six cases catheterization failed at the primary operation in five instances. These ruptures were all eventually shown to be partial and the failure to pass a catheter was probably due to the lack of rubber coudé catheters with Forward Units. The primary operations carried out on these patients varied. Two patients had a suprapubic cystostomy alone performed. Both of these patients had a perineal exploration of the urethra carried out a few days later. The rupture in each case was found to be partial and was sutured over an indwelling catheter. The perineum was closed except for a small drain. Both of these patients made extremely good recoveries.

Another patient had a suprapubic cystostomy and a perineal incision to evacuate a hæmatoma. On examining him a few days later a coudé catheter ran easily into the bladder. The perineal wound was clean, and on inspection a partial tear was seen in the urethra. This was sutured. No indwelling catheter was left in position. The perineum was sutured with drainage. Complete and rapid healing occurred.

A further patient had a suprapubic cystostomy, and as attempted catheterization had failed the two-sound method was used and an indwelling urethral catheter eventually drawn back into position. This patient made a very satisfactory recovery.

The remaining two patients had suprapubic cystostomy and perineal exploration carried out at their primary operations under difficult circumstances. Both had incomplete ruptures and in each an indwelling catheter was placed in position and the perineal wound left open. Both of these patients ran an unsatisfactory course. The first developed a perineal sinus, which only closed after two further operations. He was finally evacuated home, but his perineum again broke down. Closure finally occurred but a left pyonephrosis necessitated removal of the left kidney. The second patient developed an abscess in his left groin and a mild osteitis of the pubis. Healing finally occurred.

Traumatic Rupture of the Posterior Urethra

Twenty cases of accidental rupture of the posterior urethra have been seen. With one exception, where the cause is unknown, they were the result of traffic accidents. The pelvis was fractured in all but one instance and the fractures were severe in type. In the single instance where the pelvis was not fractured a partial rupture of the prostato-membranous urethra was caused by the kick starter of a motor-cycle passing through the anus and perineum into the prostate.

At the primary operation it was found possible to divide these patients into cases of complete and incomplete rupture. In the literature much confusion exists regarding the site of the ruptures. Some authors describe the majority of them as involving the membranous urethra; others deny having ever seen a rupture of the membranous urethra. Observation is difficult as the floor of the pelvis is always covered with much blood clot. In the present series, however, the complete ruptures appeared to result from the bladder with the prostate attached being sheared off the upper surface of the pelvic diaphragm. The partial ruptures appeared to be due to a deficiency in the anterior wall of the junction of the prostatic and membranous urethra. It was not always possible to decide whether this resulted from a splitting of the pelvic diaphragm with a tear running back into the urethra, avulsion of part of the lower anterior wall of the prostatic urethra or a shearing of the prostate off the pelvic diaphragm, which has just failed to become complete.

Complete rupture of the posterior urethra.—Nine cases of complete rupture were treated. In every one the bladder with the prostate attached was torn off the upper surface of the pelvic diaphragm and displaced backwards. Despite the severity of the injury extravasation of the urine was not always present and in at least three instances the bladder was found distended with urine and yet there was none in the pelvic tissues. The internal sphincter appeared to be quite capable of retaining the urine in the bladder.

At the primary operation a suprapubic cystostomy was performed in all cases and in seven an indwelling urethral catheter was drawn down the urethra. In the remaining two patients the suprapubic wound was opened a few days later and a urethral splint drawn into position. Primary repair by the perineal route as advocated by Hugh Young was never performed.

In two patients alignment of the urethra was lost following removal of the indwelling catheter. In one patient continuity was restored by reopening the suprapubic wound slightly and using the two-sound method. In the other the perineum had to be explored through an inverted V incision and the continuity of the prostatic and membranous urethra restored.

Partial rupture.—Eleven cases of partial rupture of the posterior urethra have been seen. Two of these were complicated by separate extraperitoneal ruptures of the bladder.

At the primary operation six of these patients had a suprapubic cystostomy and an indwelling urethral catheter drawn into position. Two of these patients also had an extraperitoneal rupture of the bladder closed.

Three patients had only a suprapubic cystostomy performed at their primary operation. On subsequent examination it was possible to pass a catheter on two of them. The third patient had to have his suprapubic wound reopened and an indwelling catheter drawn through by the double-sound method.

The patient whose perineum had been injured by the kick starter of his motor-cycle had a suprapubic cystotomy and exploration of his perineum performed at his primary operation. A prostato-rectal fistula persisted. This was later explored by the perineal route and the openings in the prostate and rectum closed.

One patient who was catheterized with ease at his primary operation was thought to have little more than a urethral contusion. The catheter was removed and he passed urine freely for a day. He then developed retention, which was relieved by an indwelling catheter. This patient had a very severe dislocation of the symphysis pubis, with a fracture of the right pubic arch and a dislocation of the right sacro-iliac joint. Attempts were made to reduce this dislocation by manipulation but were not very successful. On the eighth day his catheter was removed. On attempting to pass urine, a trickling sensation was felt in the right groin and an extravasation of urine occurred. A suprapubic cystostomy was immediately performed. A catheter still ran easily into the bladder showing that the rupture was incomplete. It seems probable that the manipulation of the pelvis or its instability had either increased the rupture or prevented its peritoneal healing. Two other patients, who had unstable pelves, also lost the continuity of the urethra during convalescence either by increase in the severity of the rupture or possibly due to stricture formation. Continuity was restored by the double-sound method in one and by open exploration of the perineum in the other. It thus became very evident that if the pelvic girdle is unstable and cannot be controlled the indwelling catheter must be retained for a longer period than usual.

The following table shows the results obtained:

(1) Returned to duty (Category B 1)	18
(2) Invalided home. Passing urine normally	46
(3) Invalided home. Passing urine normally apart from a minute urethral fistula	3
(4) Invalided home with suprapubic drainage. Urethral channel present in all	12
(5) Death	2

The urethral catheter is left in position for at least two weeks so as to ensure firm fixation of the ends of the urethra.

In two patients prostato-rectal fistulæ required operation. An inverted V perineal incision was made and separation of the rectum and prostate carried out to a level well above that of the fistula. The fistula in the posterior margin of the prostate was then sutured and the rectal opening invaginated and oversewn with two layers of sutures. The perineum was closed with a small penicillin irrigation tube in position.

ACCIDENTAL RUPTURES OF THE URETHRA

Twenty-eight cases of accidental rupture of the urethra came into the Genito-Urinary Centre. These were divided as follows:

Rupture of bulbous urethra	8	*Rupture of posterior urethra*	20
Contusion	1	Complete	9
Partial rupture ..	7	Partial	11
Complete rupture ..	0		

Ruptures of the Bulbous Urethra

With one exception all the ruptures of the bulbous urethra resulted from various types of blows in the perineum. The exception was a patient in whom a Tobruk plaster had been applied too tightly. An area in the perineum about two and a half inches in diameter became necrotic and finally sloughed away leaving the two open ends of the urethra exposed in a bed of granulation tissue and joined by a thin strand of the roof of the urethra.

At the primary operation one patient appeared to have sustained little more than a contusion of the urethra. He was catheterized with ease and as the urethral bleeding had been slight and as no perineal hæmatoma was present no further operative treatment was carried out. He had a little trouble in starting micturition and then passed urine very satisfactorily.

The patient suffering from the necrosis of the perineum had a suprapubic cystostomy performed to divert his urine. At a later date a very extensive plastic repair was carried out and the ends of the urethra were mobilized, brought together and sutured. The scrotum was brought back to cover the perineum. Complete healing occurred and normal micturition was restored.

Of the remaining six cases catheterization failed at the primary operation in five instances. These ruptures were all eventually shown to be partial and the failure to pass a catheter was probably due to the lack of rubber coudé catheters with Forward Units. The primary operations carried out on these patients varied. Two patients had a suprapubic cystostomy alone performed. Both of these patients had a perineal exploration of the urethra carried out a few days later. The rupture in each case was found to be partial and was sutured over an indwelling catheter. The first developed a perineal sinus, which only closed after two further operations. He was finally evacuated home, but his perineum again broke down. Closure finally occurred but a left pyonephrosis necessitated removal of the left kidney. The second patient developed an abscess in his left groin and a mild osteitis of the pubis. Healing finally occurred.

Traumatic Rupture of the Posterior Urethra

Twenty cases of accidental rupture of the posterior urethra have been seen. With one exception, where the cause is unknown, they were the result of traffic accidents. The pelvis was fractured in all but one instance and the fractures were severe in type. In the single instance where the pelvis was not fractured a partial rupture of the prostato-membranous urethra was caused by the kick starter of a motor-cycle passing through the anus and perineum into the prostate.

In these latter cases, while the kidney may often be grossly disrupted, the investing renal fascial planes are intact, with the result that, not only may the hæmorrhage be at least temporarily limited in extent, but also the increasing rise in subfascial tension gives rise to increasing pain.

In penetrating injuries, on the other hand, the fascia of Zuckerkandl, and the true renal fascia and sometimes also the peritoneum, are also torn and disrupted, and blood can escape in almost all directions, and so local tension does not rise, and pain does not increase nor a tumour appear. The pulse-rate is, in fact, the only safe guide to continued bleeding.

For the repair of the renal parenchyma, No. I non-chromic catgut threaded on a blunt-pointed Kouznetzoff needle, curved on the flat, was used. Interrupted ordinary sutures are preferred to mattress sutures, as there is slightly less chance of producing a further ischæmia of the already damaged renal tissue. The hæmostatic value of these stitches, tied as loosely as one dare, can be further increased by applying strips of muscle cut from the parietes, to the renal tear or tears, before tying the knots.

No attempt should be made to close a hole in the pelvis, though it should be partially sutured if it is a big tear, and it can also be used for the pyelotomy, which is, of course, essential.

The damaged renal pedicle is, in some respects, a unique problem in its urgency, in that the pressure in the renal artery, arising straight from the aorta near to the heart is high, even in shocked subjects, while the venous pressure is negative or near negative. At the moment of operation therefore, when the area is opened up, the increase in bleeding may be considerable, and the chances of an air embolism are also increased if the vein is torn.

It is this urgency which may sometimes stampede a surgeon into doing a quick nephrectomy without giving himself time to investigate the exact extent of the damage.

This urgency can be satisfied, and sometimes the kidney preserved, if, at the moment the kidney is exposed, the renal pedicle, together with its surrounding fat and blood-infiltrated tissue, be lightly but effectively grasped in a pair of sponge forceps, or a rubber-covered duodenal clamp. This will give time, while the bleeding is controlled, to make a more deliberate dissection of the pedicle, to see just what has happened.

It will often then be found that only a portion of the vascular pedicle is damaged, in or near the renal parenchyma, and that a ligature applied to damaged sub-branches of the main vessels may still leave an organ which is worth preserving.

One case was a paratrooper admitted six hours after wounding, with a large wound of entry only, in the left subcostal region, and hæmaturia. Except around the kidney, there was no muscle guarding, the pulse was rising steadily, and there was no audible peristalsis. This latter was due to the grain of morphia that he had geen given at the battalion H.Q.

At operation a large shell fragment was found and removed from the kidney substance and at the end of the operation the peritoneum was opened as a precaution and was found to contain blood. A second incision was therefore made and the peritoneum widely explored, when it was found that there was in fact no intraperitoneal injury, but that about half a pint of blood had entered the abdomen from a peritoneal tear on the anterior surface of the damaged kidney. I feel that this second incision and inevitable lengthening of the operation could have been avoided had the kidney been approached originally through a paramedian incision.

In one case only was a left kidney removed through a transdiaphragmatic approach. This man had a wound of entry in the left arm; the bullet had crossed into his left chest and he had hæmaturia and no wound of exit. The man was in great distress from a sucking pneumothorax. A large tear was found in the diaphragm, and by enlarging this still further a totally disrupted left kidney was removed without difficulty. As the metal fragment had not been found the peritoneum was also opened and an exploration satisfied me that the fragment had not left the perirenal fat, and the search was discontinued. The patient made a good recovery.

The late results of ureteral anastomosis are not impressive and in battle casualties there is the further complication of sepsis round the ureterocutaneous fistula, and a portion of the ureter may even be shot away, making anastomosis without tension impossible.

For section of the lower ureter, reimplantation into the bladder gives good results, or, if this cannot be done without tension, then a flap of bladder can be turned up, and fashioned into a sleeve, and joined to the cut end of the ureter.

For the upper lengths of the ureter, the little operation of transplantation into the extraperitoneal, or extraperitonealized colon, is well worth trying, before resorting to nephrectomy.

Mr. Parker recorded fourteen cases of bladder injury, all except one being associated with other visceral damage. In one case, the shell fragment was actually in the bladder lumen.

General Observations on Treatment

In ideal surroundings and with a patient in good condition it is often quite possible and reasonable to carry out suprapubic drainage of the bladder and a complete repair of the urethra at the primary operation. When these conditions do not exist suprapubic drainage to divert the urine together with a toilet of any perineal wounds as a primary operation and a subsequent secondary repair have given excellent results. In fact it is probable that at times these results may be superior to those obtained by a complete primary operation. In cases of complete rupture of the posterior urethra, however, alignment should be restored and maintained by an indwelling catheter at as early a time as possible.

The principles of delayed primary suture hold for perineal wounds involving the urethra. It is most desirable to avoid large granulating wounds in the perineum as they render the tissues rigid and in the event of a urethral repair being unsatisfactory make subsequent operations extremely difficult. Using parenteral and irrigation penicillin almost all perineal wounds have been completely closed.

A considerable apprenticeship is necessary to learn the art of urethral repair. The importance of an unhurried operation, good exposure, a bloodless field, adequate mobilization of the urethra and suture without tension must be stressed. Fine instruments are essential. Plain 6/0 catgut is used for the urethral suture.

Indwelling catheters should be used as little as possible. The presence of a foreign body in the urethra retards healing. For splinting the posterior urethra a small size is used (15 F.) so as to allow free drainage down the urethra around it.

Penicillin has been used very extensively both intramuscularly and for the irrigation of the urethra and perineal wounds.

In no form of surgery is good after-treatment more important. Suprapubic tubes must be kept draining perfectly. Very large perineal dressings must be used to keep the wounds aseptic.

No definite time can be laid down for the healing of urethral wounds. Suprapubic drainage should be continued until all perineal and urethral wounds are healed. No urine should pass down the urethra until this time is reached. When the time is due to try the restoration of normal micturition a spigot is placed in the suprapubic tube and the patient encouraged to pass urine through his urethra. If any leakage from perineal or penile wounds occurs the suprapubic drainage must be continued; but if after a few days all wounds remain absolutely dry then the suprapubic catheter is removed and the wound allowed to heal. Leakage from the healing suprapubic wound is slight as the patient has already learnt to micturate. Indwelling catheters should not be used to aid the closure of the suprapubic wound as it is unwise to risk starting even the mildest urethritis.

Some Observations on a Personal Series of Battle Casualties Involving the Genito-Urinary System. [*Abridged*]

By Geoffrey E. Parker, F.R.C.S.

In a series of 94 abdominal operations done in the forward areas of Africa and Italy, no less than 36 involved, among other things, the urinary apparatus.

There were 17 kidney injuries—in one case bilateral—14 bladder injuries and 5 cases with wounds of the prostate and prostatic urethra.

The overall recovery rate was 67% but as the great majority of the cases had injuries involving much more than the genito-urinary system, these specific injuries alone could not be blamed for the mortality of 33%.

Of the 17 renal cases which came to operation it was found possible to preserve and repair the kidney in 8. All the 8 cases treated conservatively involved injury to the parenchyma and, in 4 of them, the renal pelvis was also torn open.

There is no doubt that the proportion of cases in which the kidney could have been preserved would have been higher still but for the fact that so many other lesions, such as bleeding mesenteric vessels, torn and perforated bowel and liver, had also to be dealt with, and quickly; and so it often seemed more expedient to take out the damaged kidney, after confirming the presence and integrity of the other one, in order quickly to deal with no less urgent problems elsewhere in the abdomen.

In the absence of signs and symptoms of other visceral injury, the decision to operate was determined by a number of factors; the rise in pulse-rate, the spread of rigidity on the affected side, the increasing pain, and lastly and of less importance an increasing tumour in the loin.

With regard to physical signs of renal injury, the significance of pain and tumour differs in battle casualties from the crushing type of injury more often seen in civil practice.

I can recall a kidney injury from a large flying bomb fragment very similar to Mr. Parker's case. It entered through the left eleventh rib in the mid-axillary line, ploughed through the lower lobe of the lung, the diaphragm, and remained embedded in the left kidney. The missile laid open an approach which after wound excision and extension strongly resembled the Bernard Fey approach to the kidney, a method I frequently use for exploration of the kidney and suprarenal. In this case excellent opportunity was offered for closure of a hole in the pericardium, a large tear in the diaphragm and pleura, and left nephrectomy. Except for development of a fæcal fistula on the tenth day from bruising of the splenic flexure, which quickly closed spontaneously, and delayed recovery of the lung injury, convalescence was satisfactory. The patient, a senior officer, was able to return to duty four months after injury.

Finally, as to the emplacement of the splint catheter for ruptures of the prostato-membranous urethra with broken alignment, many ingenious methods are described. May I point out one I cannot remember having seen recorded and which has the virtue of simplicity, namely reduction of the prostate forwards by a finger in the rectum. On two occasions (on the ninth and fourteenth days after injury respectively) mere suprapubic drainage had been established when the cases reached me. Passing a Lister bougie with my left hand and with my right index finger in the rectum I pushed the prostate forward and so was able to direct the bougie across the rupture up through the prostatic urethra. My assistant meanwhile had his finger in the bladder through the drainage opening and so was able to tell me when the bougie entered through the internal urinary meatus. A rubber tube was then stretched over the bougie's point and so withdrawn through the urethra as described by Mr. Poole-Wilson.

Thus every variety of urogenital injury was witnessed on the home front including my three cases of gun-shot wounds of the ureter which were reported in the *British Journal of Urology*, 1946, 18, 166.

Mr. Mogg, in reply, stated that while he agreed with the majority of Mr. Everidge's views and appreciated his sound judgment and wealth of experience in traumatic urological surgery, he still thought it advisable to attempt to close wounds of the lateral walls of the bladder. This, in conjunction with suprapubic cystostomy, did prevent extravasation of urine into the pelvic cellular tissue and prevent pelvic cellulitis with all its unfortunate sequelæ.

[*April* 24, 1947]

Treatment of Hydronephrosis Associated with Abnormal Vessels[1]

By H. HAMILTON STEWART, F.R.C.S.

SOME surgeons hold the view that the mechanical obstruction caused by a lower polar or aberrant artery is a secondary obstruction. They consider that the primary enlargement of the renal pelvis is caused by a neuromuscular defect, or a congenital stricture, and that if a lower polar or aberrant artery is present, then a superimposed mechanical obstruction occurs.

I do not propose at this juncture to enter into a discussion on this problem, and will limit myself to the consideration of the relief of the mechanical obstruction caused by a lower polar or aberrant artery, and other speakers will, no doubt, discuss the other aspect later.

I have had practical experience of most of the operations recommended for the treatment of the condition. As the disadvantages and dangers of these procedures are well known, I shall only mention them briefly. They are:

(1) *Those in which the basic principle is the division of the vessel.*—Infarction of the kidney if the divided vessel is large, with a liability to infection, particularly if the urine is infected. The loss of valuable kidney tissue—a serious matter if the other kidney is diseased.

(2) *Some form of plastic operation on the pelvis with division of the uretero-pelvic continuity.*—The risk of imperfect drainage with persistence of infection which may have previously existed or been introduced through the drainage tubes, splint catheters, &c. Stenosis of the ureter with fistula formations, &c.

The dangers of the standard operations are greatly increased when they are carried out on a solitary hydronephrotic kidney resulting from a large obstructing lower polar or aberrant artery.

The advantages of the operation to be described are: (1) All cases worthy of conservative surgery may be treated by this method. (2) There is no interference with the uretero-pelvic continuity and blood supply. (3) There is no risk of introducing infection from the skin into the urinary tract, for no drainage tube is inserted into the kidney or pelvis—indeed,

---

[1] Paper illustrated by a colour film.

He suggested that the division of bladder injuries into extra- and intraperitoneal should be dispensed with as it has no surgical significance.

The incision down to the injured bladder must be mid-line, suprapubic and transperitoneal, though the peritoneum can, of course, be closed immediately, if this surface of the bladder is found to be intact.

The use of the indwelling catheter is to be condemned and all except 4 of Mr. Parker's cases were evacuated from the forward area with suprapubic drainage only.

One of these 4 cases had a floating bladder for which a perurethral de Pezza tube was used as an aid to anchoring the bladder down in the hope of shortening the stricture which is likely to occur in such cases.

Satisfactory hæmostasis in injuries round the bladder base is sometimes very difficult to obtain, and it is better to resort to extensive packing of the extravesical space, than to catch up lumps of tissue with transfixion stitches, as with gross injury and distortion it is quite impossible to make out the position of the ureters.

The differential diagnosis between low bladder and prostatic injuries is sometimes difficult though not very important. Blood oozing out of the urethra, independent of micturition, may only mean that the external sphincter is temporarily out of action, and the actual injury may be above this level, as, in the case of high-velocity missile injuries, there is always some local concussion and loss of muscular function. Hæmorrhage and systemic shock are often very severe in these cases.

In connexion with the diagnosis of these prostatic and bladder base injuries, there is a physical sign of some importance which can be elicited on rectal examination.

The profuse hæmorrhage which nearly always occurs fills the periprostatic space and the space of Denonvilliers; consequently the examining finger will only feel a soft tender mass of blood, where the prostate ought to be, or, what is even more helpful, the prostate may be felt to be mobile and placed much higher than normally, owing to disruption from its attachments to the trigone.

When the pelvic girdle and the rectum have been injured, late sepsis and secondary hæmorrhage must be only too common in these cases, and the removal of obvious bony splinters and foreign bodies, combined with provision for very free drainage, is very essential, and much easier to accomplish at the first operation than subsequently.

Finally Mr. Parker emphasized the importance of conservative surgery in the treatment of war injuries of the external genitalia by the careful undercutting of skin flaps and preservation of all viable remaining tissue and the avoidance of tension. Some of the very grossest injuries could be successfully repaired from the point of view of sexual as well as urinary function.

Mr. John Everidge: I would like to pay an especial tribute to Mr. Poole-Wilson, having seen a number of his cases who were sent to my wards on their return to England. First-hand information reaching me from another source describing the unceasing personal attention he gave to each of his cases would explain his excellent results.

The urological beds at Horton (E.M.S.) Hospital under my care received upwards of one hundred cases of traumas of the urinary tract. A considerable number were primary from enemy action—bombs and rocket bombs—an equally large number from accidental injuries, especially ruptured bladders and urethras from fractured pelves from road transport injuries. The rest were secondary from overseas, the majority from the N. European front.

Methods adopted by the former speakers are of the standard type practised by most urological surgeons. I would, however, question Mr. Mogg's advice as to searching for and suturing extraperitoneal ruptures of the bladder. Except for an anterior tear—easily reached and useful, after partial suture, as a site for drainage—I would consider it wiser to leave any lateral tears to look after themselves; their edges will fall together and heal readily if perfect drainage is established. Suture of lateral and posterior tears from their inaccessibility is a difficult undertaking and dangerous in the reduced state of a typical case, the victim of a very serious and probably complicated injury. A finger should always explore the bladder for missiles or displaced bone. In every battle casualty and in most accidental injuries where there is the slightest suspicion of bladder or urethral injury suprapubic drainage should be established at the earliest possible moment. The good results from every front amply bore this out. One glaring exception reached me from overseas three weeks after injury: a blast dislocation and wide separation of the symphysis pubis. In spite of early suprapubic exploration a ruptured bladder was overlooked and urethral catheter drainage alone was adopted. On arrival the soldier was profoundly toxic and presented extravasation abscesses in the abdominal muscles, the right groin and the perineum. I found a very low tear in the anterior wall of the bladder. With ample suprapubic drainage and evacuation of the abscesses and with the aid of blood transfusions and courses of penicillin a good recovery was eventually made.

By the way, in these midline extraperitoneal ruptures, so common a complication of a separated symphysis, union at the symphysis may be delayed although good apposition may have been accomplished by suitable orthopædic measures, preferably, in my experience, by the pelvic sling. One of my cases on starting to walk three months after injury had a sharp hæmaturia. Cystoscopy showed blood coming from a linear tear in the scar on the anterior wall of the bladder. An X-ray photograph revealed that the pubic bones hitherto in contact were separated again.

In another case, I operated for a gross hydronephrosis—20 ounces of urine were aspirated from the kidney. The patient was five months' pregnant at the time, and has since given birth to a full-time child. She is now free from symptoms, the urine is sterile, and X-rays show a fair function.

In two other cases recently performed, a horseshoe kidney was present, and the operation worked satisfactorily even in these cases, and the patients up to the present have been entirely free from symptoms and the urine sterile.

2 Kelly, H. A., and Burnam, C. F. (1914) Diseases of the Kidneys, Ureters and Bladder, 1, 125. New York.

Mr. H. P. Winsbury-White showed on the screen an illustration published by the late Andrew Fullerton of a kidney showing what happened to the lower pole when its artery of supply was divided. The lower pole was in a state of necrosis. Since seeing that illustration and reading reports of a number of cases of gangrene he had given attention when dividing that vessel to amputating the lower pole of the kidney as well, and that was an operation which gave excellent results and one which he could recommend to those who had not tried it. The convalescence was particularly satisfactory. He believed that obstruction of the ureter by a blood-vessel occurred as a complication rather than as a primary cause of the hydronephrosis. His reason for this opinion was that many years ago he went round the pathological museums in London and collected all the specimens of hydronephrosis he could find in which it was shown that the ureter was obstructed by a blood-vessel which still remained intact. He found 12 altogether, and in 11 it was obvious that the obstructing vessel was the normal inferior branch of the renal artery or vein (*Brit. J. Surg.*, 1925, 13, 247; *Trans. Amer. Ass. gen.-urin. Surg.*, 1936, 29, 381).

Mr. Winsbury-White went on to say that the question as to whether or not this obstructing vessel was the cause or a complication was not entirely academic, because after dividing the vessel one must not expect to have cured the condition, if one had left behind the original cause of the hydronephrosis. There was no doubt about the relief of symptoms on dividing the vessel; it was quite dramatic. His experience with a variety of plastic procedures was that very good results were obtained in the early part of the convalescence, but the long-term results had not been good at all, and his feeling was that plastic operations as a whole were very unsatisfactory. He agreed that there were odd cases which were satisfactory, and what he had said applied also to the relief of hydronephrosis by dividing the obstructing blood-vessel. There was a significant lack in the literature concerning long-term good results in plastic operations for hydronephrosis. The fundamental point was that such patients were lucky if the opposite kidney was quite normal, and the surgeon was free, therefore, to do a nephrectomy. Mr. Winsbury-White showed a number of illustrations to demonstrate the mechanism of the obstruction by a normal renal blood-vessel when it occurred as a complication of the hydronephrosis. Several of these showed that the vein was the obstructing vessel. He showed other illustrations which indicated that the renal fascia also contributed to the obstruction of the ureter.

Kidney with Triple Pelvis and Large Ureteric Calculus.—Mr. E. W. Riches.

(1) Congenital Hydronephrosis in a Child aged 4½ Years.—Mr. I. H. Griffiths for Mr. E. W. Riches. (2) Congenital Hydronephrosis of Unusual Type.—Mr. T. H. Cullen for Mr. E. W. Riches.

neither pelvis nor kidney is opened (except in rare cases when a needle may be used for aspiration). (4) There is no possibility of fistula formation provided the operation is carefully performed.

The first of these operations which I performed over eleven years ago was immediately successful. The patient, a young man, is in continuing good health—his urine is sterile, and a normal filling of the pelvis and calices is seen in all subsequent pyelograms. The patient was 15 years of age at the time of operation. The major part of the kidney received its blood supply from the lower polar artery, making division of the latter impracticable.

Encouraged by this initial success, I used the operation at first for cases similar to the original one, with large polar arteries which I dare not divide, but presently, as these continued to give uniformly successful results, I extended its use to all cases judged worthy of conservative surgery.

Principle [1].—At a later date I realized that in the operation I had attempted to reverse certain anatomical changes which had occurred with growth. The vessels entering the kidney following the operation had the relationship which existed in infancy.

I had noticed when operating upon infants at the Children's Hospital, that they possessed kidneys which were rounded in shape, and when studying the literature I found a reference to this fact in Kelly and Burnam's [2] book. They comment on the change of shape in the kidney as it attains adult size. The shape of the kidney in the infant is such that the poles approach each other closely over an intrarenal pelvis. In early life, therefore, I believe accessory renal vessels lie close to the main renal artery, a position in which they are not likely to obstruct and prevent the escape of urine.

As the child grows, the kidney opens out "rather like a bud developing into a flower". The lower polar or aberrant artery is carried away by the diverging poles of the kidney, and in this lower position has a relationship to ureter or pelvis enabling it to produce obstruction. Thus, a lower polar vessel may not cause obstruction in the infant, but may do so in childhood or adult life. One may say that a lower polar artery should not produce obstruction unless the kidney has assumed its adult reniform shape, or the kidney is congenitally abnormal as in a horseshoe kidney.

The main principle of the operation is to mould the kidney so that the lower polar or aberrant artery is no longer capable of causing obstruction. It is brought into close relationship with the renal artery. The capsule is dissected from the anterior surfaces of the poles, but allowed to remain attached along the convex border. The poles of the kidney are then brought together, but in order to maintain them in this new position, a second folding of the kidney is necessary. The anterior surfaces of the poles are brought together so that a broad and secure grip is obtained and adhesions will develop over a broad area. The kidney is held in its new shape until adhesions develop by: (1) Hardened catgut tape passed under the capsule around the *new* convex border of the kidney rather like a rim round a wheel, and tied or sutured on the medial aspect. (2) Plain catgut sutures 4/0 through the poles. (3) Suture of the dissected flaps of capsule.

Any adhesions or minute vessels tending to retain the kink in the ureter or in the region of the uretero-pelvic junction are divided.

The pelvis, if it has been considerably distended, is plicated in front and behind by 6/0 catgut (10 day). The sutures should not penetrate the lumen. They should be placed mainly across the long axis of the pelvis, but near the pelvi-ureteric junction a few may be placed in the long axis.

Follow-up X-rays have shown that the kidney retains its new shape permanently. The lowest major calix, as a result of the moulding, occupies a higher position, and the calices, in pyelograms, tend to assume the configuration of the petals of a flower.

Results.—I have performed 21 operations and all of them have given excellent results in that the patient has been freed from symptoms. Radiological evidence has shown that the kidneys drained satisfactorily; and the urine was free from infection. In none of these cases did a congenital stricture co-exist.

The following cases are of particular interest:

A patient aged 65 suffered from fairly severe hydronephrosis due to an aberrant artery. Her other kidney had been destroyed many years before, presumably from the same condition. An operation on this kidney was the supreme test as I did not know how soon after the operation the kidney would function. The aberrant artery was of large size and following the operation described the kidney functioned immediately; 17, 34 and 74 ounces of urine were secreted in the three post-operative days without the use of intravenous therapy. Thus, the moulding of the kidney did not cause it to cease functioning.

In another case, I operated for a gross hydronephrosis—20 ounces of urine were aspirated from the kidney. The patient was five months' pregnant at the time, and has since given birth to a full-time child. She is now free from symptoms, the urine is sterile, and X-rays show a fair function.

In two other cases recently performed, a horseshoe kidney was present, and the operation worked satisfactorily even in these cases, and the patients up to the present have been entirely free from symptoms and the urine sterile.

2 KELLY, H. A., and BURNAM, C. F. (1914) Diseases of the Kidneys, Ureters and Bladder, 1, 125. New York.

Mr. H. P. Winsbury-White showed on the screen an illustration published by the late Andrew Fullerton of a kidney showing what happened to the lower pole when its artery of supply was divided. The lower pole was in a state of necrosis. Since seeing that illustration and reading reports of a number of cases of gangrene he had given attention when dividing that vessel to amputating the lower pole of the kidney as well, and that was an operation which gave excellent results and one which he could recommend to those who had not tried it. The convalescence was particularly satisfactory. He believed that obstruction of the ureter by a blood-vessel occurred as a complication rather than as a primary cause of the hydronephrosis. His reason for this opinion was that many years ago he went round the pathological museums in London and collected all the specimens of hydronephrosis he could find in which it was shown that the ureter was obstructed by a blood-vessel which still remained intact. He found 12 altogether, and in 11 it was obvious that the obstructing vessel was the normal inferior branch of the renal artery or vein (*Brit. J. Surg.*, 1925, 13, 247; *Trans. Amer. Ass. gen.-urin. Surg.*, 1936, 29, 381).

Mr. Winsbury-White went on to say that the question as to whether or not this obstructing vessel was the cause or a complication was not entirely academic, because after dividing the vessel one must not expect to have cured the condition, if one had left behind the original cause of the hydronephrosis. There was no doubt about the relief of symptoms on dividing the vessel; it was quite dramatic. His experience with a variety of plastic procedures was that very good results were obtained in the early part of the convalescence, but the long-term results had not been good at all, and his feeling was that plastic operations as a whole were very unsatisfactory. He agreed that there were odd cases which were satisfactory, and what he had said applied also to the relief of hydronephrosis by dividing the obstructing blood-vessel. There was a significant lack in the literature concerning long-term good results in plastic operations for hydronephrosis. The fundamental point was that such patients were lucky if the opposite kidney was quite normal, and the surgeon was free, therefore, to do a nephrectomy. Mr. Winsbury-White showed a number of illustrations to demonstrate the mechanism of the obstruction by a normal renal blood-vessel when it occurred as a complication of the hydronephrosis. Several of these showed that the vein was the obstructing vessel. He showed other illustrations which indicated that the renal fascia also contributed to the obstruction of the ureter.

Gunshot Wound of the Ureter.—Mr. ANDREW M. DESMOND (introduced by Mr. H. K. VERNON).

Advanced Carcinoma of the Bladder Excised by Perineo-abdominal Cystectomy (Hydronephrosis and Pyonephrosis).—Mr. ALAN HUNT (Specimen shown by Mr. S. O. AYLETT).

Epididymoma; Histology: Old Hæmatoma.—Mr. A. WILFRID ADAMS.

Survival of a Testicle Transplanted into Scarpa's Triangle.—R. OGIER WARD, D.S.O., M.Ch.

August 1934: The patient was a boy aged 9. He was inclined to general obesity particularly of the buttocks. The pelvis appeared unduly wide. The scrotum was undeveloped. The left testicle could not be felt, the right was palpable in the inguinal canal and could just be pushed into the upper scrotum; it was very small. Operative treatment had already been advised by another surgeon but refused.

March 1936: He had been examined four times during the intervening period. Pregnyl had been tried, but there had been no improved development. A right orchidopexy was performed (Keetley-Torek technique). The testicle was minute (about 0·7 cm.) enveloped in deep subcutaneous fat.

August 1936: The second stage of the operation performed; this was difficult because of the excess of fat.

April 1937: It seemed that the right testicle had atrophied completely. The left testicle could be felt in the scrotum, it was very small.

June 1945: Now aged 20, average size and normal development. Left testicle was in the scrotum and normal. Sexual characteristics quite normal. To my surprise I found in Scarpa's triangle on the right side a swelling the size of a normal testicle.

July 1945: Exploration of Scarpa's triangle revealed a testicle two-thirds the size of the left one. Two pieces excised for microscopy (Dr. T. Joekes) showed rete testis and seminiferous tubules but no evidence of spermatogenesis.

It was considered most unlikely that any further reconstruction could be carried out successfully but as it seemed unwise to leave the testicle in the thigh an attempt was made to rejoin the right cord and epididymis to it. When, however, five months later the testicle was restored to the scrotum complete atrophy followed.

Comment.—It is obvious that in the operation of August 1936, owing to the minute size of the testicle and the excess of fat, the plane of dissection had passed between the epididymis and the testis, leaving the latter in the thigh. It is remarkable that the organ had there acquired a blood supply sufficient for it to develop to above twenty times its size.

DISCUSSION ON THE TREATMENT OF SYPHILIS WITH PENICILLIN

Dr. Joseph Earle Moore, U.S.A.: I propose to give you a brief account of the American experience with penicillin in syphilis. Treatment has been conducted on an organized co-operative basis under the auspices of the Committee of Medical Research and later under the Research Grants Division, National Institute of Public Health of the United States Public Health Service. The information from the clinics and Services collaborating in this work was reported on standard forms in a central statistical unit and analysed by the Department of Biostatistics of the Johns Hopkins School of Hygiene and Public Health. We now have data on 40,000 cases of early syphilis and a smaller but substantial number of cases in various phases of late syphilitic infection.

In addition to tne clinics co-operating in this experiment there are also eight laboratories collaborating in the study of the use of penicillin in rabbit syphilis. From their work it appears that penicillin G is superior in treponemicidal effect to X, F or K. This is in contrast to the bactericidal effects of these penicillins against certain other organisms. Penicillin X is two to ten times superior to G in *gonococcal*, *staphylococcal* and *pneumococcal* infections. In syphilitic rabbits, however, G is about six times as effective as F or X and about twenty times superior to penicillin K. It is fortunate that commercial penicillins have been composed predominantly of penicillin G and it is the easiest to prepare in relatively pure crystalline form. The other species F, dihydro F, X and K, have been available in pure form only in very small amounts for experimental study. Other antibiotic agents, in particular streptomycin and bacitracin, have not been shown to equal the effect of penicillin G.

Penicillin cures syphilis in rabbits whether the animals are treated early (within six weeks after infection) or late (six months or later after infection). Many small doses are more effective than one or a few large doses. The curative dose is related also to the duration of infection. In animals treated within four hours to four days after inoculation, therefore, before the appearance of a chancre, far less penicillin is required (total dosage) than if treatment is delayed for six weeks or longer. The results in animals are likewise related to the size of the inoculum. Animals treated soon after the injection of 2 to 20 organisms require a smaller total dose for cure than if the inoculation is a large one. Cure is accomplished within the actual period of treatment since treated animals with healing chancres still present may be reinfected as soon as four days after the completion of treatment. These facts raised the possibility of the prophylactic use of penicillin by means of oral administration. The U.S. Army and Navy have now in progress controlled experiments in selected units in which 500,000 units of penicillin administered by mouth in personnel sexually exposed is being tried for prophylactic effect.

Survival of a Testicle Transplanted into Scarpa's Triangle.—R. OGIER WARD, D.S.O., M.Ch.

August 1934: The patient was a boy aged 9. He was inclined to general obesity particularly of the buttocks. The pelvis appeared unduly wide. The scrotum was undeveloped. The left testicle could not be felt, the right was palpable in the inguinal canal and could just be pushed into the upper scrotum; it was very small. Operative treatment had already been advised by another surgeon but refused.

March 1936: He had been examined four times during the intervening period. Pregnyl had been tried, but there had been no improved development. A right orchidopexy was performed (Keetley-Torek technique). The testicle was minute (about 0·7 cm.) enveloped in deep subcutaneous fat.

August 1936: The second stage of the operation performed; this was difficult because of the excess of fat.

April 1937: It seemed that the right testicle had atrophied completely. The left testicle could be felt in the scrotum, it was very small.

June 1945: Now aged 20, average size and normal development. Left testicle was in the scrotum and normal. Sexual characteristics quite normal. To my surprise I found in Scarpa's triangle on the right side a swelling the size of a normal testicle.

July 1945: Exploration of Scarpa's triangle revealed a testicle two-thirds the size of the left one. Two pieces excised for microscopy (Dr. T. Joekes) showed rete testis and seminiferous tubules but no evidence of spermatogenesis.

It was considered most unlikely that any further reconstruction could be carried out successfully but as it seemed unwise to leave the testicle in the thigh an attempt was made to rejoin the right cord and epididymis to it. When, however, five months later the testicle was restored to the scrotum complete atrophy followed.

Comment.—It is obvious that in the operation of August 1936, owing to the minute size of the testicle and the excess of fat, the plane of dissection had passed between the epididymis and the testis, leaving the latter in the thigh. It is remarkable that the organ had there acquired a blood supply sufficient for it to develop to above twenty times its size.

the drug is used alone or with arsenic. This may be of some importance to the mass treatment of syphilis in that an adjuvant total dose of bismuth adequate to prevent relapses over the first nine to twelve months may allow the patient to develop enough immunity so that he is infectious for others for a shorter time than would otherwise be the case.

The results on the whole indicate that the failure rate of treatment with penicillin in patients with early syphilis after eighteen to twenty-four months of observation is, with the treatment systems which we have employed, in the general range of 25 to 35%. The failure rate was not materially improved upon by the addition of either arsenic or bismuth or both in the doses we employed, nor were the results materially improved upon by fever. These are results which are substantially worse than the best obtainable by metal chemotherapy without penicillin, when the failure rate may be as low as 3 to 10%, *provided the patient completes the treatment and is not seriously ill or killed as a result of it.* With metal chemotherapy, if treatment is completed within a brief period of time, the mortality rate from treatment *per se* is excessive, whereas if it is prolonged for the sake of safety comparatively few patients can be held to the conclusion of treatment. Penicillin, however, offers the advantage of complete safety when used within the time limits of practicability, which is, with penicillin in aqueous solution, about fifteen days. This is the maximum time for which we can hold patients in hospital. On the other hand, the results are such as to indicate that for the individual patient they may be poor, that is, less than can be accomplished with metal chemotherapy alone.

Penicillin resistance has not been observed in syphilis in man.

This information raises a number of fundamental questions. Why is early syphilis apparently uniformly curable in the rabbit, whereas in man there is a substantial residue of failure? Is this related to the number of treponemes to be destroyed or to some factor of tissue localization in man but not in animals, or some factor of immunity? Is man dependent on the development of resistance against the few treponemes not destroyed in the first massive attack? What is the significance of low titre seroresistance after penicillin? Does it represent persistence of treponemes or their tissue reaction or a persistence of immunity after cure? Can any evidence be evolved to differentiate relapse and reinfection? While with other organisms penicillin is effective only when the organisms are in a rapidly dividing state, it has so far not been possible to work out the time-dose factor in relation to the rate of multiplication of the treponemes, and the question of the value of repeated courses of penicillin in peanut oil–beeswax is still to be solved. Further it is still unknown how long seronegativity must continue before the patient can be discharged from further investigation.

Now, in contrast to a failure rate of 25% or more in patients with acquired early syphilis, penicillin is spectacularly and nearly completely successful in the prevention of prenatal syphilis by treatment of the pregnant syphilitic mother. The failure rate in the infant is only 1 to 2%. The total dose and duration of treatment are the same as in early syphilis. Why is it that the fœtus with a massive and overwhelming infection is cured by a substantially lower concentration than in its mother and which fails to cure the parent? The fœtus may be influenced favourably even when treatment is not begun till the eighth or ninth month.

The action of penicillin in congenital syphilis raises a similar problem. Penicillin has not reduced the mortality rate but most of the deaths in such infants are neither due to syphilis *per se* nor the Herxheimer reaction, but are due to other infections or nutritional disturbances. In infants which survive the treatment the failure rate is substantially lower than the adult rate and the clinical relapse rate is only about one-sixth as frequent. Why, again, are areas packed with treponemes more susceptible to penicillin? Is it due to difference in infantile and adult tissue localization or to unidentified immunity factors which may vary in the infant as contrasted with the adult?

In latent and late syphilis other than neurosyphilis penicillin heals lesions if any are present, but has no greater effect on the blood serologic test than has any other form of treatment. Nothing can be said of the eventual clinical outcome in these cases, since years of post-treatment observation are necessary to determine the point. In patients with latent syphilis, what matters is what happens to the patient, not what happens to his blood test and it is necessary to follow large series of patients quite literally for a lifetime.

In cardiovascular syphilis, the most that can be said of penicillin to date is that, whether initiated with large or small doses, it appears to do no harm. The Herxheimer reaction, so-called therapeutic shock, need not be greatly feared. At the Johns Hopkins Hospital we have now treated some fifty patients with saccular aneurysms or aortic regurgitation, dividing them into two groups, one treated initially with 1,000 units gradually increased to an average therapeutic dosage: the other treated with 50,000 to 100,000 units from the start. In neither group was there any evidence of damage to the patients detectable by clinical symptoms, electrocardiograms, sedimentation rates, temperature, leucocyte count, &c. No

In experimental animals, neither *in vitro* against cultured non-pathogenic strains of spirochætes nor *in vivo* has there appeared any definite evidence of penicillin resistance. The effect of penicillin in animals is apparently enhanced by the simultaneous administration of oxophenarsine hydrochloride (mapharside). The effect is likewise enhanced, in an additive sense, by the simultaneous administration of bismuth. The drug is more effective when administered at fever temperature than at normal body temperature.

In early acquired infection in man, if freedom from relapse and prolonged seronegativity up to three years after treatment indicate cure of early syphilis, then penicillin is also curative, but by no means so uniformly as in the experimental animal. In our study of the results of treatment, patients have been classified as failures if at any time after treatment there has been evidence of clinical or serologic relapse or reinfection. It is clinically impossible to differentiate reinfection from relapse; even although the presumption of reinfection was very strong, all such patients were classified as treatment failures. To the extent that there is a predominance of actual reinfection over relapse, the results I shall discuss are better than indicated. Serologic relapse includes not only patients who relapse after having become sero-negative but also those whose serologic titre only temporarily drops to a low titre followed by a subsequent rise. Patients have been classified as failure when reagins are persisting in the blood one year after treatment (seroresistant).

When the cumulative failure rate was related to the total dose of penicillin given in all types of early syphilis every three hours for seven to eight days the following results were obtained: with a total dose of 300,000 units the failure rate at the end of twenty-two months approximated 50%; with 600,000 units it dropped to 35%. When the dose reached 1·2 to 4·8 mega units, there was no appreciable difference between the failure rates at the end of one year. All these experiments were done with commercially ampouled penicillin which will have an expected quantitative error of dosage between −15 and +40%. Related to the duration of treatment a total of 2·4 million units given every three hours over periods of four, seven-and-a-half and fifteen days the cumulated failure rates at the end of nearly two years showed no difference. When the total duration of treatment remains standard at four days and the total dose 1·2 million units given at either three or six hour intervals there was no difference in the cumulative failure rates. In a small group when twenty-five million units were given by continuous intravenous drip in one day the failure rate approximated to 60% at the end of six months! There appears to be no statistically significant difference in therapeutic efficiency between penicillin of relatively low potency and penicillin of comparatively higher potency, 900 units or more per mgm.

In another series 1·2 million units of penicillin were given for seven and a half days combined with these different adjuvants, namely arsenic, bismuth or fever. Of these last, one group was treated with penicillin plus fever in four days, the other group in seven days. There appears to be no material advantage to human beings of a combination of penicillin with bismuth or arsenic, in the dosages and within the time limits in which these drugs were used. A total dose of 480 mg. of auxiliary mapharside was given; of bismuth 1,000 mg. —doses in themselves known to be not curative and subject to a high relapse rate.

The results with penicillin show an obvious advantage in giving treatment early. In patients treated within the first seven days the results are materially better than when treatment is delayed until lesions have been present for from four to seven weeks, and still better than when lesions have been present for eight weeks or longer. The data are roughly separable into the clinical groups of seronegative primary syphilis (less than seven days) and early secondary syphilis (more than fifty-six days).

It seems impossible for various reasons to develop an ambulatory method of treatment with aqueous penicillin. We have therefore concentrated in the use of penicillin in peanut oil–beeswax, a formula involving the suspension of penicillin in peanut oil which contains 4·8% of purified beeswax. This may be administered once a day rather than every few hours since a detectable blood level can be obtained from a single dose of 600,000 units which lasts twenty to twenty-four hours. Patients have been so treated with three different systems; one with the administration of 600,000 units penicillin daily for eight days, another, daily injections of 600,000 units for sixteen days and the third by twice-weekly injections, given over eight weeks to a total of sixteen injections. The results with these systems are relatively indistinguishable. The data further suggest that at the end of twelve to twenty-four months the results from penicillin in peanut oil–beeswax are as good as, and may be better than may be expected from penicilllin in aqueous solution. This is being confirmed by still further observations. The incidence of clinical relapse, including reinfection, is about the same, regardless of how the penicillin was employed, whether the dosage was low or relatively high, and whether the drug was or was not combined with metal chemotherapy. The time of appearance of relapse when penicillin is combined with bismuth is slightly later than when the drug is used alone or with arsenic. This may be of some importance to the mass treatment of syphilis in that an adjuvant total dose of bismuth adequate to prevent relapses over the first nine to twelve months may allow the patient to develop enough immunity so that he is infectious for others for a shorter time than would otherwise be the case.

The results on the whole indicate that the failure rate of treatment with penicillin in patients with early syphilis after eighteen to twenty-four months of observation is, with the treatment systems which we have employed, in the general range of 25 to 35%. The failure rate was not materially improved upon by the addition of either arsenic or bismuth or both in the doses we employed, nor were the results materially improved upon by fever. These are results which are substantially worse than the best obtainable by metal chemotherapy without penicillin, when the failure rate may be as low as 3 to 10%, *provided the patient completes the treatment and is not seriously ill or killed as a result of it.* With metal chemotherapy, if treatment is completed within a brief period of time, the mortality rate from treatment *per se* is excessive, whereas if it is prolonged for the sake of safety comparatively few patients can be held to the conclusion of treatment. Penicillin, however, offers the advantage of complete safety when used within the time limits of practicability, which is, with penicillin in aqueous solution, about fifteen days. This is the maximum time for which we can hold patients in hospital. On the other hand, the results are such as to indicate that for the individual patient they may be poor, that is, less than can be accomplished with metal chemotherapy alone.

Penicillin resistance has not been observed in syphilis in man.

This information raises a number of fundamental questions. Why is early syphilis apparently uniformly curable in the rabbit, whereas in man there is a substantial residue of failure? Is this related to the number of treponemes to be destroyed or to some factor of tissue localization in man but not in animals, or some factor of immunity? Is man dependent on the development of resistance against the few treponemes not destroyed in the first massive attack? What is the significance of low titre seroresistance after penicillin? Does it represent persistence of treponemes or their tissue reaction or a persistence of immunity after cure? Can any evidence be evolved to differentiate relapse and reinfection? While with other organisms penicillin is effective only when the organisms are in a rapidly dividing state, it has so far not been possible to work out the time-dose factor in relation to the rate of multiplication of the treponemes, and the question of the value of repeated courses of penicillin in peanut oil–beeswax is still to be solved. Further it is still unknown how long seronegativity must continue before the patient can be discharged from further investigation.

Now, in contrast to a failure rate of 25% or more in patients with acquired early syphilis, penicillin is spectacularly and nearly completely successful in the prevention of prenatal syphilis by treatment of the pregnant syphilitic mother. The failure rate in the infant is only 1 to 2%. The total dose and duration of treatment are the same as in early syphilis. Why is it that the fœtus with a massive and overwhelming infection is cured by a substantially lower concentration than in its mother and which fails to cure the parent? The fœtus may be influenced favourably even when treatment is not begun till the eighth or ninth month.

The action of penicillin in congenital syphilis raises a similar problem. Penicillin has not reduced the mortality rate but most of the deaths in such infants are neither due to syphilis *per se* nor the Herxheimer reaction, but are due to other infections or nutritional disturbances. In infants which survive the treatment the failure rate is substantially lower than the adult rate and the clinical relapse rate is only about one-sixth as frequent. Why, again, are areas packed with treponemes more susceptible to penicillin? Is it due to difference in infantile and adult tissue localization or to unidentified immunity factors which may vary in the infant as contrasted with the adult?

In latent and late syphilis other than neurosyphilis penicillin heals lesions if any are present, but has no greater effect on the blood serologic test than has any other form of treatment. Nothing can be said of the eventual clinical outcome in these cases, since years of post-treatment observation are necessary to determine the point. In patients with latent syphilis, what matters is what happens to the patient, not what happens to his blood test and it is necessary to follow large series of patients quite literally for a lifetime.

In cardiovascular syphilis, the most that can be said of penicillin to date is that, whether initiated with large or small doses, it appears to do no harm. The Herxheimer reaction, so-called therapeutic shock, need not be greatly feared. At the Johns Hopkins Hospital we have now treated some fifty patients with saccular aneurysms or aortic regurgitation, dividing them into two groups, one treated initially with 1,000 units gradually increased to an average therapeutic dosage: the other treated with 50,000 to 100,000 units from the start. In neither group was there any evidence of damage to the patients detectable by clinical symptoms, electrocardiograms, sedimentation rates, temperature, leucocyte count, &c. No

one is yet prepared to offer any statement as to whether penicillin does cardiovascular syphilis any good, but since it heals visible lesions it should heal lesions which cannot be seen. In contrast to man, however, rabbits with late syphilis appear to be as readily curable with penicillin as do those with early infections. A smaller total dose of penicillin, even, may be required to cure the animals with late than with early syphilis. Is late syphilis in man curable with this drug? Only much further study will give us the information.

In syphilis of the nervous system, regardless of the clinical syndrome present, there are profound and uniform effects from penicillin administered intramuscularly. Whether in asymptomatic neurosyphilis, acute syphilitic meningitis, tabes dorsalis or general paresis, cell count and protein content are reduced to normal in practically all cases. This occurs within a few weeks and in many cases within a few days. Colloidal tests tend towards normal as protein decreases. The spinal fluid Wassermann test is also favourably though more slowly influenced; the rate of reversal of this test depends on the duration of infection with syphilis and the original complement-fixation titre of the fluid. The more strongly positive the fluid the longer it takes for the Wassermann test to become negative. These evidences of laboratory improvement, regardless of the clinical type of the disease, persist at least for three years in about 90% of cases treated: only about 10% of the total showing a later return of fluid abnormalities. There is no need for the technically difficult administration of penicillin by the subdural or intrathecal route. Clinically, penicillin appears to be superior to any form of metal chemotherapy. Regardless of the type of neurosyphilis, clinical improvement may be expected from penicillin to the extent to which symptoms and physical signs depend on inflammation rather than on degeneration. Neither penicillin nor any other form of treatment will restore dead brain cells or fibre tracts, although further destruction and clinical progression may be prevented. In certain of the relatively benign forms of neurosyphilis, penicillin alone gives satisfactory results. In the more serious forms the combination of penicillin and fever from induced malaria may be superior to penicillin alone, both from clinical and laboratory standards. The time-dosage relationship in neurosyphilis is not so clearly established as in early syphilis. Most American observers believe that a large total dose is superior to smaller dosage and that ten to twenty days' treatment is better than a short duration.

The advent of penicillin has made it possible to accomplish as much or more in most cases of neurosyphilis as previously was obtainable with fever and several years of subsequent metal chemotherapy. Its immediate effects appear to be more striking in neurosyphilis than in early syphilis. Available data indicate that penicillin penetrates the tissue of the nervous system in a concentration far lower than that of other tissues. If improvement depends on tissue concentration of the drug, why are results apparently better in neurosyphilis than early syphilis in which the nervous system is spared? Are the good results permanent?

Penicillin represents a major advance in syphilotherapy. There are still a number of curious and unexplained differences in its effect in various stages of syphilitic infection, whether the variable mixtures of commercial penicillin or crystalline penicillin G are used. It probably represents only the first faltering steps in the antibiotic therapy of this disease. Further studies may replace penicillin by a new and more powerful antibiotic. Pending such a development the organized study of penicillin has provided information within four years, which otherwise would have required a generation to accumulate. Further, the co-operative study has re-emphasized the gaps in our knowledge of the fundamental biology of syphilitic infection which must be filled in before the perfect form of treatment of syphilis can be found.

Dr. E. M. Lourie (*Director of the Department of Chemotherapy, Liverpool School of Tropical Medicine*) recalled that his original observations that penicillin was effective against spirochætoses had been made on *Spirochæta recurrentis* and *Spirillum minus* infections in mice in August 1942. Although no secret had been made of the work and its potential significance for syphilis, it did not appear in print until July and December 1943 [1, 2], that is practically simultaneously with the announcement by Mahoney *et al.* [3] that penicillin is, in fact, efficacious against syphilis. Prior to this he had tried unsuccessfully to obtain an allocation for human trials. Detailed plans had already been laid with Dr. A. O. F. Ross for trials against syphilis before Mahoney's paper had appeared, and it was by the merest coincidence that they had chosen a total dosage per case of 2·4 mega units, exactly twice that chosen by the Americans. If penicillin proved to be ineffective at maximal dosages it would then be possible to dismiss the whole subject with relatively little waste of time or penicillin, while, if effective, later effort could be devoted to determining the minimum effective dosage. The results of the first four cases of secondary syphilis he and Dr. Ross treated with 2·4 mega units [4] made them doubt whether penicillin had been as effective as arsenicals and bismuth. The concurrent investigation in the United States [5] of some 1,500 cases of early syphilis treated with 60,000 to 1·2 mega units led to a similar cautionary conclusion that "certainly the minimum dose, especially in secondary syphilis, should not be less than 1,200,000 units; probably it should be more".

It seemed to him that there had been a singular reluctance to determine whether the efficacy of penicillin could not be stepped up by a bold increase in dosage. The laboratory evidence of Eagle and Musselman [6] had been adduced against the value of massive dosage, but other laboratory work [7] had encouraged his group to find out what penicillin could do against syphilis when given in massive dosage. Dosage was such as obviated hospitalization and serious interference with the patient's daily work. They had obtained equally good results with two such courses, (i) three intramuscular doses of 500,000 units at hourly intervals for five consecutive days, or (ii) two intramuscular doses of 1,000,000 units at hourly intervals, on each of five days. The combined results of these two courses gave 87 to 92% success in twenty-four cases of primary syphilis and 76 to 92% success in fifty secondary cases. The results of the small series may not be as good as might be obtained by other forms of treatment, but they have the great virtue of having been produced by ambulatory treatment. If course (ii) were supplemented with daily injection of say 0·09 gramme neohalarsine or 0·06 gramme mapharside given in the hour between the two penicillin injections, results might be obtained as good as by any other method but involving far smaller demands on the patients' time and convenience.

He concluded by paying a tribute to the truly remarkable organization, scope and achievement of the American effort, so largely guided and inspired by Dr. Earle Moore.

Lieut.-Colonel **J. W. Eames, R.A.M.C.**, stated that in 1944 2·4 mega units of penicillin were given in the Army with a failure rate of 8% at the end of six months. Since then further methods have been used but the follow up was difficult. In the case of patients suffering from primary syphilis treated with 2·4 mega units of penicillin (aqueous) over seven and a half days the maximum relapse incidence was in the first six months. The calculated cumulative relapse rate at twelve months for seronegative primary cases was 14% and for seropositive primary cases 13%, and for secondary cases 17·5%. In patients treated with 4 mega units over twelve and a half days, the relapse rate, as far as could be seen from the small follow-up, appeared to be essentially the same. The results of using 2·4 mega units of penicillin plus 0·6 gramme mapharside in ten days, and a similar course giving 0·4 gramme mapharside and 1 gramme bismuth did not appear to differ materially from those obtained by using penicillin alone, but the number followed up had been small. With 2·4 mega units in treatment seroresistance occurred in 3% of seropositive primary cases and 8% of secondary cases and with 4 mega units seropositive primary cases showed a resistance rate of 1·6% and secondary cases 3·8%.

Present treatment in the Army is 50,000 units penicillin three-hourly for ten days, combined with 1·35 grammes N.A.B. and 0·6 gramme bismuth in divided doses on the second, fifth and ninth day followed by 0·6 gramme N.A.B. and 0·2 gramme bismuth weekly for eight weeks. It was too early yet to evaluate this scheme. Bismuth had apparently no effect on the penicillin level of the blood.

Mr. **A. J. King** felt that now that Dr. Moore had produced the figures it was clear enough there was a considerable failure rate in cases of early syphilis with penicillin alone although such findings did not accord with his own experience. Dr. Curtis and he had limited their inquiries at the Whitechapel Clinic to those discharged soldiers who had received in the Army a total of 2·4 mega units of penicillin in sixty three-hourly injections of 40,000 units each in watery solution. Of 82 patients in this class observed over twelve months at least, in only 4 had treatment failed. This was a very small group and he hoped that other medical officers at other clinics would make similar investigations to obtain a large number of cases observed for a long period.

Section of Ophthalmology

President—Harold Levy, F.R.C.S.

[*May* 8, 1947]

CLINICAL MEETING HELD AT THE ROYAL WESTMINSTER OPHTHALMIC HOSPITAL, LONDON

FOUR CASES by A. S. PHILPS, F.R.C.S.

I.—Tuberculous Choroiditis.

A. M., married woman, aged 35. Vision in both eyes has failed for last four months and is now R. 3/60; L. 2/60.

Past history.—One child born eight months ago; followed by mild degree of puerperal sepsis.

Examination.—Cells on the back of both corneæ. and some free cells in the aqueous humour. Lens and vitreous clear. Both fundi show pale masses apparently deep to the retina and most marked around the macular area. The maculæ are both swollen and have deep central pits. No hæmorrhages seen. Appearance resembles that seen in tuberculous choroiditis. No improvement in condition during period under observation.

Mr. P. Moffatt said that in Case I the distribution of the lesions seemed to follow the direction of the vessels to some extent. He wondered whether this condition had started as a phlebitis, possibly of a tuberculous nature.

II.—Retinitis Proliferans.

H. S., married woman, aged 60. Has suffered from diabetes for ten years.

Two years ago.—L. vitreous hæmorrhage, vision reduced to light perception. This hæmorrhage has slowly organized so that at the present time the vitreous contains a number of vascular loops which can be seen growing out from the vessels at the optic disc and forming an almost complete circle.

III.—Palsy of L. Inferior Oblique Muscle.

R. V., aged 34, lorry driver.

Eighteen months ago.—Accident while driving. Crush injury of the face. Depression of the L. maxilla and fracture of the floor of the L. orbit. The depressed fracture was raised by operation shortly after the accident. The history of the muscle palsy and its gradual recovery was shown on the series of Hess charts taken at two-monthly intervals since the accident.

IV.—Asthma, Eczema, Cataract.

P. D., married woman, aged 30.

Skin has always been dry and scaly, sometimes breaking out into a red rash. Asthma started when she was 15 years old, and is so severe that she can never lie flat. Always sleeps with five pillows.

Seven years ago.—The left eye became dim, and subsequently the right.

October 1940: Linear extraction of L. lens. Successful result but later the L. retina detached below.

1947: The R. lens is now quite opaque.

This woman presents the syndrome of asthma, eczema and cataract. Asthma and eczema have often been associated, and dermatogenic cataract has been described by several writers, but the three conditions do not often present themselves in the same patient. The lens being ectodermal in origin, it is not surprising that it develops defects when the skin and epithelium lining the air passages are also affected. The asthma is of such severity that adrenaline injections have frequently to be given and cataract extraction had to be performed with the patient sitting up.

FOUR CASES by P. M. MOFFATT, F.R.C.S.

I.—Intra-ocular Foreign Body. Non-magnetic.

The President said that the intra-ocular foreign body seemed to be definitely metallic, not wood or glass, and his own feeling was that a metallic foreign body inside the eye should be removed. If it was left in, there was invariably degeneration of the retina, and it did not have to be iron or copper to cause that.

Dr. R. Forgan asked whether aqueous penicillin had been given up to 4·8 mega units as had the oil–beeswax suspension and whether there was any indication of a different penicillin optimum for Negroes as compared with whites. Further, were the latest results with crystalline penicillin G so good that an infected American doctor would dare to dispense altogether with metallotherapy?

Dr. David Nabarro stressed Dr. Earle Moore's extraordinarily interesting results in the antenatal treatment of the pregnant mother. When such a drug as penicillin was available it was criminal that positive pregnant mothers should not be treated. The mother need not be treated with a toxic drug but the child would be saved by the use of penicillin. Why children with congenital syphilis responded more readily than adults he could not say. While penicillin would not cure all syphilis, could it so modify the disease that congenital syphilis might appear in unexpected places?

Dr. J. Earle Moore, in reply, said, with reference to Dr. Lourie's series, that one of the things which had been learned and of which he was convinced, was that little or nothing could be said about the results of a small series of patients from any individual clinic. Working with some thirty-five to forty different clinics he had found that clinics using identical treatment schemes had turned up with widely variable results.

In reply to the question "What would you do if you got syphilis?" he would use an ambulatory treatment with penicillin oil–beeswax suspension, mapharside and bismuth.

As regards the use of more than 2·4 million units in aqueous solution, there had been a number of schemes using 4·8 million units and a few with 9·6 million units. With the higher doses there was a suggestion that the results were not quite so good but the differences were not yet statistically significant. With regard to Negroes the point was as to the duration of infection, the negro male being notoriously inaccurate as to the date of his last exposure to infection.

With regard to Dr. Nabarro's remarks he added that in women with primary and secondary syphilis the morbidity and mortality in infants, if the mothers were untreated, was 95%: if the mothers were treated with penicillin it was reduced to somewhere between 1 and 2%. For this one state of syphilitic infection, at any rate, all other methods of treatment should be abandoned and complete reliance placed on penicillin administered to pregnant women. The results were equally good when the mothers were treated late.

A full report of this meeting will appear in the *British Journal of Venereal Diseases.*

Section of Ophthalmology

President—HAROLD LEVY, F.R.C.S.

[*May* 8, 1947]

CLINICAL MEETING HELD AT THE ROYAL WESTMINSTER OPHTHALMIC HOSPITAL, LONDON

FOUR CASES by A. S. PHILPS, F.R.C.S.

I.—Tuberculous Choroiditis.

A. M., married woman, aged 35. Vision in both eyes has failed for last four months and is now R. 3/60; L. 2/60.

Past history.—One child born eight months ago; followed by mild degree of puerperal sepsis.

Examination.—Cells on the back of both corneæ, and some free cells in the aqueous humour. Lens and vitreous clear. Both fundi show pale masses apparently deep to the retina and most marked around the macular area. The maculæ are both swollen and have deep central pits. No hæmorrhages seen. Appearance resembles that seen in tuberculous choroiditis. No improvement in condition during period under observation.

Mr. P. Moffatt said that in Case I the distribution of the lesions seemed to follow the direction of the vessels to some extent. He wondered whether this condition had started as a phlebitis, possibly of a tuberculous nature.

II.—Retinitis Proliferans.

H. S., married woman, aged 60. Has suffered from diabetes for ten years.

Two years ago.—L. vitreous hæmorrhage, vision reduced to light perception. This hæmorrhage has slowly organized so that at the present time the vitreous contains a number of vascular loops which can be seen growing out from the vessels at the optic disc and forming an almost complete circle.

III.—Palsy of L. Inferior Oblique Muscle.

R. V., aged 34, lorry driver.

Eighteen months ago.—Accident while driving. Crush injury of the face. Depression of the L. maxilla and fracture of the floor of the L. orbit. The depressed fracture was raised by operation shortly after the accident. The history of the muscle palsy and its gradual recovery was shown on the series of Hess charts taken at two-monthly intervals since the accident.

IV.—Asthma, Eczema, Cataract.

P. D., married woman, aged 30.

Skin has always been dry and scaly, sometimes breaking out into a red rash. Asthma started when she was 15 years old, and is so severe that she can never lie flat. Always sleeps with five pillows.

Seven years ago.—The left eye became dim, and subsequently the right.

October 1940: Linear extraction of L. lens. Successful result but later the L. retina detached below.

1947: The R. lens is now quite opaque.

This woman presents the syndrome of asthma, eczema and cataract. Asthma and eczema have often been associated, and dermatogenic cataract has been described by several writers, but the three conditions do not often present themselves in the same patient. The lens being ectodermal in origin, it is not surprising that it develops defects when the skin and epithelium lining the air passages are also affected. The asthma is of such severity that adrenaline injections have frequently to be given and cataract extraction had to be performed with the patient sitting up.

FOUR CASES by P. M. MOFFATT, F.R.C.S.

I.—Intra-ocular Foreign Body. Non-magnetic.

The President said that the intra-ocular foreign body seemed to be definitely metallic, not wood or glass, and his own feeling was that a metallic foreign body inside the eye should be removed. If it was left in, there was invariably degeneration of the retina, and it did not have to be iron or copper to cause that.

II.—Familial Macular Degeneration, Adolescent Type.

C. S., male, aged 18, clerk, attended on account of inability to see in the distance. He had been tested many times but was not helped.

R. and L. vision with correction for a small amount of simple myopic astigmatism is 6/60. The fundi show degenerative changes at both maculæ.

He is a Cypriot and has one brother and one sister similarly affected.

III.—Hole at the Macula following Trauma.

IV.—Intra-ocular Secondary Neoplasm.

C. T., aged 58, financier, noticed blurred vision and a dark curtain coming down over the left eye in January 1947. He had been receiving deep X-ray treatment to the left side of the neck in the submaxillary region on account of a mixed salivary tumour which had undergone malignant change.

The retina is now completely detached and can be seen by slit-lamp lying close behind the lens. It shows numerous nodular opacities but no vessels can be traced into them. The intra-ocular tension is raised. Within the last few days some engorged vessels have appeared in the nasal and temporal conjunctiva.

There is a small hard movable nodule in the mid-line of the neck and another in the preauricular region on the right side.

In reply to Mr. Davenport, who asked with regard to Case IV what the retina looked like when first seen, Mr. Moffatt said that it looked like a simple detachment. He examined it by transillumination, and it did transilluminate as far as he could tell. The man had agreed to have the eye excised, and they would then discover what it was.

TWO CASES by M. L. HINE, F.R.C.S.

I.—Retinitis Proliferans.

Male, aged 23.

Loss of vision left eye November 1946. Spots in front of right eye January 1947. All investigations negative.

Left eye: Organizing vitreous hæmorrhage.

Right eye: A few retinal hæmorrhages, with new vessels coming forward into vitreous from an organized hæmorrhage above and out from macula; many retinal bands. Vision is, rather unexpectedly, 6/6.

Diagnosis.—Eales' disease.

II.—? Coats's Disease.

Male, aged 18.

Showed large patches of exudative retinitis, with little pigmentation, mainly external to central area. Some failure of vision commenced in February 1947.

FOUR CASES by T. KEITH LYLE, M.D., M.Chir.

I.—Thrombophlebitis Retinæ.

E. S., female, aged 38.

History.—First attended Royal Westminster Ophthalmic Hospital on February 21, 1947, complaining of sudden loss of vision in the left eye five weeks previously. She noticed this loss first thing in the morning. No improvement had taken place in the meanwhile.

Her vision was 6/6 in the right eye and 3/60 in the left eye. The fundus of the right eye showed some tortuosity of the vessels, particularly below. In the left eye there was œdema of the upper part of the disc, several circular hæmorrhages near the disc and the macular area and the vessels were rather congested.

Her fields showed a large central scotoma in the left eye and constriction of the peripheral field. Fixation was too poor to be accurate. Right eye field was normal. Her W.R. was negative.

Progress.—Very little change has occurred though the hæmorrhage showed a tendency to absorb. A large subhyaloid hæmorrhage was noticed on April 1.

II.—Relative Palsy of Left Superior Rectus Due to Local Orbital Trauma.

E. H., male, aged 32, hairdresser.

Severe head injury whilst on active service in Italy, in July 1945, since when he has suffered from vertical diplopia when looking upwards. No diplopia when looking downwards. Diplopia now becoming worse, but manages to do his job.

Clinical and X-ray examination showed signs of old fracture of left superior maxilla, with resulting enophthalmos and downward displacement of the left eyeball.

There was vertical diplopia when looking upwards a few degrees above the mid-plane. Maximum vertical separation of the images on lævo-elevation, with defective lævo-elevation of left eye. Vision 6/6 each eye. The Maddox rod test (at 6 metres) showed R/L 25^{Δ}; and Eso. 6^{Δ}. Fusion was obtained at $+5^{\Delta}$ with R/L 12^{Δ} on the synoptophore. (Charts were shown of the Hess screen test, the field of binocular single vision and the Maddox rod test at one metre.)

Operation was performed on April 14, 1947. Resection (5 mm.) of the left superior rectus. The result was that all diplopia disappeared and the Maddox rod test (at 6 metres) showed orthophoria. (Charts were shown of post-operative Hess screen test, &c.)

III.—Congenital Palsy of Right Superior Oblique with Compensatory Head Posture (Ocular Torticollis).

A. B., male, aged 38, engineer.

Remembers that his parents noticed he held his head at a peculiar angle. At age of 5 was taken to see Dr. Maddox of Bournemouth who advised an operation (but the advice was not taken!). Prismatic glasses were prescribed instead which he had worn (with periodic alteration in their strength) ever since, but in spite of the glasses he has noticed an increasing tendency to see double (vertical type), which he can sometimes overcome by "cutting out" the vision of the left eye.

He adopts the head posture typical of a case of right superior oblique palsy, i.e. chin depressed, head turned and tilted to left. He has diplopia of the vertical type with maximum vertical separation of images on lævo-depression.

There is defective lævo-depression of right eye, and gross upshoot of right eye on lævoversion. Vision 6/6 each eye. The Maddox rod test (at 6 metres) shows R/L 15^{Δ} with excyclophoria 14°. Fusion was obtained on the synoptophore at 0 with R/L 4^{Δ} but there was no fusional duction power. (The Hess screen chart was shown.)

Operation was performed on December 10, 1946—right inferior oblique myectomy. This was followed by orthoptic treatment.

The diplopia disappeared and the Maddox rod test (at 6 metres) was R/L 1^{Δ} with no cyclophoria. (The post-operative Hess screen chart was shown.) As a result of the orthoptic treatment a full range of fusional duction power was restored.

IV.—Right Superior Oblique Paralysis Due to Right Fourth Cerebral Nerve Palsy Caused by Head Injury.

C. R., male, aged 26, house decorator.

Road accident October 1944. Was unconscious for 9 days. Constant vertical diplopia since the accident.

In spite of two operations performed elsewhere, i.e. (*a*) left inferior rectus recession, (*b*) right inferior oblique myectomy, he still saw double the whole time.

There was vertical diplopia with maximum vertical separation of the images on lævo-depression. He could overcome the diplopia for a short period of time by turning his head to the left, depressing his chin, and tilting his head to left.

There was defective lævo-depression of right eye. The Maddox rod test (at 6 metres) showed R/L 20^{Δ} to 24^{Δ}. Vision was 6/6 each eye. (Charts were shown of the Hess screen test, the field of binocular single vision and the Maddox rod test at one metre.) Fusion was obtained at R/L 4^{Δ} on the synoptophore. Fusional duction power was defective.

Operation was performed on April 1, 1947—re-recession of left inferior rectus (4 mm.). The diplopia disappeared. The Maddox rod test (at 6 metres) was R/L 1^{Δ}, and after a short course of orthoptic treatment full fusional duction power was restored. (Charts were shown of the post-operative Hess screen test.)

THREE CASES by G. G. PENMAN, F.R.C.S.

I.—Choroidal Neoplasm.

A. B., male, aged 34.

History.—First attended Royal Westminster Ophthalmic Hospital on October 21, 1946, complaining of being unable to see clearly for six months with his right eye.

His vision on examination was 6/5 with glasses with each eye. The right fundus showed a pigmented raised area below and temporal to the macula. His field showed a scotoma to red and green corresponding to this appearance.

There has been no change in his condition since, except that on the last occasion he did not read 6/5 as accurately as usual.

II.—Eales' Disease.

II.—Familial Macular Degeneration, Adolescent Type.

C. S., male, aged 18, clerk, attended on account of inability to see in the distance. He had been tested many times but was not helped.

R. and L. vision with correction for a small amount of simple myopic astigmatism is 6/60. The fundi show degenerative changes at both maculæ.

He is a Cypriot and has one brother and one sister similarly affected.

III.—Hole at the Macula following Trauma.

IV.—Intra-ocular Secondary Neoplasm.

C. T., aged 58, financier, noticed blurred vision and a dark curtain coming down over the left eye in January 1947. He had been receiving deep X-ray treatment to the left side of the neck in the submaxillary region on account of a mixed salivary tumour which had undergone malignant change.

The retina is now completely detached and can be seen by slit-lamp lying close behind the lens. It shows numerous nodular opacities but no vessels can be traced into them. The intra-ocular tension is raised. Within the last few days some engorged vessels have appeared in the nasal and temporal conjunctiva.

There is a small hard movable nodule in the mid-line of the neck and another in the pre-auricular region on the right side.

In reply to Mr. Davenport, who asked with regard to Case IV what the retina looked like when first seen, Mr. Moffatt said that it looked like a simple detachment. He examined it by trans-illumination, and it did transilluminate as far as he could tell. The man had agreed to have the eye excised, and they would then discover what it was.

TWO CASES by M. L. HINE, F.R.C.S.

I.—Retinitis Proliferans.

Male, aged 23.

Loss of vision left eye November 1946. Spots in front of right eye January 1947. All investigations negative.

Left eye: Organizing vitreous hæmorrhage.

Right eye: A few retinal hæmorrhages, with new vessels coming forward into vitreous from an organized hæmorrhage above and out from macula; many retinal bands. Vision is, rather unexpectedly, 6/6.

Diagnosis.—Eales' disease.

II.—? Coats's Disease.

Male, aged 18.

Showed large patches of exudative retinitis, with little pigmentation, mainly external to central area. Some failure of vision commenced in February 1947.

FOUR CASES by T. KEITH LYLE, M.D., M.Chir.

I.—Thrombophlebitis Retinæ.

E. S., female, aged 38.

History.—First attended Royal Westminster Ophthalmic Hospital on February 21, 1947, complaining of sudden loss of vision in the left eye five weeks previously. She noticed this loss first thing in the morning. No improvement had taken place in the meanwhile.

Her vision was 6/6 in the right eye and 3/60 in the left eye. The fundus of the right eye showed some tortuosity of the vessels, particularly below. In the left eye there was œdema of the upper part of the disc, several circular hæmorrhages near the disc and the macular area and the vessels were rather congested.

Her fields showed a large central scotoma in the left eye and constriction of the peripheral field. Fixation was too poor to be accurate. Right eye field was normal. Her W.R. was negative.

II.—Relative Palsy of Left Superior Rectus Due to Local Orbital Trauma.

E. H., male, aged 32, hairdresser.

Severe head injury whilst on active service in Italy, in July 1945, since when he has suffered from vertical diplopia when looking upwards. No diplopia when looking downwards. Diplopia now becoming worse, but manages to do his job.

Clinical and X-ray examination showed signs of old fracture of left superior maxilla, with resulting enophthalmos and downward displacement of the left eyeball.

There was vertical diplopia when looking upwards a few degrees above the mid-plane. Maximum vertical separation of the images on lævo-elevation, with defective lævo-elevation of left eye. Vision 6/6 each eye. The Maddox rod test (at 6 metres) showed R/L 25$^{\Delta}$; and Eso. 6$^{\Delta}$. Fusion was obtained at +5$^{\Delta}$ with R/L 12$^{\Delta}$ on the synoptophore. (Charts were shown of the Hess screen test, the field of binocular single vision and the Maddox rod test at one metre.)

Operation was performed on April 14, 1947. Resection (5 mm.) of the left superior rectus. The result was that all diplopia disappeared and the Maddox rod test (at 6 metres) showed orthophoria. (Charts were shown of post-operative Hess screen test, &c.)

III.—Congenital Palsy of Right Superior Oblique with Compensatory Head Posture (Ocular Torticollis).

A. B., male, aged 38, engineer.

Remembers that his parents noticed he held his head at a peculiar angle. At age of 5 was taken to see Dr. Maddox of Bournemouth who advised an operation (but the advice was not taken!). Prismatic glasses were prescribed instead which he had worn (with periodic alteration in their strength) ever since, but in spite of the glasses he has noticed an increasing tendency to see double (vertical type), which he can sometimes overcome by "cutting out" the vision of the left eye.

He adopts the head posture typical of a case of right superior oblique palsy, i.e. chin depressed, head turned and tilted to left. He has diplopia of the vertical type with maximum vertical separation of images on lævo-depression.

There is defective lævo-depression of right eye, and gross upshoot of right eye on lævoversion. Vision 6/6 each eye. The Maddox rod test (at 6 metres) shows R/L 15$^{\Delta}$ with excyclophoria 14°. Fusion was obtained on the synoptophore at 0 with R/L 4$^{\Delta}$ but there was no fusional duction power. (The Hess screen chart was shown.)

Operation was performed on December 10, 1946—right inferior oblique myectomy. This was followed by orthoptic treatment.

The diplopia disappeared and the Maddox rod test (at 6 metres) was R/L 1$^{\Delta}$ with no cyclophoria. (The post-operative Hess screen chart was shown.) As a result of the orthoptic treatment a full range of fusional duction power was restored.

IV.—Right Superior Oblique Paralysis Due to Right Fourth Cerebral Nerve Palsy Caused by Head Injury.

C. R., male, aged 26, house decorator.

Road accident October 1944. Was unconscious for 9 days. Constant vertical diplopia since the accident.

In spite of two operations performed elsewhere, i.e. (*a*) left inferior rectus recession, (*b*) right inferior oblique myectomy, he still saw double the whole time.

There was vertical diplopia with maximum vertical separation of the images on lævo-depression. He could overcome the diplopia for a short period of time by turning his head to the left, depressing his chin, and tilting his head to left.

There was defective lævo-depression of right eye. The Maddox rod test (at 6 metres) showed R/L 20$^{\Delta}$ to 24$^{\Delta}$. Vision was 6/6 each eye. (Charts were shown of the Hess screen test, the field of binocular single vision and the Maddox rod test at one metre.) Fusion was obtained at R/L 4$^{\Delta}$ on the synoptophore. Fusional duction power was defective.

Operation was performed on April 1, 1947—re-recession of left inferior rectus (4 mm.). The diplopia disappeared. The Maddox rod test (at 6 metres) was R/L 1$^{\Delta}$, and after a short course of orthoptic treatment full fusional duction power was restored. (Charts were shown of the post-operative Hess screen test.)

THREE CASES by G. G. PENMAN, F.R.C.S.

I.—Choroidal Neoplasm.

A. B., male, aged 34.

History.—First attended Royal Westminster Ophthalmic Hospital on October 21, 1946, complaining of being unable to see clearly for six months with his right eye.

His vision on examination was 6/5 with glasses with each eye. The right fundus showed a pigmented raised area below and temporal to the macula. His field showed a scotoma to red and green corresponding to this appearance.

There has been no change in his condition since, except that on the last occasion he did not read 6/5 as accurately as usual.

II.—Eales' Disease.

III.—Dermoid Cyst, Simulating Neoplasm of Lacrimal Gland.

Mrs. J. S., aged 26.

History.—Two years ago a lump in the left upper lid near the outer canthus was incised by her own doctor as ? meibomian cyst. In spite of this, it continued to grow. She was sent to me four months ago. There was then a well-marked ridge in the upper lid, and on everting the lid this ridge was found to be caused by an enlarged lacrimal gland. A small piece of the gland was excised and sectioned, and found to be normal lacrimal tissue. On the assumption that a neoplasm was present deep in the gland, operation was undertaken for its removal. In the gland and deep to it was found a dermoid cyst, with ramifications adherent in one place to the roof of the orbit and in another to its outer wall.

Pathological report.—Dermoid cyst with adjacent normal lacrimal gland.

Cyst is lined partly by keratinized, stratified squamous epithelium, partly by epithelium two or three cells thick, with no keratinization. Contents are amorphous debris with some hairs. In subepithelial tissue are many hair follicles and sebaceous glands, and some inflammatory round cells. A few pieces of cartilage are seen.

A dense fibrous capsule, which has undergone hyaline degeneration, surrounds the cyst, and embedded in this are islands of degenerate striped muscle.

Mr. Eugene Wolff said that he saw the operation done by Mr. Penman on Case III, and the condition was remarkable. He had never seen a dermoid cyst producing that amount of inflammation.

FOUR CASES by EUGENE WOLFF, F.R.C.S.

I.—Lymphoma. ? Diagnosis.

A. B., male, aged 45.

History.—This patient first attended here in 1938 when he was given glasses to correct astigmatism. His vision was 6/5 in each eye. He attended from time to time after that for alteration to his glasses and in August 1946 a small red area appeared just above the upper limbus of the left eye.

Diagnosis was made of episcleritis. He was treated with dionin drops 2% and mist. soda sal. but no relief occurred, in fact the area increased in size.

He was admitted on March 17, 1947, when this area was seen to consist of a mass on the sclera and under the conjunctiva, extending as far forward as the cornea but not actually involving the corneal issue. Biopsy was done and it was noted that the sclera was clean and that the mass was not attached to it.

Investigation.—W.R. negative. Gonococcal fixation test negative; X-ray teeth negative, general physical examination also negative. Microscopic examination of a section showed that the mass consisted of small round cells. It was impossible to say whether it was inflammatory or neoplastic. Further sections are being examined.

Mr. M. L. Hine asked whether if Mr. Wolff regarded Case I as a lymphoma he had considered trying very weak doses of X-rays. In a case which he himself had reported of a woman who had a tumour in the orbit which had been present for a long time, and which was reported on biopsy to be a lymphoma, quite small doses of, he thought, deep X-rays were given in the orbit, and the tumour disappeared as if by magic. The doctor in charge of the department reported that it was an extremely radiosensitive tumour. It was the kind of case which was the dream of the radiologist.

The President said that he remembered once seeing a case of this sort, covering a much larger area than the one now shown, and appearing as something like a sausage across the top of the sclera. It was reported to be a lymphosarcoma. It was a kind of exaggerated edition of the case shown that day and had the same deep colour.

II.—Dermo-Lipoma.

III.—Detached Retina. ? Treatment.

Mr. R. C. Davenport, speaking on Case III of detached retina following injury, said that he saw the case shortly after the injury which was a very severe one. The vitreous was then full of hæmorrhage. That was two years ago. Later the eye showed a lower temporal detachment: the retina was no more detached now and in his opinion was better left alone.

IV.—Result of Blaskowicz Operation for Congenital Ptosis.

Peripheral Cystic Degeneration. ? Prognosis.—J. G. MILNER, F.R.C.S.

L. R., female, aged 45.

History.—For three weeks she had seen a black speck in front of the left eye.

On examination.—Examination showed this was a vitreous opacity in a myopic eye.

Her vision with: $\dfrac{-\ 10\ \text{sph}}{-\ 4{\cdot}5\ \text{cyl. at}\ 20}$: 6/9 Rt. $\dfrac{-\ 10\ \text{sph}}{-\ 4\ \text{cyl. at}\ 160}$: 6/9 Lt.

Both fundi showed inactive peripheral choroiditis in multiple patches. In the upper temporal periphery of the right fundus there was a honeycomb reticulated appearance akin to peripheral cystic degeneration. The problem was whether this area was of great prognostic importance.

Bilateral Coloboma of the Optic Disc.—H. L. Hughes, M.B., B.S., D.O.M.S., (introduced by Professor Arnold Sorsby, F.R.C.S.).

Bilateral coloboma of the optic disc more marked in the right than in the left. In both eyes the coloboma involves mainly the lower part of the disc.

Vision.—Right eye P.L. only. Left eye 6/6.

Refraction under homatropine and cocaine:

$$\text{R.}\quad \begin{array}{c|c} \multicolumn{2}{c}{-5{\cdot}0} \\ \hline & \end{array}\ -4{\cdot}5 \qquad \text{L.}\quad \begin{array}{c|c} \multicolumn{2}{c}{+1{\cdot}25} \\ \hline & \end{array}\ +1{\cdot}25$$

R. Not improved with lenses: L. $\dfrac{+\,0{\cdot}5}{+\,0{\cdot}25 \text{ at 90 degrees}} = 6/5$

Right eye divergent (angle = 40 degrees)

A Family Showing Arachnodactyly with Colobomata of Lenses and Choroid.—R. C. Davenport, F.R.C.S.

The grandmother, deceased, was a patient at Moorfields and had such bad vision that she was nine years at a blind school. She had very long hands and feet (wore size 8 shoes). Nil else known in family.

The mother, aged 33, highly myopic, has worn glasses since childhood and has good vision with them.

Flattened lower edge to each lens, and by slit-lamp section a typical rounded lower border and defective zonule. No displacement of lens. Remnants of fœtal vascular system on lens and in vitreous, particularly in right eye. Fundi appear normal.
Arachnodactylic hands and feet (size 6 in shoes).

The daughter, aged 13. 6/5 vision each eye. Eyes apparently normal, except for defect along line of choroidal cleft in lower right fundus periphery. Hands and feet long, but perhaps not beyond normal.

The son, aged 9. High mixed astigmatism, but sees well with glasses. Like his mother has flattened lower edge of each lens and, like her, no ectopia lentis, but with none of the vestigial vascular remnants. Fundi appear normal. Hands and feet longer than sister's.

Toxoplasmosis: Two Cases.—Professor A. Franceschetti.

Professor A. Franceschetti showed the fundus pictures of two new cases of toxoplasmosis seen in Geneva. They presented coloboma-like destructive lesions of the macular region and some peripheral foci of chorioretinitis. Furthermore there were some sequelæ of a more or less generalized encephalitis. He showed the microscopical section illustrating the first case of toxoplasmosis diagnosed on the Continent by F. Bamatter in Geneva. The mulberry-like aspect of the toxoplasmosis could be demonstrated in the cerebral substance as well as in the retina. Other cases of this kind had been lately discovered in Holland and in Switzerland.

Sir Stewart Duke-Elder said that this was extremely interesting. He had never himself seen a case of toxoplasmosis, and as far as he knew none had been published in this country. The diagnosis ophthalmologically depended upon a coloboma-like destructive lesion of the macula. Was the eye condition necessarily connected with encephalitis elsewhere or could the macula lesion be a condition by itself?

Professor Franceschetti said that in one case not much cerebral alteration was found, but there were symptoms of hypertension. Intracerebral calcification was not seen in all cases. He thought it possible to find certain lesions which, with the ophthalmological symptoms, established the diagnosis.

Asked whether cases terminated fatally, he said that one case had gone on for seven years and another for six, and mentally the patients were able to carry on.

Sir Stewart Duke-Elder said that he thought it quite possible that these cases were occurring and were being missed.

[*June 12, 1947*]

DISCUSSION ON ILLUMINATION

Mr. J. G. Drummond Currie: The subject of artificial illumination is one which is filled with difficulties and interest for ophthalmologists. There is the provision of adequate light, of a right type, in the right place; and there is the fact that all known commercial forms of light are accompanied by a relatively large dissipation of heat. This, in its train, brings in the question of ventilation. Few workers agree upon what is, or is not, a comfortable light in which to work. As ophthalmologists it is so easy for us to be satisfied with our provision of spectacles, when to a large extent we will be ignorant of the conditions under which our prescription will be used. To those who have never had the opportunity of seeing workers at their tasks, I would suggest many visits to factories, not forgetting that the large modern scientifically designed and lighted establishments are by no means typical of the working and lighting conditions under which many people labour. The Factory Lighting Act lays down certain standards, but there is a vast field of offices, &c., not covered by this, and in many cases little count is taken of the decrease in efficiency or strain on the personnel which results from inadequate or badly placed illumination.

There are in general use three main sources of light: The metal filament lamp, the mercury vapour or sodium lamp, and the latest fluorescent tube. Of the three, the metal filament is cheap in first cost, small in bulk, and fairly efficient provided that the fitments are properly placed, adequate in number and of sufficient candle power. But these are fairly high dissipators of heat, poor for colour matching unless proper "correcting" methods are used. The mercury or sodium lamp costs more to install, is cheaper to run, but the wave bands emitted cover a very limited range and therefore coloured objects lose much of their original value. On the other hand the fluorescent tube has all the merits of the mercury or sodium lamp plus a very fair colour rendering and heat losses are relatively small. Stroboscope defects are much more marked in any lamp functioning on the gas discharge principle because, there being no hot filament to cool between the peaks of the cycles, the response to alternating current is almost instantaneous, and, of necessity, a rapid flicker is present all the time. It is true that this fluctuation is not visible under ordinary conditions, but it can make movement in machinery at certain speeds give the deceptive effect of being stationary or produce the rather unpleasant effect of a jerky movement. This stroboscope effect can be minimized by such devices as installing the lights in "staggered" phase, but it is still present, and one wonders if one day a combination of fluorescent materials with those of the phosphorescent group may not give continuous light. Fear by the workers that harmful ultraviolet rays may be emitted by these new lamps is, I think, groundless. By the time the existing wavelength of ultraviolet has stimulated the fluorescent material and passed through the glass, no more radiation takes place than occurs from an ordinary metal filament bulb.

I would suggest a few short rules to be borne in mind: First, that light should be adequate for the type of work, and the source chosen should be of a suitable type both as regards lamp and fitting, not forgetting colour rendering. Secondly, that it should be installed in such a position that the source of light is not too near the direct line of vision. Thirdly, that shadows should be avoided as much as possible, with the exception of those types of "operation" where unidirectional light is desirable. Fourthly, that specular reflection and too much heat are great disadvantages. Lastly, that too great a contrast of surrounding objects can be tiring and even dangerous. And in this last category do not forget the beneficial effect of reflection from properly decorated walls and ceilings.

Dr. J. W. T. Walsh (*National Physical Laboratory*): *Brightness and illumination.*—It has sometimes been said that the illuminating engineer should more properly regard himself as a brightness engineer since what the eye appreciates is brightness and not illumination. On the other hand the engineer is in two difficulties if he tries to design for brightness. In the first place the brightness of an object, measured by a photometer, depends partly on the illumination and partly on the reflection characteristics of the object, and the latter are usually quite out of the illuminating engineer's control. Even worse than this is the fact that the photometer does not tell the whole story. The word "brightness", as it is commonly used, may mean either of two things which are related but not uniquely. The word as used by the engineer generally denotes the quantity which the photometer measures, the physical attribute of an illuminated object. The same word is, however, at least as commonly used to denote one attribute of the sensation produced when an object is looked at, viz. that attribute by means of which objects may be arranged in a series of increasing or decreasing brightness. It is necessary to draw a clear distinction between these two meanings and to qualify the word by an adjective which shows clearly which meaning is intended. For the engineering or physical meaning the term "photometric brightness" may be used, the term "subjective brightness" being employed whenever the sensation is meant.

Illumination.—The photometric brightness of any given surface is proportional to its illumination, i.e. to the amount of luminous flux it receives per unit area. For a long time the notion of illumination was derived from that of luminous intensity, or candle-power. A surface was imagined to be placed at a known distance from a source of light of known candle-power and the illumination of the surface, if perpendicular to the light rays, was said to be equal to I/d^2 when I was the candle-power of the source in the direction of the surface and d the distance of the surface from the source. If d was measured in feet and I in candles, I/d^2 was expressed in foot-candles. Of course if the surface was inclined at an angle θ from perpendicularity to the light, the illumination was reduced to the value $(I/d^2) \cos \theta$ foot-candles.

This method of deriving the expression for illumination and the unit in which it was measured has now been superseded in illuminating engineering and it is customary to regard illumination as the surface density of incident light or, more precisely, of luminous flux. Luminous flux is measured in lumens and to indicate the order of magnitude it may be mentioned that the tungsten lamp (in the sizes used for indoor lighting) gives about 10 lumens per watt, while the new fluorescent tubular lamp gives about 38 lumens per watt (taking the average figure throughout the life of the tube) so that the luminous flux output from an 80 watt lamp is about 3,000 lumens.

Illumination, being the surface density of luminous flux, is measured in lumens per sq. ft. In fact, one lumen per sq. ft. is precisely the same as one foot-candle; they are two names for the same thing and only the method of approach is different.

The objection has been raised that the term "lumens per sq. ft.", although self-explanatory and satisfactory in written form, especially if abbreviated as lm/ft^2, does not lend itself readily to speech and it must be admitted that the full term is cumbersome. Alternative names have been suggested but the whole matter is still *sub judice*. Meanwhile, values of illumination in such documents as the Illuminating Engineering Society's Code of Good Lighting Practice are all now expressed in lumens per square foot, instead of in foot-candles.

Photometric brightness.—The photometric brightness of a surface may be measured and expressed in two ways. Every object can be regarded as a source of light, either primary or secondary. Objects which generate the light they emit are termed primary sources, while all others, which act as sources only in so far as they reflect some of the light they receive from a primary source, are secondary sources. Although the distinction is convenient the fact remains that any object is a light source and as such has a photometric brightness. In the case of a primary source the brightness is usually expressed as the candle-power of the source divided by its apparent area, both measured in the direction of view, e.g. in candles per square inch.

In an exactly similar way, the photometric brightness of any secondary source, such as an illuminated surface, can be expressed by its candle-power per unit area, but as the brightness is usually much lower the unit of area chosen is most often the square foot instead of the square inch.

It will be clear that the relation between the photometric brightness of a surface and its illumination is dependent on that property of the surface which is usually called its reflection factor. This quantity is defined as the fraction of the incident luminous flux which the surface reflects, the remainder being absorbed or transmitted.

Different kinds of surfaces distribute the luminous flux which they reflect in different ways. For matt surfaces the distribution is sufficiently uniform to give the impression that the photometric brightness is the same in all directions, but for every practical purpose the brightness varies with the direction of view. With some surfaces the departures from uniformity are comparatively small and an ideal surface in which the brightness is perfectly uniform is a convenient conception, usually referred to as a perfect diffuser.

The importance of the perfect diffuser is that, since the flux distribution is completely defined by the fact that the brightness is independent of the direction of view, this brightness can be related immediately to the illumination and to the reflection factor. In fact the brightness, in candles per sq. ft., is equal to the illumination in lumens per sq. ft. multiplied by the reflection factor and divided by the constant π.

The intrusion of this constant is often avoided by using a different unit for photometric brightness, a unit which is equal to $1/\pi$ candle per sq. ft. This unit is known as the foot-lambert and it will be seen that the brightness of a perfectly diffusing surface in foot-lamberts is equal to its illumination in lumens per sq. ft. multiplied by its reflection factor. For an ordinary matt surface the relation, although not strictly true, holds sufficiently well for many practical purposes.

[*June* 12, 1947]

DISCUSSION ON ILLUMINATION

Mr. J. G. Drummond Currie: The subject of artificial illumination is one which is filled with difficulties and interest for ophthalmologists. There is the provision of adequate light, of a right type, in the right place; and there is the fact that all known commercial forms of light are accompanied by a relatively large dissipation of heat. This, in its train, brings in the question of ventilation. Few workers agree upon what is, or is not, a comfortable light in which to work. As ophthalmologists it is so easy for us to be satisfied with our provision of spectacles, when to a large extent we will be ignorant of the conditions under which our prescription will be used. To those who have never had the opportunity of seeing workers at their tasks, I would suggest many visits to factories, not forgetting that the large modern scientifically designed and lighted establishments are by no means typical of the working and lighting conditions under which many people labour. The Factory Lighting Act lays down certain standards, but there is a vast field of offices, &c., not covered by this, and in many cases little count is taken of the decrease in efficiency or strain on the personnel which results from inadequate or badly placed illumination.

There are in general use three main sources of light: The metal filament lamp, the mercury vapour or sodium lamp, and the latest fluorescent tube. Of the three, the metal filament is cheap in first cost, small in bulk, and fairly efficient provided that the fitments are properly placed, adequate in number and of sufficient candle power. But these are fairly high dissipators of heat, poor for colour matching unless proper ''correcting' methods are used. The mercury or sodium lamp costs more to install, is cheaper to run, but the wave bands emitted cover a very limited range and therefore coloured objects lose much of their original value. On the other hand the fluorescent tube has all the merits of the mercury or sodium lamp plus a very fair colour rendering and heat losses are relatively small. Stroboscope defects are much more marked in any lamp functioning on the gas discharge principle because, there being no hot filament to cool between the peaks of the cycles, the response to alternating current is almost instantaneous, and, of necessity, a rapid flicker is present all the time. It is true that this fluctuation is not visible under ordinary conditions, but it can make movement in machinery at certain speeds give the deceptive effect of being stationary or produce the rather unpleasant effect of a jerky movement. This stroboscope effect can be minimized by such devices as installing the lights in ''staggered'' phase, but it is still present, and one wonders if one day a combination of fluorescent materials with those of the phosphorescent group may not give continuous light. Fear by the workers that harmful ultraviolet rays may be emitted by these new lamps is, I think, groundless. By the time the existing wavelength of ultraviolet has stimulated the fluorescent material and passed through the glass, no more radiation takes place than occurs from an ordinary metal filament bulb.

I would suggest a few short rules to be borne in mind: First, that light should be adequate for the type of work, and the source chosen should be of a suitable type both as regards lamp and fitting, not forgetting colour rendering. Secondly, that it should be installed in such a position that the source of light is not too near the direct line of vision. Thirdly, that shadows should be avoided as much as possible, with the exception of those types of ''operation'' where unidirectional light is desirable. Fourthly, that specular reflection and too much heat are great disadvantages. Lastly, that too great a contrast of surrounding objects can be tiring and even dangerous. And in this last category do not forget the beneficial effect of reflection from properly decorated walls and ceilings.

Dr. J. W. T. Walsh (*National Physical Laboratory*): *Brightness and illumination.*—It has sometimes been said that the illuminating engineer should more properly regard himself as a brightness engineer since what the eye appreciates is brightness and not illumination. On the other hand the engineer is in two difficulties if he tries to design for brightness. In the first place the brightness of an object, measured by a photometer, depends partly on the illumination and partly on the reflection characteristics of the object, and the latter are usually quite out of the illuminating engineer's control. Even worse than this is the fact that the photometer does not tell the whole story. The word ''brightness'', as it is commonly used, may mean either of two things which are related but not uniquely. The word as used by the engineer generally denotes the quantity which the photometer measures, the physical attribute of an illuminated object. The same word is, however, at least as commonly used to denote one attribute of the sensation produced when an object is looked at, viz. that attribute by means of which objects may be arranged in a series of increasing or decreasing brightness. It is necessary to draw a clear distinction between these two meanings and to qualify the word by an adjective which shows clearly which meaning is enough of it, hence the eyes are required to operate too long at a distance which involves an undue muscular effort for accommodation and convergence.

This statement, which applies to many offices, factories, homes and other places, raises the question, "how much illumination is necessary for the performance of different visual tasks efficiently and without eyestrain?"

There is more than one method of getting an answer to this question. One way is to ascertain what, on the average, is the illumination currently used for different purposes. I need not enumerate the shortcomings of this method: suffice it to say that actual usage at any time is not necessarily determined by the real need of the user and, even in pre-Shinwellian times, there was always a general tendency towards direct economy in artificial lighting. When practice is freely determined, we find people who have really fine work to do choosing very high illuminations : For example, the lace-makers of Bruges and Geneva, who do their work, when they can, out-of-doors, where they often get more than 1,000 lumens per square foot; while most of us prefer to read, write or do other close work, near a window from which, in daytime, we can often get ten or twenty times more light than we put up with from artificial sources at night.

Another way is to determine, experimentally, the level of illumination at which the performance of particular visual tasks comes to a maximum. By this means, the optimum illuminations have been found for some specific occupations, and since the latter are visually comparable with others, it can be inferred that similar illuminations are suitable for these.

A third method consists in analysing the particular objects involved in any given task and appraising them in respect of certain characteristics, whose magnitudes determine the visual capacities required to see the objects easily. The principal characteristics with which we are concerned are the size and distance of the details that need to be distinguished, as well as the reflectivity of these details and of their immediate surrounds. Then—from what is known concerning the way in which visual performance varies with variation of size, contrast and illumination—a value of the latter can be found which will be appropriate for the task considered.

For practical application this method has been simplified, as far as possible, by the preparation of a chart which is included, with suitable explanatory notes, in the Illuminating Engineering Society's Lighting Code.

A point to notice particularly is that illumination values should rise in geometrical or equal ratio steps. The reason for this is that successively larger increments of illumination are necessary to increase visual capacity step by step, just as they are to produce, successively, an apparent difference of brightness. In other words, illumination should be increased in *proportion* to its value at the beginning of each step, rather than by equal increments, which would become progressively less effective; just as an increment of £10 when income is £1,000 would be far less satisfying than it would be when income is only £100.

The proportional increase upon each value to the next above it in the I.E.S. scales is not strictly constant, simply because to make it so would lead to inconvenient fractional values. The average increment, however, is one of nearly 50%, and, in practice, it is difficult to discriminate between visual tasks for which any smaller relative difference of illumination would be appropriate.

In the I.E.S. Code there is also a schedule of values of illumination necessary on the objects of special regard in various Interiors or Occupations. These values have been arrived at by the methods I have mentioned—chiefly, however, by the first and second. They can be accepted with considerable confidence, but are not final, and are subject to revision as and when the need for this becomes apparent.

Three values may be selected to show how widely different are the requirements for different visual tasks. First, in the home, 7 lumens per sq. ft. is recommended on cookers, sinks and tables, where there are specific visual tasks to be done. These involve the perception of detail which, on the whole, is of "ordinary" size, and is in moderate contrast with its background. The recommended value is found on the I.E.S. chart in the B scale—which is applicable to cases of moderate contrast—opposite the division numbered 5 on the size scale.

Secondly, in industry, 30 lumens per sq. ft. is recommended for weaving medium worsted fabrics. Here, the detail involved just comes within the small category and, again, there is only a moderate difference between the reflection factors of detail and ground. Thirdly, in the hospital, 300 lumens per sq. ft. is recommended on operating tables, because the detail to be seen is often very small, and the contrast between the parts the surgeon must distinguish may be very poor, so that the appropriate illumination is to be looked for on the C scale of the Chart.

(Mr. Weston showed a slide illustrating the I.E.S. Illumination Chart.)

It may, perhaps, be regarded as regrettable that there should be two systems of photometric brightness units, but actually they are generally used for different purposes; the brightness of a primary source, such as a fluorescent lamp, is usually expressed in candles per square inch, while the brightness of illuminated surfaces is expressed in foot-lamberts. It may be worth noting that the former unit is, to an accuracy of about 10%, 500 times as large as the latter.

Measurement.—Both illumination and brightness can be measured visually with a special form of portable photometer which contains a comparison surface illuminated by a small battery lamp. The brightness of this surface is varied, by moving the lamp or otherwise, until it matches an external white surface placed at the position at which the illumination is to be measured. A scale attached to the device by which the brightness of the comparison surface is varied gives, by previous calibration, the illumination of the external surface.

In order to measure brightness with this instrument it is necessary to know the ratio of brightness to illumination for the external white surface. This is usually given as the "reflection factor" of the surface, and it will be seen that if this is ρ and the instrument reading when viewing *any* surface is multiplied by ρ the product will be the photometric brightness of the surface in foot-lamberts.

For illumination measurements photo-electric instruments are replacing visual photometers. Light reaching the surface of the photocell is converted into electrical energy and the current generated by the cell is, within certain limitations, proportional to the illumination of the cell. One of the limitations is that the cell does not behave in the same way as the eye to light of different colours, with the result that if the instrument is calibrated for, say, the light given by a tungsten lamp the readings for daylight or for the light given by a fluorescent lamp have to be multiplied by a correction factor. Further, the response of the cell is less when the light is incident obliquely, at any rate for angles of 60 degrees or more with the normal. The familiar photo-electric exposure meter used by the photographer is an example of the application of an instrument of this kind to brightness measurement.

Mr. H. C. Weston (*Medical Research Council*): Dr. Walsh has dealt with the measurement of illumination and brightness, and my remarks will be confined to the illumination requirements of the eye, and to one or two points concerning artificial lighting.

The view is still often expressed that artificial light is not good for the eyes, at any rate if one has to rely upon it for long periods. One of the reasons advanced for this belief is that artificial light differs qualitatively and visibly from natural light. True, the spectral composition of the light given by artificial sources now commonly used is not identical with that of daylight; nor can it be made so, since the latter is subject to diurnal variations of colour quality. Nevertheless, most of these sources give what is broadly called "white" light, and it has never been shown that healthy eyes suffer any harmful effects which can be attributed to the "make-up" of the luminous flux emitted by such sources.

Even in the case of mercury and sodium electric discharge lamps, which have a discontinuous spectrum and emit bluish and yellow light respectively, there is no evidence that this characteristic is responsible for any organic changes which impair the sight. These lamps may be unsuitable for use in some circumstances, because of their colour-rendering properties and of the inconvenience or displeasure this may occasion, but these effects do no harm to the visual system.

The relatively new, but now widely used, fluorescent lighting, although generally very popular, has led to a number of complaints of ill-effects, as well as to some ill-considered speculations concerning the harm it might do. Most of the complaints of which I have personal knowledge have been vaguely expressed, and in these cases there have been no external signs of ocular disturbance. A sensation of strain is usually mentioned, so also is headache. Inquiry has usually elicited the fact that headaches were not uncommonly experienced before exposure to fluorescent lighting. The complaints have come chiefly from persons of psychoneurotic type—as judged by interview and medical history—and most of these people have been found to be working with low illumination. Badly planned installations are certainly responsible for some cases of dissatisfaction, and this is equally true when other types of light source are used.

Fears have been expressed concerning the effects of ultraviolet radiation emitted by fluorescent lamps, but there is none of shorter wavelength than is present in diffuse daylight, and its intensity at ordinary levels of illumination appears to be much less than is believed to be necessary for any abiotic action.

The only other objection to fluorescent lighting which seems to me to be worth discussion is on the score of flicker, as apparent in the so-called stroboscopic effect. There is no doubt that this is more or less disconcerting to some people, but certainly not to the majority. It can be made unobjectionable in multi-lamp installations.

I think there is no doubt that artificial light is not bad for the eyes on account of any qualitative dissimilarity to daylight; but it is very often bad for them because there is not enough of it, hence the eyes are required to operate too long at a distance which involves an undue muscular effort for accommodation and convergence.

This statement, which applies to many offices, factories, homes and other places, raises the question, "how much illumination is necessary for the performance of different visual tasks efficiently and without eyestrain?"

There is more than one method of getting an answer to this question. One way is to ascertain what, on the average, is the illumination currently used for different purposes. I need not enumerate the shortcomings of this method: suffice it to say that actual usage at any time is not necessarily determined by the real need of the user and, even in pre-Shinwellian times, there was always a general tendency towards direct economy in artificial lighting. When practice is freely determined, we find people who have really fine work to do choosing very high illuminations : For example, the lace-makers of Bruges and Geneva, who do their work, when they can, out-of-doors, where they often get more than 1,000 lumens per square foot; while most of us prefer to read, write or do other close work, near a window from which, in daytime, we can often get ten or twenty times more light than we put up with from artificial sources at night.

Another way is to determine, experimentally, the level of illumination at which the performance of particular visual tasks comes to a maximum. By this means, the optimum illuminations have been found for some specific occupations, and since the latter are visually comparable with others, it can be inferred that similar illuminations are suitable for these.

A third method consists in analysing the particular objects involved in any given task and appraising them in respect of certain characteristics, whose magnitudes determine the visual capacities required to see the objects easily. The principal characteristics with which we are concerned are the size and distance of the details that need to be distinguished, as well as the reflectivity of these details and of their immediate surrounds. Then—from what is known concerning the way in which visual performance varies with variation of size, contrast and illumination—a value of the latter can be found which will be appropriate for the task considered.

For practical application this method has been simplified, as far as possible, by the preparation of a chart which is included, with suitable explanatory notes, in the Illuminating Engineering Society's Lighting Code.

A point to notice particularly is that illumination values should rise in geometrical or equal ratio steps. The reason for this is that successively larger increments of illumination are necessary to increase visual capacity step by step, just as they are to produce, successively, an apparent difference of brightness. In other words, illumination should be increased in *proportion* to its value at the beginning of each step, rather than by equal increments, which would become progressively less effective; just as an increment of £10 when income is £1,000 would be far less satisfying than it would be when income is only £100.

The proportional increase upon each value to the next above it in the I.E.S. scales is not strictly constant, simply because to make it so would lead to inconvenient fractional values. The average increment, however, is one of nearly 50%, and, in practice, it is difficult to discriminate between visual tasks for which any smaller relative difference of illumination would be appropriate.

In the I.E.S. Code there is also a schedule of values of illumination necessary on the objects of special regard in various Interiors or Occupations. These values have been arrived at by the methods I have mentioned—chiefly, however, by the first and second. They can be accepted with considerable confidence, but are not final, and are subject to revision as and when the need for this becomes apparent.

Three values may be selected to show how widely different are the requirements for different visual tasks. First, in the home, 7 lumens per sq. ft. is recommended on cookers, sinks and tables, where there are specific visual tasks to be done. These involve the perception of detail which, on the whole, is of "ordinary" size, and is in moderate contrast with its background. The recommended value is found on the I.E.S. chart in the B scale—which is applicable to cases of moderate contrast—opposite the division numbered 5 on the size scale.

Secondly, in industry, 30 lumens per sq. ft. is recommended for weaving medium worsted fabrics. Here, the detail involved just comes within the small category and, again, there is only a moderate difference between the reflection factors of detail and ground. Thirdly, in the hospital, 300 lumens per sq. ft. is recommended on operating tables, because the detail to be seen is often very small, and the contrast between the parts the surgeon must distinguish may be very poor, so that the appropriate illumination is to be looked for on the C scale of the Chart.

(Mr. Weston showed a slide illustrating the I.E.S. Illumination Chart.)

So much for the illumination required on objects to which we must give special attention; but the illumination of the general field of view should be suitably proportioned to that of the restricted field of interest, so that there may be no great difference between the brightness of the latter and that of the panorama. As you know, this has been shown to be a necessary condition for the development of high acuity. It is also desirable to prevent the need for any considerable change of adaptation every time the gaze is shifted from the local field of work, and to avoid the feeling of gloom so generally associated with dark surrounds.

When local areas of the visual field have a brightness greatly exceeding the prevailing general level glare is usually experienced. This happens in rooms having very small windows and dark-coloured walls, but it is more frequently due to artificial lighting, owing to the still common practice of using unsuitable lighting fittings which do not screen the bare lamps from the eyes at all usual angles of view, or do not have a sufficiently low surface brightness.

People who complain of artificial light as being "too bright" generally mean—whether they realize it or not—that the *sources of light* are glaring, and not that there is too much light on the objects it is desired to see.

I need not enlarge upon the undesirable effects of glare, but will only remind you that they are quite frequently caused by the reflection of light from shiny surfaces in the normal field of view, and not only by the direct view of lighting units. When the presence of such surfaces is unavoidable—and they are often the actual objects of work—the lighting installation needs to be carefully planned to prevent images of the actual light sources from being seen in these surfaces.

Providing there is careful design for the avoidance of glare, the highest general illumination which is likely to be provided by artificial lighting in most buildings cannot be harmful to healthy eyes, for it is known that vision continues to improve as illumination rises, at least up to 1,000 lumens per sq. ft.

All the values of illumination given in the I.E.S. Code, and in other Codes of Practice, as well as in the Factory Lighting Regulations, have reference to the needs of average-sighted persons, and their effectiveness is conditional upon the avoidance of glare and the proper direction and diffusion of the light. For sub-sighted persons higher values of illumination are desirable.

In view of the growing proportion of the working population distributed in the older age-groups, the standard of vision that must be taken as the average is becoming lower.

The effect of this upon our industrial productivity may be more serious than might be supposed, unless the standards of illumination are improved, and a more extensive use is made of other aids to vision.

The effect of age upon the amplitude of accommodation of the eye is well known. Advancing age is also accompanied by some loss of visual acuity, some loss of transparency of the media, particularly to blue light, and by a reduction of the mean size of the pupil. It is also well known that partly for these reasons, most people—at any rate from middle-age onwards—become increasingly conscious of the need for good illumination for the performance of common visual tasks.

Surprisingly, however, very little is known concerning the actual relationship between age and the speed and accuracy with which different grades of visual task can be performed, and of the way in which this relationship is modified by varying the illumination of the objects of vision.

Recent experimental evidence—not yet published—shows that visual performance in this sense falls off continuously from an unexpectedly early age, and the rate of decline with age—though it naturally differs according to the severity of the visual task—is not inconsiderable, except with very easy tasks.

For example, if the visual task consists of distinguishing the name of a subscriber printed in the Telephone Directory, it seems likely that year by year, after the age of 21, we shall do it more slowly, and the *annual* loss of speed, between the twenties and the forties, may be as much as 3 or 4%.

[Here Mr. Weston showed a graph plotted from the results of two series of experiments made with small groups of subjects differing in age, who performed a visual task comparable with the practical example mentioned. It showed the continuous decline of visual performance during the middle third of the normal span of life, the annual decrement being of the magnitude suggested.]

If the visual task is made more difficult, either by reducing the size of the objects, or reducing the contrast between them and their background, then the slope of the curve relating performance with age becomes steeper, i.e. the annual loss of visual performance becomes greater. Conversely, with easier visual tasks, the adverse effect of advancing age is less marked.

Because its occurrence is insidious—like the depreciation of the power of accommodation—this loss of visual efficiency is not realized until it has progressed so far as to become a nuisance in daily life, as it does at about the age when it is usual to get a first prescription for so-called presbyopia. But it is probably not a loss which can be ascribed to ocular changes alone. Presumably there is ageing of the extra-ocular central nervous parts of the visual apparatus, and this may account partly for the decline in performance.

The rate of decline can be diminished by improving illumination, although the effect of age cannot be offset entirely by this means. As age advances, a given increment of illumination, say a doubling, is relatively more effective; that is to say, it brings about a greater *percentage* improvement of visual performance, for example, at the age of 45 than it does at the age of 35, and the more so the smaller the objects which have to be seen. Even so, the improvement is not enough to nullify the toll of time. All we can do is to minimize this toll and, if this is to be done, even the under-forties require higher levels of illumination for some everyday visual tasks than are often provided by artificial light.

Two short films made by the General Electric Company of Wembley were then shown, both illustrating the effect of illumination and colour on the ease with which fine work could be executed.

The first showed the threading of a needle, and the second industrial lathe work. They showed especially that the direction of illumination was even more important than the quality and amount.

The President, in opening the discussion, drew attention to a question ophthalmic surgeons were often asked by patients, namely, what was the best light by which to do a certain type of work. He had personally found that a somewhat difficult question to answer.

Mr. F. A. Williamson-Noble said that he would like to obtain a copy of the artificial lighting chart[1] shown on the screen because he, like the President, was constantly bombarded with the question as to the best light a certain piece of work should be done by. His usual answer was to hand to the inquirer the pamphlet on lighting in schools which gave at the end a table showing the amount of light required for various purposes but that was not so comprehensive as the chart shown during the opening remarks.

With regard to the use of glazed paper in books he personally was constantly bothered by the reflection from the paper and often wondered whether the use of glazed paper should be banned from books. A matt surface would be very much better though that might affect the contrast between the printing ink and the background.

Dr. F. W. Sharpley said he was always finding himself up against the question of glare; although a great deal of work had already been done in that regard much more required to be done. He did not think the effect of glare in everyday life was sufficiently realized. He was not referring particularly to such glare as that caused by specular reflection from glazed paper but, more generally, to the effect of direct light from the source of illumination both in the case of artificial illuminants and natural illumination from the sky through windows. He had noticed in practice so many instances in which glare effect could be reduced by very simple means. It was, to some extent, a matter of educating the public. A matter which might be of interest to ophthalmic surgeons was the question of the more extensive use of eyeshades, such as compositors used, for operations for which they were not now used. One might find, for instance, that a typist was typing against the light, which was obviously wrong, but there were instances in which it was difficult to avoid that position. In such cases an eyeshade would be helpful, to mitigate the effects of glare but one seldom saw it used. It would be interesting to hear what ophthalmic surgeons had to say with regard to the more extensive use of eyeshades.

The use of fluorescent lamps was often recommended as a means of reducing glare because there was a larger source and, consequently, a lower surface brightness for a given candle-power. It did not seem to be as fully appreciated as it might be that that lower brightness did reduce the glare in one sense, but there was still an appreciable degree of glare from the disability point of view, just as there was from a large daylight window. One could easily detect the effect of that glare by simply shading the eyes momentarily from the source while observing an object in the same field of view.

With regard to the flicker from fluorescent lamps, the use of lamps on different phases staggered over the factory system was one way of reducing the flicker though it did not altogether abolish the effect, particularly in the peripheral field of view. The speaker did not think a self-contained three-phase lamp had yet been produced, but such a lamp with a

[1] Procurable from the Illuminating Engineering Society, 32, Victoria Street, London, S.W. Included in "I.E.S. Code for the Lighting of Building Interiors." 1s. 6d.

So much for the illumination required on objects to which we must give special attention; but the illumination of the general field of view should be suitably proportioned to that of the restricted field of interest, so that there may be no great difference between the brightness of the latter and that of the panorama. As you know, this has been shown to be a necessary condition for the development of high acuity. It is also desirable to prevent the need for any considerable change of adaptation every time the gaze is shifted from the local field of work, and to avoid the feeling of gloom so generally associated with dark surrounds.

When local areas of the visual field have a brightness greatly exceeding the prevailing general level glare is usually experienced. This happens in rooms having very small windows and dark-coloured walls, but it is more frequently due to artificial lighting, owing to the still common practice of using unsuitable lighting fittings which do not screen the bare lamps from the eyes at all usual angles of view, or do not have a sufficiently low surface brightness.

People who complain of artificial light as being "too bright" generally mean—whether they realize it or not—that the *sources of light* are glaring, and not that there is too much light on the objects it is desired to see.

I need not enlarge upon the undesirable effects of glare, but will only remind you that they are quite frequently caused by the reflection of light from shiny surfaces in the normal field of view, and not only by the direct view of lighting units. When the presence of such surfaces is unavoidable—and they are often the actual objects of work—the lighting installation needs to be carefully planned to prevent images of the actual light sources from being seen in these surfaces.

Providing there is careful design for the avoidance of glare, the highest general illumination which is likely to be provided by artificial lighting in most buildings cannot be harmful to healthy eyes, for it is known that vision continues to improve as illumination rises, at least up to 1,000 lumens per sq. ft.

All the values of illumination given in the I.E.S. Code, and in other Codes of Practice, as well as in the Factory Lighting Regulations, have reference to the needs of average-sighted persons, and their effectiveness is conditional upon the avoidance of glare and the proper direction and diffusion of the light. For sub-sighted persons higher values of illumination are desirable.

In view of the growing proportion of the working population distributed in the older age-groups, the standard of vision that must be taken as the average is becoming lower.

The effect of this upon our industrial productivity may be more serious than might be supposed, unless the standards of illumination are improved, and a more extensive use is made of other aids to vision.

The effect of age upon the amplitude of accommodation of the eye is well known. Advancing age is also accompanied by some loss of visual acuity, some loss of transparency of the media, particularly to blue light, and by a reduction of the mean size of the pupil. It is also well known that partly for these reasons, most people—at any rate from middle-age onwards—become increasingly conscious of the need for good illumination for the performance of common visual tasks.

Surprisingly, however, very little is known concerning the actual relationship between age and the speed and accuracy with which different grades of visual task can be performed, and of the way in which this relationship is modified by varying the illumination of the objects of vision.

Recent experimental evidence—not yet published—shows that visual performance in this sense falls off continuously from an unexpectedly early age, and the rate of decline with age—though it naturally differs according to the severity of the visual task—is not inconsiderable, except with very easy tasks.

For example, if the visual task consists of distinguishing the name of a subscriber printed in the Telephone Directory, it seems likely that year by year, after the age of 21, we shall do it more slowly, and the *annual* loss of speed, between the twenties and the forties, may be as much as 3 or 4%.

[Here Mr. Weston showed a graph plotted from the results of two series of experiments made with small groups of subjects differing in age, who performed a visual task comparable with the practical example mentioned. It showed the continuous decline of visual performance during the middle third of the normal span of life, the annual decrement being of the magnitude suggested.]

If the visual task is made more difficult, either by reducing the size of the objects, or reducing the contrast between them and their background, then the slope of the curve relating performance with age becomes steeper, i.e. the annual loss of visual performance becomes greater. Conversely, with easier visual tasks, the adverse effect of advancing age is less marked.

Because its occurrence is insidious—like the depreciation of the power of accommodation—this loss of visual efficiency is not realized until it has progressed so far as to become a nuisance in daily life, as it does at about the age when it is usual to get a first prescription for so-called presbyopia. But it is probably not a loss which can be ascribed to ocular changes alone. Presumably there is ageing of the extra-ocular central nervous parts of the visual apparatus, and this may account partly for the decline in performance.

The rate of decline can be diminished by improving illumination, although the effect of age cannot be offset entirely by this means. As age advances, a given increment of illumination, say a doubling, is relatively more effective; that is to say, it brings about a greater *percentage* improvement of visual performance, for example, at the age of 45 than it does at the age of 35, and the more so the smaller the objects which have to be seen. Even so, the improvement is not enough to nullify the toll of time. All we can do is to minimize this toll and, if this is to be done, even the under-forties require higher levels of illumination for some everyday visual tasks than are often provided by artificial light.

Two short films made by the General Electric Company of Wembley were then shown, both illustrating the effect of illumination and colour on the ease with which fine work could be executed.

The first showed the threading of a needle, and the second industrial lathe work. They showed especially that the direction of illumination was even more important than the quality and amount.

The President, in opening the discussion, drew attention to a question ophthalmic surgeons were often asked by patients, namely, what was the best light by which to do a certain type of work. He had personally found that a somewhat difficult question to answer.

Mr. F. A. Williamson-Noble said that he would like to obtain a copy of the artificial lighting chart[1] shown on the screen because he, like the President, was constantly bombarded with the question as to the best light a certain piece of work should be done by. His usual answer was to hand to the inquirer the pamphlet on lighting in schools which gave at the end a table showing the amount of light required for various purposes but that was not so comprehensive as the chart shown during the opening remarks.

With regard to the use of glazed paper in books he personally was constantly bothered by the reflection from the paper and often wondered whether the use of glazed paper should be banned from books. A matt surface would be very much better though that might affect the contrast between the printing ink and the background.

Dr. F. W. Sharpley said he was always finding himself up against the question of glare; although a great deal of work had already been done in that regard much more required to be done. He did not think the effect of glare in everyday life was sufficiently realized. He was not referring particularly to such glare as that caused by specular reflection from glazed paper but, more generally, to the effect of direct light from the source of illumination both in the case of artificial illuminants and natural illumination from the sky through windows. He had noticed in practice so many instances in which glare effect could be reduced by very simple means. It was, to some extent, a matter of educating the public. A matter which might be of interest to ophthalmic surgeons was the question of the more extensive use of eyeshades, such as compositors used, for operations for which they were not now used. One might find, for instance, that a typist was typing against the light, which was obviously wrong, but there were instances in which it was difficult to avoid that position. In such cases an eyeshade would be helpful, to mitigate the effects of glare but one seldom saw it used. It would be interesting to hear what ophthalmic surgeons had to say with regard to the more extensive use of eyeshades.

The use of fluorescent lamps was often recommended as a means of reducing glare because there was a larger source and, consequently, a lower surface brightness for a given candle-power. It did not seem to be as fully appreciated as it might be that that lower brightness did reduce the glare in one sense, but there was still an appreciable degree of glare from the disability point of view, just as there was from a large daylight window. One could easily detect the effect of that glare by simply shading the eyes momentarily from the source while observing an object in the same field of view.

With regard to the flicker from fluorescent lamps, the use of lamps on different phases staggered over the factory system was one way of reducing the flicker though it did not altogether abolish the effect, particularly in the peripheral field of view. The speaker did not think a self-contained three-phase lamp had yet been produced, but such a lamp with a suitable fusing glass would combine the light from each phase and give a single light unit from which there would be no appreciable flicker. Had that been attempted and, if not, were there any real difficulties in the way? He personally could not see any insurmountable difficulties.

---

[1] Procurable from the Illuminating Engineering Society, 32, Victoria Street, London, S.W. Included in "I.E.S. Code for the Lighting of Building Interiors." 1s. 6d.

Much had been said as to the intensity of illumination and instruments for measuring that intensity. It was, of course, widely recognized that intensity was only one aspect of lighting, but it was possibly not fully recognized how small an aspect of the whole it was. It seemed that there should be an endeavour to use the individual himself as a meter for assessing lighting. If it were possible to measure the output of a group of individuals under conditions which were otherwise completely controlled it might be possible to get a better evaluation of lighting effect. The speaker here had in mind output from factories; it was not, of course, possible to measure output, say, from a home. One could, however, conceivably adapt the results obtained from the factory investigation. A measure of output in the factory would take into account the accidents, mistakes and speed of working; it would measure, in a sense, the glare and discomfort effects; it would reflect the psychological effect of the lighting and other factors not taken into account by intensity measurements alone and of which little was known.

Mrs. Dorothy Campbell drew attention to two points: (1) That the clerical staff in a factory are often denied good illumination owing to the expense of installation; and (2) that in the dirtier trades, such as moulding, illumination is allowed to fall deplorably low because the lights are not kept clean.

Mr. D. V. Giri asked for some explanation of what was meant by absorption of light. Also he wanted from the lighting engineers information as to goggles so frequently used now, and of all tints. Did the trade go upon any scientific principle in introducing the tints of the goggles and why should the public resort to them without having any test beforehand? He frequently went to winter sports and had never taken any steps to protect his eyes and, moreover, he had never felt the need for so doing. Many others also went to winter sports and did not need eye protection. In the vast majority of cases that was unnecessary. The tints of the goggles varied so much that the speaker wondered on what basis the manufacturers produced the various tints.

Dr. Brian Stanford said that the point made earlier, that many people found the new fluorescent lighting "a strain" on their eyes, could not be dismissed just because there was no evidence of pathological changes. He thought there was a psychological explanation: If the intensity of ordinary outdoor daylight was assessed as 1,000 to 10,000 units, then in the house it was about 40 units. When it reached 15 to 12 units one switched on the light and as daylight further faded one was working with electric lighting at about 8 units. The colour of the new daylight fluorescent bars matched daylight extremely closely, and in an ordinary room one lamp gives about 12 units, that is an illumination at which one would normally want to switch on the electric light, and yet the lights were on. That sensation might account for the sense of strain complained of; the lights were on and yet one wanted to put them on. If the daylight bar were replaced by the Type B bar, which has a reddish light, then it was accepted as artificial light. The level of illumination was much the same, but one knew that lights were on and felt happier. But one daylight bar in a small kitchen with white walls caused no strain because the level of illumination here reached 20 units.

Mr. Williamson-Noble had referred to glazed paper for books, which raised an interesting point. The reflectivity of good white paper was about 80% and of black ink about 3%, which gave a contrast range of about 30 to 1. In a well-lit room that was too much, but it was necessary for bad lighting conditions. Most homes were ill-lit, but books designed for the richer people who had more brightly lit homes were printed on off-white paper, so bringing the contrast down to about 20 to 1.

The President, after some closing remarks, referred to Mr. Giri's point on the wearing of goggles. He (the President) thought it might be said that goggles were worn often merely as a contrast, just as the black patch was in earlier days!

An Explanation of the Difference Between a Papilloma and an Adenoma of the Rectum

By Cuthbert E. Dukes, O.B.E., M.D.

(*Pathologist to St. Mark's Hospital, London*)

Two varieties of benign epithelial tumour occur in the rectum, the villous papilloma and the adenoma. Both arise from the mucous membrane but they seem to develop along different lines so that each comes to have a characteristic appearance and histological structure. A villous papilloma is a soft shaggy tumour, often with rather ill-defined edges, attached by a broad base and extending over a wide area. An adenoma, on the other hand, is a compact rounded mass of glandular tissue, sessile at first but later attached by a relatively narrow pedicle.

The striking difference in gross characters of these two tumours is reflected also in their histology. In a villous papilloma the mucus-secreting epithelium covers the outside of the supporting central core of connective tissue and blood-vessels and the secretion is poured out on the surface, whereas in an adenoma the secreting cells are arranged as in tubular glands and the mucus is therefore discharged into a confined space.

Why should these two tumours, derived from a similar source and composed of identical elements, differ so strikingly both in appearance and intimate structure? The most obvious reply is that the differences are due to the fact that a papilloma projects from the surface and has therefore ample room in which to expand whereas the development of an adenoma is to some extent restricted by the tissues in which it is embedded. This explanation presupposes that a papilloma is derived from surface epithelium whereas an adenoma is derived from epithelium deeper down in the mucous membrane. I think this explanation is the right one and to illustrate it I have prepared two series of diagrams, one representing the proliferation of surface epithelium and the other a similar proliferation of epithelial cells situated at the bottom of the crypts of Lieberkühn.

The first consequence of the proliferation of a group of superficial cells (such as those indicated by shading in fig. 1A) is the formation of a small villous-like projection (fig. 1B). This arrangement is all that is needed to accommodate the twofold increase in cells resulting from their first division, but when the tumour cells divide a second time, resulting in a fourfold increase the central stroma must either become unduly long and fragile or begin to branch as shown in fig. 1C. This is what takes place. Nourishment and support for the eightfold and sixteenfold increase in numbers resulting from the third and fourth division can only be provided by further branching of the stroma as illustrated in fig. 1D and E. Thus the natural consequence of the proliferation of a small group of superficial cells is a tumour with the architecture of a villous papilloma.

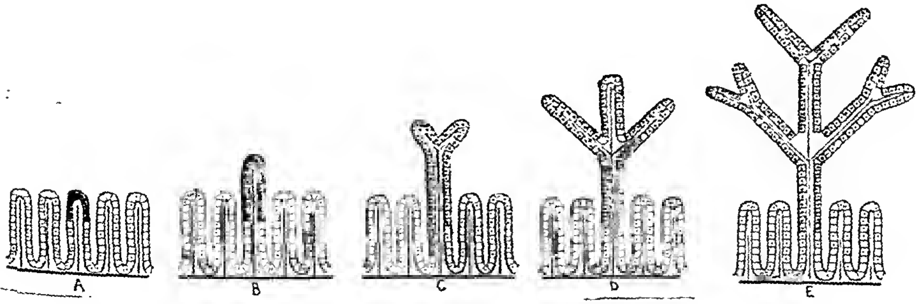

Fig. 1.—Proliferation of superficial glandular epithelium.

Let us now consider what is likely to happen when a similar number of epithelial cells situated in the depths of the mucous membrane begin to divide and to demand room to expand (fig. 2A). The first result will be a compact nodule of new growth embedded in the deeper layers of the submucosa (fig. 2B). The increased space necessitated by this doubling of the cell population can only be gained by encroaching on tissues below and on each side and by bulging from the surface (fig. 2C). A further cell division will result in an acute problem of "Lebensraum". Below and on either side there are obstacles to further expansion and the path of least resistance is obviously upwards to the surface (fig. 2D) Once this is reached there is ample room for the sixteenfold increase resulting from the fourth division (fig. 2E). Finally, any tumour with a narrow base of attachment which projects into the lumen of the bowel tends to become pedunculated because of peristaltic movements and the traction exerted by the passage of intestinal contents over its surface, so I have represented this inevitable rearrangement of the tumour tissue in fig. 2F. This now has the familiar characteristics of a pedunculated adenoma, consisting of a compact rounded mass of glandular tissue attached by a pedicle containing blood-vessels and supporting tissues only.

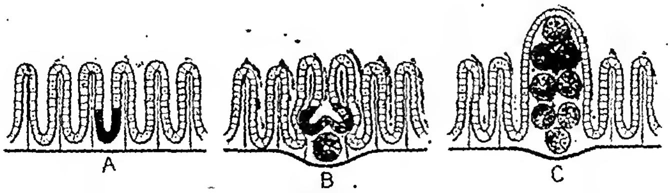

FIG. 2, A, B, C.—Proliferation of deep glandular epithelium.

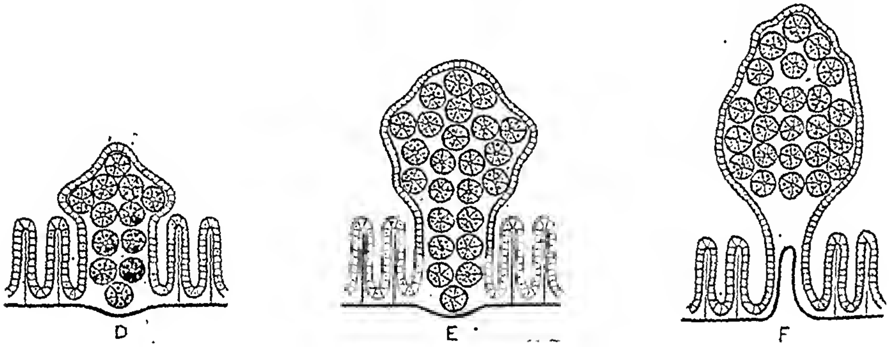

FIG. 2, D, E, F.—Proliferation of deep glandular epithelium.

In constructing these diagrams to illustrate the development of papilloma and adenoma it has been assumed that the cells undergoing proliferation were limited in each case to one small area. Under natural conditions such a narrow restriction of the field of proliferation must rarely occur. None the less it probably is true that the villous papilloma type of growth is the end-result of the action of an agent which has affected *chiefly* the superficial epithelium, whereas an adenoma results when the group of neoplastic cells are situated *chiefly* at a deeper level. In practice we can distinguish tumours which are pure papillomas, others pure adenomas and also an intermediate group which are papillomatous on the surface but adenomatous at the centre.

It may perhaps be thought that the question of the site of origin of these tumours is not of much practical importance and merely another example of the sort of idle speculations in which a pathologist is apt to indulge. But I must remind you that the view is often expressed that an adenoma is more likely to undergo malignant change than a papilloma. Is this really the case? Allowance must first be made for the fact that an adenoma is a much commoner lesion than papilloma and obviously therefore adenomas are much more frequently sectioned. This is certainly the chief reason why it is commoner for carcinoma to be reported in an adenoma. Still, even when allowance has been made for the greater number of adenomatous tumours examined I think it is probably true to say that carcinoma *is* more likely to occur in an adenoma than a papilloma. The most obvious reason for this is that the secretion from a papilloma is poured out on the surface whereas in an adenoma it is discharged into a confined space and therefore liable to be retained, and retention of secretion often acts as a source of irritation. However, although there may be slight differences dependent on considerations such as these it should be said in conclusion that in liability to malignancy there are no fundamental differences between adenomas and papillomas.

Right Hemicolectomy

By E. G. MUIR, M.S., F.R.C.S.

"AT last a case was satisfactorily completed so far as the operation was concerned; but I knew from the first that this was one of the typically malignant class, and that life could not be much prolonged." Thus Paul (1895), the British apostle of large bowel surgery, ended the description of his first successful case of resection and restoration of continuity for a carcinoma of the ascending colon. From that time he put away the decalcified bone tubes with which he had been attempting to anastomose the large bowel and used only the method which bears his name. Though the first successful case in this country was on the right, the Paul or Paul-Mikulicz operation soon became popular on the left colon while other methods were adopted for an ileocæcal resection. Arbuthnot Lane, reputedly a master of technique, who in 1895 dismissed colectomy in his "Manual of Operative Surgery" in a few lines and the note that "Mr. Bryant first performed this operation successfully" ,was in 1909 advising a right, or even larger colectomy for chronic constipation and intestinal toxæmia and relying on intra-abdominal anastomosis without bowel drainage. His usual method was a two-stage resection with a preliminary ileotransverse colostomy. This, or the one-stage resection and anastomosis, has remained the most popular operation in this country. In 1932 Gabriel described the combination of this method with catheter drainage of the colon at the anastomosis. Lahey's revised Paul-Mikulicz operation for right hemicolectomy has recently been advocated by Maingot (1945), who has stressed the safety of this method. The American symposium on colonic surgery published in 1943 gave an interesting cross-section of present American surgical opinion which is by no means in favour of this method, whose necessary defects are the small bowel fistula and the delay in closure. Thus Wangensteen prefers primary resection with end-to-end aseptic anastomosis under constant suction with a duodenal or Millar-Abbot tube for five days. Whipple considers pre- and post-operative decompression with a Millar-Abbott tube and an open anastomosis to be the choice. Jones advises a right end-to-side ileotransverse colostomy with a small catheter inserted into the ileum 6 to 8 in. (15 to 20 cm.) above the anastomosis, but adds that he now prefers a Millar-Abbott tube instead of the catheter. Allen advises the two-stage attack with a preliminary ileotransverse colostomy.

There are certain points in connexion with this operation and indeed all colonic surgery which all surgeons will accept as fact; others depend on individual fancy. Thus, fluid balance and the body requirements, the prevention and treatment of shock, good anæsthesia, bowel chemotherapy before operation, the prevention, early recognition and effective treatment of chest complications are all accepted as important. To Wangensteen, amongst others, surgery owes a debt for the stress laid on intestinal distension, its prevention and treatment; gastric suction is now widely used. The extent of the resection for a right hemicolectomy shows little variation, nor would any now contend that less can be resected by an exteriorization method than by another. On the other hand there are many different methods of anastomosis and suture. Right hemicolectomy cannot always be a planned operation; the conditions requiring it may be discovered unexpectedly or in emergency surgery.

The ideal operation is surely one which permits of a one-stage resection and anastomosis in all but the worst cases; where no secondary operation is required; where no factor making for safety is ignored and provision is made, should an intra-abdominal anastomosis leak, to minimize the disaster.

I believe that the following operation fulfils most of these requirements.

THE OPERATION

I have employed a Millar-Abbott tube in those cases with pre-operative distension and a resection below it gives a pleasant feeling of security but while I have not had the opportunity to use the tube when fitted with a stylet, the ordinary pattern can occasion both irritation and distress to patient and surgeon alike if it takes long to pass through the pylorus. Since other provision is made by this operation it is not used as a routine. Gastric or duodenal tube suction is employed either immediately before, or as soon after operation as possible.

A right paramedian incision is used. After clearing the omentum from the right third of the transverse colon, the part to be resected is mobilized in the usual manner and the mesentery divided. Non-crushing clamps are then applied above and below, that on the ileum being applied, after emptying the bowel as much as possible, some 10 in. (25·4 cm.) above the point of resection. The bowel is removed, ensuring a good blood supply at the point of colonic division. The end of the ileum is now closed and a side-to-side antiperistaltic anastomosis made with the colon 2 in. (5 cm.) distal to the clamp closing the divided end of the colon. This clamp is now oversewn and the divided end of the colon closed except for half a centimetre at that corner farthest from the anastomosis. A soft rubber tube, about the size of a 12 or 13 catheter, but with a rather larger lumen, some 16 in. (40·6 cm.) in length and with lateral holes cut in it for 10 in. (25·4 cm.) from the end, is now inserted through this gap in the end of the colon, through the anastomosis and up the lumen of the ileum. The last lateral hole should lie about 1 in. (2·5 cm.) within the colon. The tube is stitched to the colon and the bowel turned in around it with a number of circular sutures as in a gastrostomy. The soft clamps are now removed and some of the terminal coils of ileum are gently threaded along the rubber ileostomy tube. At the same time suction can be applied to the tube and if there has been any distension some quiet effective decompression of the terminal ileum can be carried out without any harsh treatment of the small bowel. The gap in the mesentery and the raw surface on the posterior abdominal wall are now closed. The omentum is wrapped round the ileostomy tube and the anastomosis.

A small stab incision is now made through the abdominal wall about 2 in. (5 cm.) below the right costal margin and outside the rectus sheath, about the size of that made for a terminal colostomy but without the excision of skin. The peritoneum is opened and its edges held in forceps. The ileostomy tube is now brought out through this incision and the colon around it sutured to the peritoneal edges by a number of interrupted sutures. The skin edges may require a stitch and the tube is anchored to the skin. The abdomen is then closed.

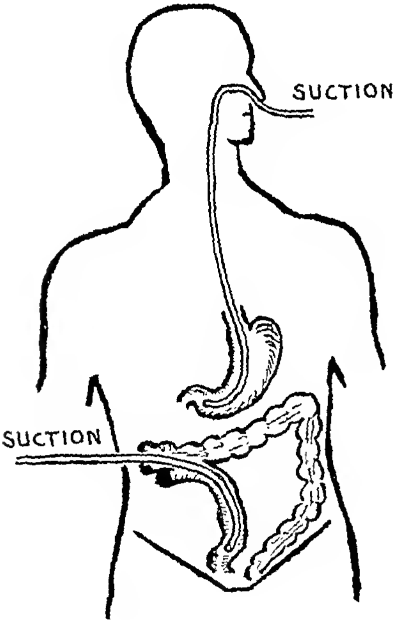

FIG. 1.—Combined gastric and ileal suction drainage.

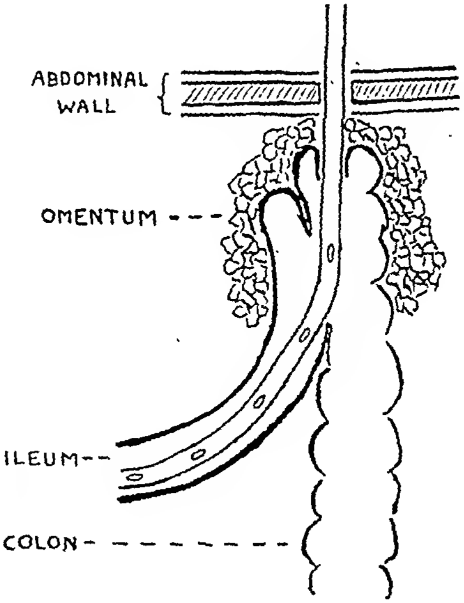

FIG. 2.—Ileostomy tube.

POST-OPERATIVE TREATMENT

In a planned proceeding an intravenous drip is set up before the abdomen is opened. If not, it is commenced either during or immediately after the operation. Apart from the prevention and treatment of shock the patient relies on this route for all his fluid requirements for at least forty-eight hours, that amount being judged sufficient which will approximate a normal urinary output.

Constant suction is applied to both the gastric and ileostomy tubes. The ileostomy tube may become blocked and require gentle syringing through with a little water or saline. Gastric suction is discontinued after forty-eight hours if the ileostomy tube is satisfactory in its drainage and fluids are then started by mouth. The intravenous drip is discontinued when the patient is taking sufficient by mouth.

The ileostomy tube is removed after a week or when it is loose. Some leakage may take place through the wound for a few days, but in a third of my cases no leakage occurred and the longest that an intestinal fistula persisted was a fortnight. No secondary operation has ever been necessary.

I have now performed this operation on twenty cases: Carcinoma 10, Crohn's disease 7, sarcoma 1, volvulus 1, intussusception 1.

There has been no mortality but one post-operative mishap. Here the patient's paramedian incision broke down, a coil of small bowel became lodged in the wound, a small bowel fistula from this coil developed and the wound took three months before it was finally healed.

Comment

I believe this operation has certain advantages and that it is applicable to all but the worst cases. It is a one-stage resection; no second operation to close a fistula is necessary. Though the anastomosis is intraperitoneal it is fixed to the parietal peritoneum beneath an abdominal incision and should sepsis occur within its omental wrappings it has at least an excellent opportunity to reach the exterior. The anastomosis is placed so that it covers the upper part of the "raw" area left by the resection. Not only is decompression drainage provided for the upper part of the alimentary tract by the gastric suction but the lower reaches of the ileum, that danger area in the post-operative case, are also drained and can be emptied considerably at operation. There may be dangers in introducing a rubber tube through an anastomosis, but I have seen no ill-effects. It is perhaps apposite to point out that Wangensteen (1943) has described two cases in which, with a Millar-Abbott tube in the lower ileum, it was yet necessary to put a duodenal tube down the patient's other nostril for post-operative distension. That this can occur once the small bowel has been "swept and garnished" by the passage of a Millar-Abbott tube and with the tube still in position, is surely good evidence of the part played in post-operative distension by aerophagy.

A Small High-grade Carcinoma of the Rectum with Extensive Lymphatic Spread.—W. B. Gabriel, M.S.

R. B., male, aged 48.

History.—His chief complaint was of piles, with latterly more prolapse and some burning pain at defæcation.

Examination on 12.11.45 at St. Mark's Hospital revealed a curious indurated elongated plaque in the left anterior quadrant of the anal canal and extending up the rectal wall for about ½ in. (1·25 cm.). The condition suggested at first a recent thrombosis or possibly an early squamous-cell carcinoma.

Biopsy.—A month later the condition was unchanged and an examination under low spinal anæsthesia was done. An indurated cord of lymphatic spread was felt running up the mesorectum in the left posterior quadrant which strongly indicated the diagnosis of malignancy. A biopsy was done and Dr. C. E. Dukes reported that the tumour was a very undifferentiated type of carcinoma of a high grade of malignancy.

Operation.—On 17.12.45 a laparotomy was done under a nupercaine spinal, 1·2 c.c., with pentothal, gas, oxygen, ether. The liver was smooth but some palpably enlarged glands were felt in the mesorectum on the left side. A perineo-abdominal excision was carried out and uneventful recovery followed, the patient being discharged home on the twenty-sixth post-operative day, 12.1.46.

Pathological findings (Dr. C. E. Dukes).—*Gross characters*: The specimen measured 15 in. (38 cm.). There was no obvious tumour, the only visible abnormality being a small hard ridge in the anal canal and lower third of the rectum over which the mucous membrane was not ulcerated. This ridge could be felt to be in continuity with a thickening around the hæmorrhoidal vessels lying in the perirectal tissues. A cord of hard tissue extended up the course of the hæmorrhoidal vessels for several inches. No papillomata were present but diverticula were seen in the distal end of the pelvic colon.

Microscopic structure: The tumour is a colloid carcinoma, very undifferentiated in character, consisting chiefly of isolated signet cells or clusters of signet cells embedded in mucoid material.

the colon. This clamp is now oversewn and the divided end of the colon closed except for half a centimetre at that corner farthest from the anastomosis. A soft rubber tube, about the size of a 12 or 13 catheter, but with a rather larger lumen, some 16 in. (40·6 cm.) in length and with lateral holes cut in it for 10 in. (25·4 cm.) from the end, is now inserted through this gap in the end of the colon, through the anastomosis and up the lumen of the ileum. The last lateral hole should lie about 1 in. (2·5 cm.) within the colon. The tube is stitched to the colon and the bowel turned in around it with a number of circular sutures as in a gastrostomy. The soft clamps are now removed and some of the terminal coils of ileum are gently threaded along the rubber ileostomy tube. At the same time suction can be applied to the tube and if there has been any distension some quiet effective decompression of the terminal ileum can be carried out without any harsh treatment of the small bowel. The gap in the mesentery and the raw surface on the posterior abdominal wall are now closed. The omentum is wrapped round the ileostomy tube and the anastomosis.

A small stab incision is now made through the abdominal wall about 2 in. (5 cm.) below the right costal margin and outside the rectus sheath, about the size of that made for a terminal colostomy but without the excision of skin. The peritoneum is opened and its edges held in forceps. The ileostomy tube is now brought out through this incision and the colon around it sutured to the peritoneal edges by a number of interrupted sutures. The skin edges may require a stitch and the tube is anchored to the skin. The abdomen is then closed.

Unilateral Hypoplasia of Face and Teeth

By Professor EVELYN C. SPRAWSON, M.C., D.Sc., M.R.C.S., L.D.S.

B. B., a male aged 6½ years (fig. 1), presents many abnormalities of a hypoplasic character involving the left side of his face, jaws and teeth, but the condyle itself does not appear to be implicated. All the deciduous molars and most of their successional teeth are absent on the left side. There is no external scarring. He is below average intelligence (I.Q. 79). The abnormality is not familial and there is no history of any difficulty in parturition. The asymmetry was noticed soon after birth.

On examination there is marked asymmetry of the face, so that the left side is flattened and the chin deviates slightly to the left, the deviation being more noticeable during movement. The left mandibular angle is higher than that of the right, but neither is unduly prominent. Both condyles can be felt and are apparently symmetrical and movements normal. The temporal fossæ are symmetrical.

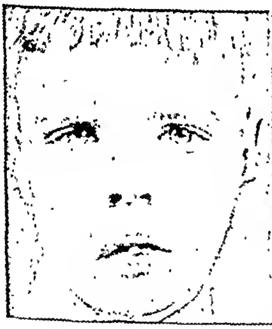

FIG. 1.—Full face.

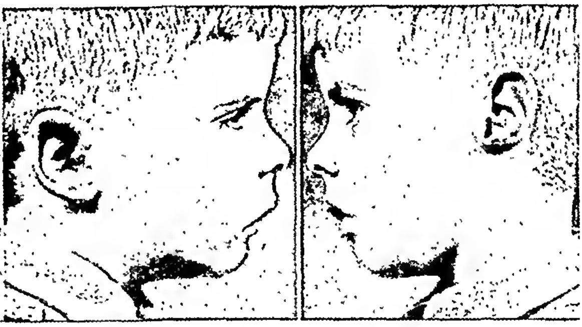

FIG. 2.—Side face.

The left ear (fig. 2) is smaller than the right, is more highly placed, and they are asymmetrical.

In the mouth the left anterior pillar of the fauces passes forward to blend with the loose movable mucous membrane covering the mandibular alveolar ridge; the posterior pillar appears to be normal. The left half of the tongue is markedly smaller than the right, and the tongue deviates to the left on protrusion.

There is no dental caries.

On the right side all the deciduous teeth are present in maxilla and mandible and are normal in size and shape, and the permanent first molars are erupted and in occlusion.

There are only three mandibular deciduous incisors.

In the left maxilla there are only three deciduous teeth, two incisors and a canine.

In the left mandible there are only two deciduous teeth, one incisor and a canine. The left alveolar ridges appear wasted or atrophied in both maxilla and mandible, and shortened antero-posteriorly, the depth of bone in the mandible being very shallow. There is no evidence that there have ever been any deciduous teeth behind the canines in either jaw and the ridges give no indication of any successional permanent teeth and appear as if there is no alveolar bone present. A large hamular process can be felt. Both ridges are placed more medially than is normal.

Methods of spread: (1) *By direct continuity*—The growth had extended by permeation of the lymphatic channels causing a continuous extension along the hæmorrhoidal vessels. (2) *Venous spread*—There was no sign of venous spread. (3) *Lymphatic spread*—Eleven out of fourteen glands removed at dissection contained metastases and so did the gland marked "uppermost" sent separately for examination.

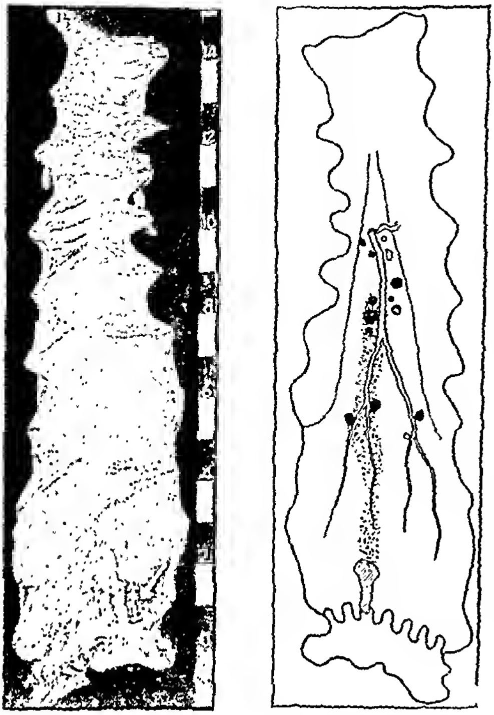

Fig. 1.—A small high-grade carcinoma of the rectum (marked by arrow) with extensive lymphatic spread.

Classification.—Colloid carcinoma of rectum. Extensive lymphatic permeation and twelve glandular metastases. C 2 case.

Subsequent Course.—He remained in fairly good health until 6.5.46, when he reported for examination complaining of some difficulty in micturition. A deep induration in the perineum indicated local recurrence and in addition he presented an enlarged gland in the left groin. He was then referred to St. Bartholomew's Hospital for consideration as to high-voltage X-ray therapy, but when admitted there he was found to have retention with overflow, and cystoscopy showed malignant infiltration of the prostate and bladder. Decompression by an indwelling catheter was required and it was decided that X-ray treatment was contra-indicated.

Re-examination towards the end of June 1946 revealed a very hard irregular fixed mass in the perineum. The patient subsequently went steadily downhill and died of recurrence on 28.8.46, that is, a little over eight months after operation.

Commentary.—The case is of interest from several aspects: (1) The history and clinical findings were anomalous, but the biopsy was of great value in establishing the diagnosis of malignancy; the histological grading rightly indicated a bad prognosis.

(2) The presence of palpable extrarectal spread was revealed by digital examination of the rectum prior to operation and the grave prognosis which accompanies this finding was confirmed by the progress of the case.

(3) Although the primary growth was extremely small, early and extensive lymphatic spread had taken place by the time operation was undertaken and the rapid onset of recurrence shows that even then the growth was surgically inoperable.

Carcinoma of the Paroophoron, invading the Rectum.—A. LAWRENCE ABEL, M.S.

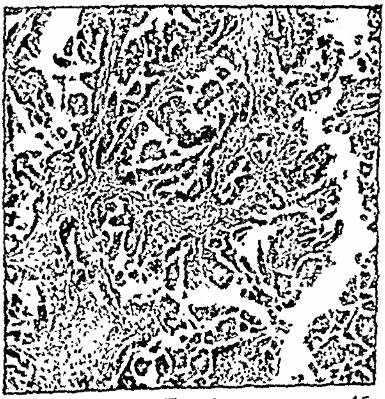

Fig. 1 × 45.

Female, aged 66.

History.—Difficulty in defæcation and occasional slight rectal incontinence for three months, with recent vaginal discharge of blood-stained fluid.

Examination.—P.V.: Ulcer crater in the posterior fornix which was closely adherent to the rectum. Biopsy showed a papilliform adenocarcinoma.

Operation.—Wertheim's panhysterectomy and abdomino-perineal resection of the rectum.

Specimen.—The lower sigmoid rectum and anal canal with the attached uterus and its adnexa and vagina (shown at the meeting).

Histology (Dr. L. Woodhouse Price). — Shows the general structure of a malignant ovarian cystadenoma (fig. 1).

Diagnosis.—Carcinoma of the paroophoron, invading the rectum.

(The report of this meeting will be concluded in the December issue of the Proceedings.)

Unilateral Hypoplasia of Face and Teeth

By Professor Evelyn C. Sprawson, M.C., D.Sc., M.R.C.S., L.D.S.

B. B., a male aged 6½ years (fig. 1), presents many abnormalities of a hypoplasic character involving the left side of his face, jaws and teeth, but the condyle itself does not appear to be implicated. All the deciduous molars and most of their successional teeth are absent on the left side. There is no external scarring. He is below average intelligence (I.Q. 79). The abnormality is not familial and there is no history of any difficulty in parturition. The asymmetry was noticed soon after birth.

On examination there is marked asymmetry of the face, so that the left side is flattened and the chin deviates slightly to the left, the deviation being more noticeable during movement. The left mandibular angle is higher than that of the right, but neither is unduly prominent. Both condyles can be felt and are apparently symmetrical and movements normal. The temporal fossæ are symmetrical.

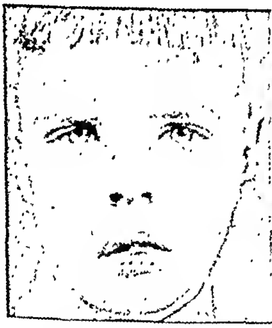

Fig. 1.—Full face.

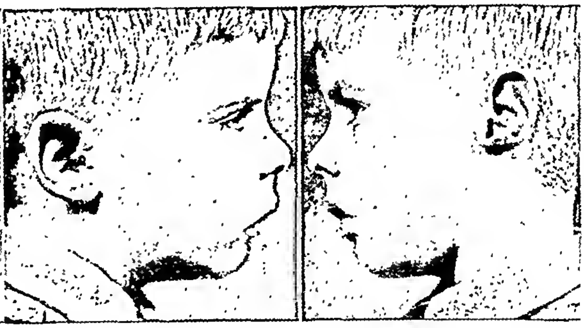

Fig. 2.—Side face.

The left ear (fig. 2) is smaller than the right, is more highly placed, and they are asymmetrical.

In the mouth the left anterior pillar of the fauces passes forward to blend with the loose movable mucous membrane covering the mandibular alveolar ridge; the posterior pillar appears to be normal. The left half of the tongue is markedly smaller than the right, and the tongue deviates to the left on protrusion.

There is no dental caries.

On the right side all the deciduous teeth are present in maxilla and mandible and are normal in size and shape, and the permanent first molars are erupted and in occlusion.

There are only three mandibular deciduous incisors.

In the left maxilla there are only three deciduous teeth, two incisors and a canine.

In the left mandible there are only two deciduous teeth, one incisor and a canine. The left alveolar ridges appear wasted or atrophied in both maxilla and mandible, and shortened antero-posteriorly, the depth of bone in the mandible being very shallow. A Note on Ten Romano-British Skulls from a Burial Ground at Compton, Berkshire

By Sir FRANK COLYER, K.B.E., LL.D., F.R.C.S.

DURING the years 1945-46 a Romano-British burial ground at Roden Down, Compton, Berkshire, was excavated by Mr. M. S. F. Hood and Mrs. Walton and the remains of the skeletons—ten in number—were presented by the owner of the land Mr. J. Trevor, to the Royal College of Surgeons.

The burial ground is 75 feet long and 50 feet wide and is made up of two enclosures. Mr. Hood informs me that during the excavations two cremation hearths were discovered and that these "were in use at some point during the first and early second centuries A.D. After they went out of use the area where they had been was surrounded by the first enclosure which consisted of a ditch with slight banks on either side". The date of the enclosure was approximately the middle of the second century. About the beginning of the fourth century the enclosure was used for burials and three skeletons were found in the area. At a later date a second enclosure was added which was also surrounded by a ditch and shallow banks, in this seven burials were unearthed, the internments dating from about the middle to the end of the fourth century. Mr. Hood suggests that in view of the small number of graves it seems possible that the whole cemetery belonged to one family.

The remains of the burials were examined by Professor F. Wood Jones in relation to sex and age, the measurements of the skulls and the femora by Dr. Lunn.

The dental conditions of the skulls are given below.

Grave 1.—Female, aged 40 to 45. The date of the burial was the early part of the fourth century. In the maxillæ, fig. 1, the right incisor is absent and the canine is in contact with the first incisor. The second premolars, first molars and the left second molar have been lost from parodontal disease and there has been considerable loss of the bone between the left second and third molars and on the posterior aspect of the right third molar. In the mandible the left first premolar is represented by a root, the second premolar has tilted forwards and the crown is close to the canine. Extensive destruction of the alveolar bone is noticeable around the molars, the loss being especially marked on the inner aspects of the left teeth. Calculus is present on the external surfaces of the teeth, the largest deposit being on the incisors.

In occlusion the teeth meet "edge-to-edge" and show a fair degree of attrition.

The posterior surface of the right maxillary second molar has been attacked by caries and there is a cavity in the root of the tooth. As already stated the greater part of the interdental bone between the second and third molars has been destroyed and it is evident that the caries started in the cement about the region of the cervix.

An idea of the septic condition of the mouth of this individual can be formed from the view of the left teeth shown in fig. 2.

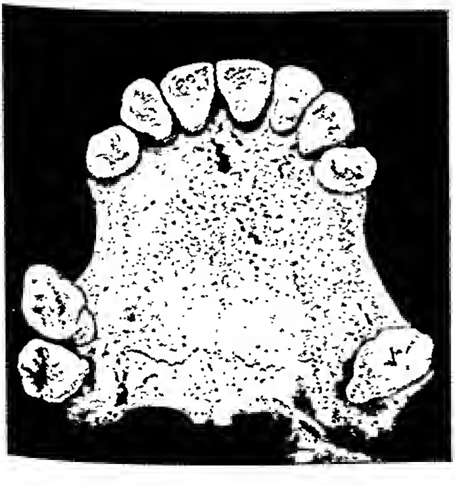

FIG. 1.

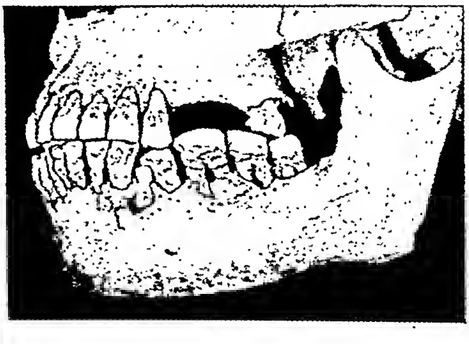

FIG. 2.

FIG. 1.—The maxillary teeth of a female, aged 40 to 45. The right second incisor is absent.

FIG. 2.—View of the left teeth of a female, aged 40 to 45.

Grave 2.—Female, aged 40 to 45. Date of burial, the early part of the fourth century. In this skull all the teeth are present with the exception of the maxillary third molars which

Radiologically (fig. 3) the left coronoid process is absent and there appears to be failure of neighbouring bone growth, which may also account for the left eye appearing to open wider than the right (*see* fig. 1).

On the right side (fig. 4) both bony and dental development appear to be normal for a boy of his age.

On the left side (fig. 5) the only teeth to be seen are:

Deciduous $\left.\frac{|\text{ABC}}{|\ \text{BC}}\right\}$erupted. Permanent $\left.\frac{|1\ 345}{|\ 23}\right\}$unerupted.

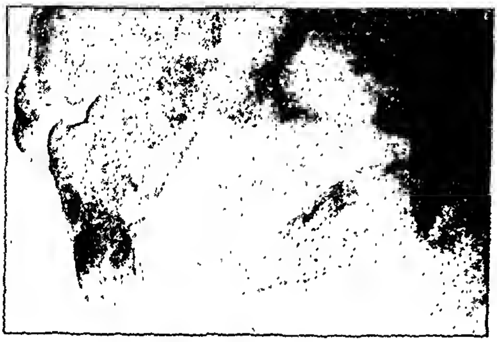

FIG. 3

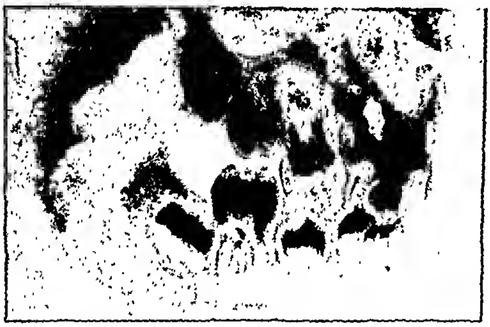

FIG. 4

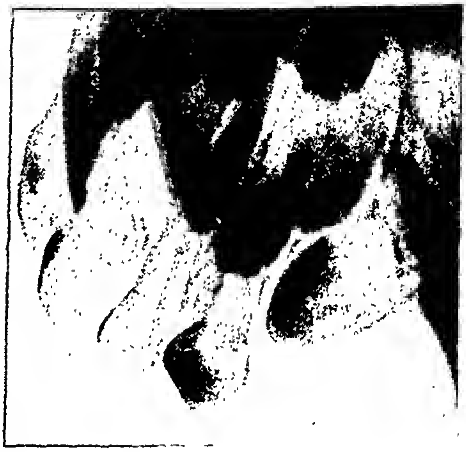

FIG. 5

X-rays: Fig. 3 left mandible; fig. 4 right mandible; fig. 5 left maxilla.

The maxillary second premolar appears to be misplaced and directed towards the deciduous canine. From visual and radiological evidence the size and shape of all teeth on the left side appear to be normal. Just in front of the angle of the mandible it appears as if a molar might be going to develop, but it is very doubtful. There are only three mandibular permanent incisors. The antra are almost symmetrical, that on the left being perhaps slightly larger. The abnormalities appear to be developmental errors having origin partly from the first and partly from the second branchial arch, though, as Rushton has pointed out, not all structures so derived are involved.

Three cases of unilateral hyperplasia of the face, accompanied by enlargement of teeth on the affected side have been recorded by Rushton (1937, 1942) and Miles (1944) during the past ten years, and others recorded earlier make up the total to some eight cases.

In another paper Rushton (1944), referring to unilateral hypoplasia of the mandibular condylar process of congenital origin, states that there may be incomplete or delayed eruption of the molar teeth on the affected side, and that it is generally accompanied by a number of other defects involving the ear and neighbouring parts.

A Note on Ten Romano-British Skulls from a Burial Ground at Compton, Berkshire

By Sir FRANK COLYER, K.B.E., LL.D., F.R.C.S.

DURING the years 1945-46 a Romano-British burial ground at Roden Down, Compton, Berkshire, was excavated by Mr. M. S. F. Hood and Mrs. Walton and the remains of the skeletons—ten in number—were presented by the owner of the land Mr. J. Trevor, to the Royal College of Surgeons.

The burial ground is 75 feet long and 50 feet wide and is made up of two enclosures. Mr. Hood informs me that during the excavations two cremation hearths were discovered and that these "were in use at some point during the first and early second centuries A.D. After they went out of use the area where they had been was surrounded by the first enclosure which consisted of a ditch with slight banks on either side". The date of the enclosure was approximately the middle of the second century. About the beginning of the fourth century the enclosure was used for burials and three skeletons were found in the area. At a later date a second enclosure was added which was also surrounded by a ditch and shallow banks, in this seven burials were unearthed, the internments dating from about the middle to the end of the fourth century. Mr. Hood suggests that in view of the small number of graves it seems possible that the whole cemetery belonged to one family.

The remains of the burials were examined by Professor F. Wood Jones in relation to sex and age, the measurements of the skulls and the femora by Dr. Lunn.

The dental conditions of the skulls are given below.

Grave 1.—Female, aged 40 to 45. The date of the burial was the early part of the fourth century. In the maxillæ, fig. 1, the right incisor is absent and the canine is in contact with the first incisor. The second premolars, first molars and the left second molar have been lost from parodontal disease and there has been considerable loss of the bone between the left second and third molars and on the posterior aspect of the right third molar. In the mandible the left first premolar is represented by a root, the second premolar has tilted forwards and the crown is close to the canine. Extensive destruction of the alveolar bone is noticeable around the molars, the loss being especially marked on the inner aspects of the left teeth. Calculus is present on the external surfaces of the teeth, the largest deposit being on the incisors.

In occlusion the teeth meet "edge-to-edge" and show a fair degree of attrition.

The posterior surface of the right maxillary second molar has been attacked by caries and there is a cavity in the root of the tooth. As already stated the greater part of the interdental bone between the second and third molars has been destroyed and it is evident that the caries started in the cement about the region of the cervix.

An idea of the septic condition of the mouth of this individual can be formed from the view of the left teeth shown in fig. 2.

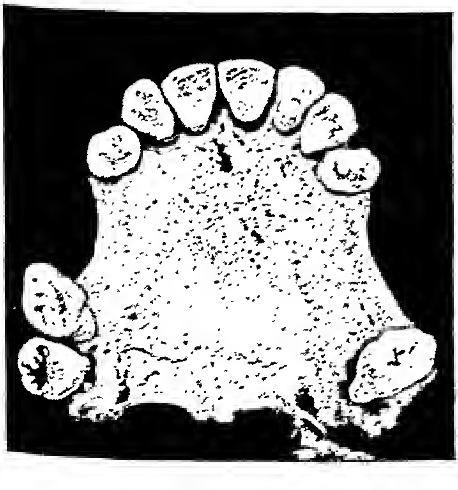

FIG. 1.

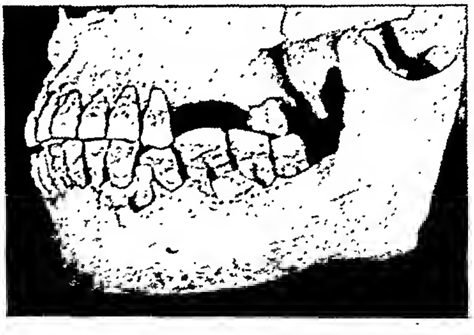

FIG. 2.

FIG. 1.—The maxillary teeth of a female, aged 40 to 45. The right second incisor is absent.

FIG. 2.—View of the left teeth of a female, aged 40 to 45.

Grave 2.—Female, aged 40 to 45. Date of burial, the early part of the fourth century. In this [illegible] teeth are present with the exception of the maxillary third molars which are absent. There is a slight degree of "crowding" of the mandibular incisors and canines, the latter teeth are rotated. In occlusion the maxillary incisors overlap the mandibular teeth.

The alveolar process exhibits a slight but regular recession and there is no rarefaction beyond the margin of the bone. A small deposit of calculus is present on the external surfaces of the teeth all of which show a fair degree of attrition.

Grave 3.—Male, aged 40 to 45. The date of the burial about the middle part of the fourth century. This skull exhibits several interesting variations:

(1) The left maxillary third molar is absent.

(2) The mandibular left third molar is not present but from the appearance of the bone it is not possible to determine whether the tooth was lost from disease or had not developed.

(3) The maxillary second molars are slightly abnormal in shape, they are compressed in the antero-posterior direction.

(4) In the mandible the left second incisor and the canine are transposed. The second incisor, as will be seen from fig. 3, is rotated to a degree sufficient to bring the internal surface of the tooth against the anterior surface of the first premolar.

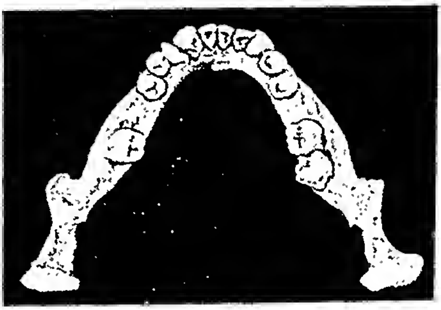

FIG. 3.—Mandible of a male, aged 40 to 45. The left second incisor and canine are transposed.

(5) The maxillary incisors are a little abnormal in position; the mandibular right canine is rotated, the internal surface is in contact with the distal surface of the second incisor.

(6) The mandibular right third molar is tilted against the posterior surface of the second molar and there is a deep "pocket" between the teeth.

In occlusion the incisors meet practically "edge-to-edge", the teeth, with the exception of the maxillary first incisors, show but little attrition. A small deposit of calculus is present on the teeth; the alveolar bone may be regarded as normal.

Grave 4.—Female, aged 65 to 70. Date of burial, the late fourth century. The mandible is edentulous. The maxillæ (fig. 4) are unfortunately defective but the condition of the bone shows that at the time of death the following teeth were present:

$$\underline{3\ \text{x} \mid 12345}\ .$$

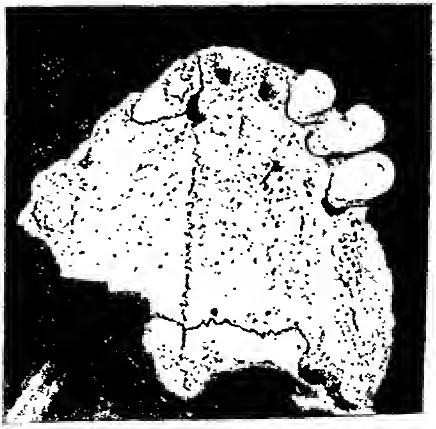

FIG. 4.—Portion of the maxillæ of a female, aged 65 to 70. The right canine is misplaced.

The right canine is misplaced in a horizontal direction, the root, when the premolars were in position, was on the inner aspect of these teeth.

Grave 5.—Female, aged 50 years to a little more. The date of the burial was about the middle of the fourth century. The maxillæ are so defective that it is not possible to form an idea of the state of the dentition. Five maxillary teeth, much worn, were recovered from the coffin, a second incisor, two canines, a premolar and a molar.

The portion of the mandible posterior to the right first premolar is missing. The left second premolar, first and second molars have been lost. In the region of the first incisors there were three teeth, the one next to the right second incisor is in position, the root alone remains of the one next to the left second incisor and between these teeth there is a gap which was occupied by the third tooth. The teeth have been subjected to considerable wear and the alveolar bone shows an advanced stage of destruction.

Grave 6.—Female, aged 55 to 60. The date of the burial is uncertain. The dentition is complete with the exception of the left maxillary first molar which has been lost and of the left second premolar, the root of which alone remains.

There is a slight degree of "crowding" of the mandibular incisors. The teeth show a fair degree of attrition, the condition of the alveolar bone, taking into consideration the age of the woman, may be regarded as normal.

Grave 7.—Male, aged 50 years to a little more. The date of burial was about the last quarter of the fourth century. The following teeth have been lost: The right maxillary first and second molars, the left maxillary third molar and the mandibular molars. The left maxillary first and second molars are represented by roots and the mandibular left first molar is split in a vertical direction leaving the roots separate. The portion of the crown covering the anterior root has been lost and there is an abscess cavity in the bone over the apex of the root. The anterior aspect of the right maxillary third molar has been attacked by caries and a small cavity is present in the root near the cervix.

The teeth exhibit a considerable amount of wear, the occlusal surfaces of the premolars being entirely bared of enamel. The disintegration of the left maxillary molars and the mandibular left first molar is due to the extreme attrition and it is to that cause the loss of the teeth is to be attributed. In occlusion the bite is "edge-to-edge".

Considerable portions of the roots of the cheek teeth are exposed but there is no rarefaction of the bone in the maxillæ and none in the mandible. Calculus is present in fair quantity on the premolars and molars and there is a small deposit on the incisors.

Grave 8.—Male, aged 35 to 40. The burial was probably towards the end of the fourth century. The dentition is almost perfect with the exceptions that there is a slight "crowding" of the mandibular incisors and that the maxillary third molars occlude just internal to their normal relationship with the mandibular teeth. The teeth show but a slight degree of wear and the maxillary incisors overlap the mandibular teeth. The alveolar bone is normal. A view of the teeth is shown in figs. 5A and 5B.

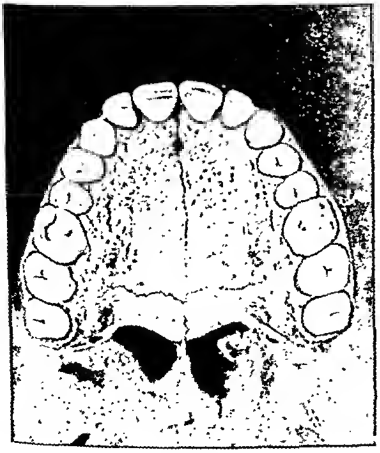

FIG. 5A.

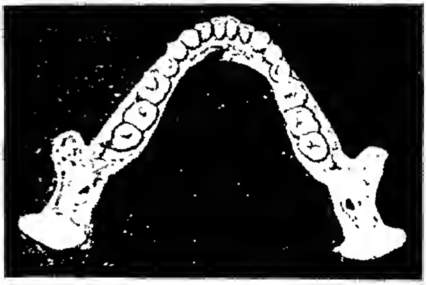

FIG. 5B.

FIG. 5 A and B.—The maxillary and mandibular teeth of a male, aged 35 to 40; date about the end of the fourth century.

Grave 9.—Female, aged 18 to 20. The date of burial was probably the late fourth century. The mandibular third molars are absent and the maxillary third molars are unerupted. The arch of the maxillary teeth is somewhat narrow but there is ample room for the premolars. The left maxillary first premolar is rotated slightly but the abnormality is not due to insufficient room in the arch. In occlusion the maxillary incisors overlap those of the mandible; the alveolar bone is normal.

Grave 10.—Male, aged 50 to 60. The date of burial was well towards the end of the fourth century. The coins with the remains were the latest datable found with the burials. In this skull the right maxillary third molar has been lost and the root alone remains of the left maxillary second premolar. The teeth, with the exception of the incisors, show but little wear and the alveolar bone is in good condition. Calculus is present on the external surfaces of the teeth, the largest deposit being on the incisors. The mandibular left canine and the premolars are slightly abnormal in position, the incisors in occlusion are "edge-to-edge".

Such then are the brief details of the dental condition of these ten skulls from the Compton burial ground. The chief feature is the comparatively large number of variations in the series. In four of the skulls teeth are absent, in one there is an extra incisor in the mandible, in one there is a marked displacement of a maxillary canine, in one the mandibular left second incisor and canine are transposed and the right third molar tilted, facts which suggest instability of the tooth band.

Another feature is the varying degree of attrition of the teeth, for example in skulls 8 and 3 the teeth are very little worn while in skulls 1 and 7 the wear is marked. The amount of parodontal disease varies, in skull 1, a female aged 40 to 45, and in skull 7, a male about 50 years of age, there is evidence of marked destruction of the alveolar bone, on the other hand in skull 6, a female aged 55 to 60, the bone may be regarded as normal for a person of that age.

I may be wrong in my surmise but there would appear to have been a marked difference in the hygienic condition of the mouths of the various individuals. In skulls 2 and 7 the condition of the dental tissues suggests a fairly clean mouth but in skulls 1 and 5 the mouths must have been in a thoroughly septic state. It is tempting to speculate whether this difference in the hygiene of the mouth is related to a difference in the social status of the individuals.

Malaria Control with D.D.T. on a National Scale—Greece, 1946.

[*Abridged*]

By J. M. Vine, M.B., B.S.Melb., D.P.H.Eng.

(*Chief, Greece Mission, World Health Organization Interim Commission; late Director, Health Division, UNRRA Greece Mission,* 1946)

Résumé.—Quand cette lutte fut entreprise la situation en Grèce avait déjà été étudiée en détail, et il existait donc une collection abondante de données biologiques, géologiques, météréologiques et entomologiques. Avec la collaboration de l'Ecole d'Hygiène grecque, UNRRA fit des travaux préliminaires avec le DDT en 1945, suivis par une attaque à fond sur les moustiques hibernants pendant l'hiver et sur les insectes adultes pendant le printemps et l'été de 1946, employant uniquement le DDT.

Quatre préparations furent employées: (*a*) une solution à 5% dans le kérosène à l'intérieur des bâtiments, (*b*) une émulsion aqueuse à 26% diluée au cinquième, pour l'intérieur des bâtiments, les meubles et la literie, (*c*) une solution à 5% dans le mazout pour les bâtiments extérieurs et autres refuges de moustiques, (*d*) une solution à 20% dans le velsicol NR 70, en forme d'aérosol distribué par avion, ou diluée avec du mazout pour donner une concentration de 5% de DDT pour vaporisation à la main des dépendances.

La population a coopéré volontiers, non seulement à cause de la réduction des moustiques mais aussi en raison de l'effet secondaire sur d'autres insectes nuisibles. Ce détail est très important dans les campagnes de ce genre.

Le résultat de cette attaque fut une diminution marquée de l'incidence du paludisme pendant cette saison, d'après le taux parasitaire, l'incidence infantile et l'index splénique. Des villages non traités servant de contrôles ont prouvé que l'an 1946 ne fut pas une saison de basse incidence naturelle en Grèce. Le gouvernement a voté sans hésiter la même affectation de fonds pour l'an 1947.

Leçons essentielles: (1) Il est nécessaire de connaître la situation en détail avant d'établir les plans d'attaque. Le problème du paludisme varie d'un pays à un autre, et dans les différentes régions d'un pays.

(2) L'importance des plans détaillés et de la coopération sans réserve du gouvernement central et local, des malariologistes, des ingénieurs et inspecteurs de l'administration sanitaire, des officiers d'approvisionnement et de transport, des fonctionnaires de finance et, surtout, de la population.

(3) L'opération doit être exécutée d'une façon régulière, et le moment doit être choisi selon les habitudes des anophèles.

(4) L'information publique par la propagande, les imprimés, les journaux et la radio est essentielle.

(5) Il est avantageux de lancer une dernière attaque sur les lieux de reproduction à la fin de la saison, pour diminuer le nombre de moustiques hibernants ayant accumulé de la graisse.

(6) Il faut des recherches supplémentaires sur divers aspects du DDT, sur les substances les plus appropriées pour la préparation d'émulsions, la détermination du contenu *para-para* de diverses produits commerciaux, l'effet d'une chaleur continue sur la préservation, et sur le matériel le plus approprié pour les récipients.

(7) Ces questions restent à répondre: "Quel est l'effet du des quantités et des concentrations de DDT employées dans ces expériences sur les anophèles adultes?" et "Quel est le temps de contact nécessaire pour assurer une efficacité de 100% avec diverses concentrations de vaporisation résiduelle par unité de superficie?"

(8) Il reste beaucoup de recherches expérimentales, techniques et entomologiques à faire pour trouver la méthode la plus efficace et la plus économe d'employer le DDT dans la lutte anti-malarienne.

(9) Les valeurs relatives de la vaporisation des maisons pour exterminer les insectes adultes et des mesures larvicides ou des deux ensemble ne peut être décidée que par la considération des conditions locales et par des expériences locales pendant plusieurs saisons.

(10) L'effet toxique du DDT sur l'homme est négligible, mais, d'après l'observation de 6000 travailleurs employés pendant les six mois de l'été, il est nécessaire de protéger la peau contre les infections dues au kérosène et à l'huile employés comme diluents.

Extracto.—Grecia, donde existian gran cantidad de datos biológicos, geológicos, metereológicos y entomológicos, fué de los paises en que se llevó tempranamente a cabo la lucha antipalúdica en gran escala. Ya en 1945, la UNRRA, conjuntamente con la Escuela Griega de Higiene, realizó un trabajo preliminar con DDT contra los mosquitos invernadores durante los meses de invierno, que, después, en la primavera y verano de 1946, se extendió a mosquitos adultos y larvas. Para ello se usó DDT como única arma.

Fueron empleados cuatro distintos preparados de DDT: (*a*) Al 5% en petróleo para el interior de las viviendas; (*b*) Al 26% en emulsión acuosa, diluida cinco veces, usada en interiores, mobiliario, colchones y ropas de cama; (*c*) Al 5% en aceite Diesel para los exteriores de las casas y lugares ocupados por los mosquitos; (*d*) Al 20% en velsicol NR 70, empleado como aerosol para ser lanzado desde aeroplanos, o también diluido en aceite Diesel al 5% DDT, para rociar el exterior de las viviendas.

La población cooperó, no solamente por lo que la lucha contra el mosquito representaba, sinó también porqué el efecto beneficioso alcanzaba a librarles de otros molestos insectos domésticos. Este es el punto mas valioso de tales campañas.

Los resultados, determinados por la proporción de parásitos, proporción de niños afectos e índice esplénico, mostraron un decidido descenso en el número de casos de paludismo, mientras que, por las cifras obtenidas en aldeas usadas como controles, y por tanto, no tratadas, quedó demostrado que el 1946 no fué un año de naturalmente baja incidencia en Grecia. El Gobierno griego, sin vacilación alguna, adoptó para 1947 las mismas medidas adoptadas en 1946.

Enseñanzas obtenidas: (1) Importancia de recoger datos lo más completos posible antes del planeamiento de las operaciones. El problema del paludismo difiere no solo entre las diversas regiones, sino también entre las distintas partes de una misma región.

(2) Importancia del planeamiento detallado en completa colaboración cón las autoridades gubernamentales, tanto centrales como locales, servicios antipalúdicos, de saneamiento e inspección, provisión de materiales y transporte, servicios financieros y, especialmente, cooperación de la población local.

(3) Las operaciones deben ser realizadas uniformemente y con oportunidad, considerando los hábitos del anopheles.

(4) Es de esencial importancia la informacion pública por medio de folletos de propaganda, prensa y radio.

(5) Ventajas de realizar un ataque intenso contra los criaderos de mosquitos al final de la estación, con el objeto de disminuir el número de insectos que invernan a expensas de sus reservas de grasa.

(6) Se requiere ademas ulterior investigación sobre varios aspectos del DDT: cuales son los agentes más efectivos para la preparación de emulsiones; determinación del contenido en *para-para* de los distintos productos comerciales; efecto del calor prolongado durante el almacenamiento y tipos de envase mas apropiados.

(7) Quedan todavia por dilucidar las siguientes preguntas: ¿Que efecto tienen sobre el anopheles las diferentes concentraciones y cantidades empleadas por área de superficie? y ¿Cual es el tiempo de contacto mínimo para obtener una efectividad de un 100% con diferentes concentraciones de DDT por área de superficie?

(8) Deben realizarse grandes trabajos experimentales, técnicos y entomológicos antes de poder determinar las mejores condiciones de uso del DDT, en cuanto a eficacia y economía se refiere.

(9) El valor de las pulverizaciones en el interior de las casas, comparado con la exterminación de las larvas o, con una combinacion de ambos procedimientos, puede unicamente ser decidido considerando las condiciones locales y solo después de haber estado experimentando durante varias temporadas en la misma localidad.

(10) El efecto tóxico del DDT sobre los seres humanos es tan insignificante que puede ser despreciado. Deben, sin embargo, tomarse precauciones para proteger la piel contra las infecciones debidas al petróleo o al aceite usados como vehículo. Esta conclusión viene demostrada por la observación de 6000 obreros empleados durante los seis meses de verano.

КОНСПЕКТ.—В предыдущие годы в Греции была поизведена тщательная исследовательная работа. Были собраны обширные данные — биологические, геологические, метеорологические и энтомологические. УНРРА, совместно с греческой школой гигиены, произвела предварительную работу с Д.Д.Т. в 1945-ом году. В течении зимы удалось, пользуясь одним только Д.Д.Т., справиться с зимующими насекомыми, а весной и летом 1946-го года тем же путем были уничтожены как насекомые, так и их личинки.

При этом употреблялось четыре различных препарата Д.Д.Т.: а/ 5% раствор в керосине для внутренних помещений; б/ 26% водянистая эмульсия, растворенная в 5 раз, для внутренних помещений, для мебели и постельного белья; в/ 5% раствор в Дизельном масле для наружных помещений и для других мест, куда садится комары; г/ 20% раствор в версиколе HP70 в виде аэрозола посредством аэропланов, а также разбавленный в Дизельном масле до 5% Д.Д.Т. для ручного обрызгивания наружных помещений.

Население оказывало полное содействие, так как оно не только освобождалось от комаров, но одновременно и от других назойливых домашних насекомых. Это последнее обстоятельство чрезвычайно важно в подобных кампаниях.

Результаты показали резкое падение заболеваний малярией во время сезона, исчисляемых количеством паразитов, количеством заболевших детей и селезеночным указателем. Было произведено наблюдение над некоторыми недезинфицированными деревнями и при этом установлено, что 1946 год не был годом естественно низкого количества заболеваний в Греции. Греческое правительство без всякого колебания решило применить те же способы в 1947-ом году, как и в 1946-ом.

Главные заключения: 1. Необходимость иметь полные данные до того как составлять план работ. Проблемы малярии различны в разных странах и в различных частях той же самой страны.

2. Необходимость точного составления планов и полного сотрудничества со стороны

центрального и местного правительства, малириологов, санитарных инженеров и инспекторов, продовольственных, транспортных и финансовых чиновников, а главное всего местного населения.

3. Действие должно быть планомерным и вполне совпадать с привычками комаров.

4. Весьма важны информационные листки для населения и пропаганда посредством печати и радио.

5. В конце сезона рекомендуется особенно заняться теми местами, где разводятся комары. для того, чтобы уничтожить зимующих жироносных насекомых.

6. Требуется дальнейшее исследование других видов Д.Д.Т., для выяснения наилучших способов приготовления эмульсий, определения наилучшего пара-об'ема технических степеней, а также для определения эффекта длительной жары на хранение и выбор прочнейшего материала для сосудов.

7. Нужно выяснить точный ответ на следующие вопросы: а/ "Какие количества и концентрации Д.Д.Т. влияют на анофелесса в данном районе", и б/ "Какой срок эффективного действия Д.Д.Т. в различных концентрациях можно считать 100% успешным для известных площадей намеченных для обрызгивания".

8. Нужно еще много экспериментальной, технической и энтомологической работы для установления наиболее удовлетворительного и экономичного применения Д.Д.Т. в борьбе против малярии.

9. Насколько важно производить обрызгивание домов для уничтожения как комаров, так и их личинок, можно выяснить только при учете местных условий и в результате местных опытов в продолжении нескольких сезонов.

10. Токсический эффект Д.Д.Т. на людей до того ничтожен, что о нем не стоит и упоминать. Нужно только принимать меры предосторожности против инфекции кожи от действия керосина и масла, употребляемых вместе с Д.Д.Т. Этот вывод основан на наблюдении 6.000 рабочих, занятых за шесть летних месяцев.

SINCE 1935 sufficient information about malaria in Greece has been available for the practical purpose of planning schemes of control. Much work was done before then by Greek physicians and by a team sent by the Rockefeller Foundation in 1932. By 1945 more experience had been gained of control measures such as chemical and biological larvicides, nets and house screening, repellents and sprays of the "Flit" type, drainage schemes and suppressive drugs. In the civilian population these measures had had a degree of success in suitable areas (Table I), and in the British Army in Greece in 1945-46 the malaria rate was kept low by the controlled use of mepacrine, nets, dress regulations and larvicidal measures. However, the lack of discipline and co-operation in the civilian population and the shortage of labour and finance in 1945 gave little hope of success in an attempt to apply these measures or a combination of some of them on a national scale.

By 1945 the value of DDT as an insecticide and particularly in malaria control had been demonstrated by experiments in the U.S.A. The Sanitation Section of UNRRA Greece Mission under the direction of Colonel D. E. Wright, who had worked with the Rockefeller Foundation since Panama days and had been engaged in antimalarial work in Greece off and on since 1930, devised a plan for a nation-wide assault on both adult and larval anophelines using DDT in various forms as their sole weapon.

Briefly the plan was to use DDT wherever there was evidence of the presence of anophelines in an attempt at eradication. Four phases of operation were planned. The first was to handspray the interiors and overhanging portions of all buildings, houses, outhouses, stables, in fact any kind of erection or ruin where the hibernating insect might be found. Secondly, this spraying was to be repeated during the summer at intervals when the presence of not only mosquitoes but also common house-flies showed that there were parts omitted or that the DDT had lost its killing power.. Thirdly, on the first sign that surviving anophelines had emerged and were breeding, or on the generally accepted date when this was known to occur, to handspray every pool, watercourse, drain and swamp accessible to and capable of being effectively covered by this method. Control was to be maintained by dipping for larvæ and the spraying repeated at more or less regular intervals. Experimentally it appears that DDT spray is not affected by rainfall on water surfaces, and we did not automatically repeat spray for this reason. Fourthly, at the same time as the larvicidal attack by hand, we brought the aeroplanes into service over the more inaccessible swamps, lakes and water courses, under the same controls as by handspray.

UNRRA, backed by the opinion of eminent U.S. malariologists, was confident that malaria could be controlled by DDT alone. Greek malariologists, following experimental work with DDT, had no doubts as to its potentialities when used for house-spraying but they were not convinced that malaria could be eradicated from their country in one or two years. They maintain the same view to-day and reserve judgment on the widespread use of aeroplanes for spraying. UNRRA offered to provide skilled technical direction and to supply gratis the necessary DDT, oil, other materials, sprays, pumps, and a large fleet of trucks and motor cycles. UNRRA also offered to furnish the aeroplanes with a flying instructor and chief mechanic for their maintenance. By these offers and by Wright's enthusiasm the Greek Government was persuaded to vote large sums for the operation of the scheme.

THE PLAN IN ACTION

A trial of the ground methods was made in 1945 during the summer and autumn. This was more a period of training and organization than an operation, but where we worked the results in the fall in malaria incidence and in the eradication of other insect pests were so satisfactory that the Greek Government agreed from its straitened finances to increase the subsidy of £62,500 for 1945 to £300,000 for the major onslaught in 1946.

The organization set up was based on UNRRA HQ Athens and the Malariological Division of the Greek School of Hygiene, together with the Ministry of Hygiene. In each of eleven regions into which Greece had been divided under the British Military Government there were a Greek malariologist, an American Sanitary Engineer of the U.S.P.H.S., Greek Sanitary Engineers, and Greek inspectors and foremen trained in the technique of preparing the mixtures and spraying. These in their turn hired gangs of labourers and trained them to do the actual work. The Greek staff were paid by the malariologist acting as the Government agent. The scheme was directed and controlled in its major aspects from Athens.

During the winter of 1945-46 work commenced on the eradication of hibernators. For this a 5% mix of DDT in either kerosene or Diesel oil was used. Hudson sprayers delivered a heavy dose of 220 mg. DDT powder per sq. foot. As might be expected in a country so politically and economically disturbed as Greece was then and for that matter still is, there were many troubles both of operation and of supply, but at least the work had commenced and the machine was under way. At this time, too, clinical surveys were commenced both by the U.S.N. Epidemiological teams in Crete, Epirus and in the Peloponnesus, and by the Wellcome Research Foundation team, Foy and Kondi, working out of Salonica. The spleen and parasite findings of these surveys were to be compared with similar findings at the end of the year.

In the month of April attention was turned to the larvicidal work proper. Using DDT 5% in Diesel oil the well-established technique of spraying water accumulations up to about 5 kilometres from the outskirts of villages and hamlets was followed. Inspectors made frequent dippings for control. This continued throughout the summer and was terminated on September 30, which coincided with the early onset of cold weather. For political reasons a considerable disorganization of labour took place at this time and the return to the attack on possible hibernators was not as thorough as was planned.

We sprayed about 700,000 houses and outbuildings to November 1, using DDT prepared in four different ways as follows:

(1) DDT in kerosene using 7 oz. DDT to one gallon kerosene, approximately a 5% solution. The cost of this delivered to the villages was about two shillings per gallon. It

was used on the interior of houses only. An effort was made to give a uniform coat on the surface of 200 mg. per sq. foot.

(2) DDT 26% emulsion. This was received ready prepared in drums. We diluted it with five parts of water to one part of the emulsion and used it for the interiors of houses, beds and furniture. It does not stain and gives results as good as or better than pure DDT in kerosene. For larva control we diluted it to as much as eight parts of water with good results and a reduced price. The cost of the mix delivered and diluted five times was about one shilling and ninepence per gallon.

(3) DDT pure in Diesel oil as for kerosene. This was used for outbuildings, stables, sheepsheds, poultry houses and any other possible resting places for mosquitoes. The cost was about one shilling and ninepence per gallon.

(4) DDT 20% in Velsicol (Velsicol NR 70, polymethyl naphthalene, good solvent, high boiling range and flash point) was used for all aeroplane work without further dilution, but it also gave excellent results for outbuildings by diluting five gallons of Diesel oil to one gallon of the mix. It causes a heavy stain but its lasting qualities are excellent and give protection for as long as six months with one application. There is also a 35% emulsion available, an advantage where the portage of a quantity by a labourer is a problem.

Aeroplanes were intended to play a role secondary to the ground methods but as the work went on we found more and more uses for air-spraying. The Press dramatized the flying part of the programme and we had difficulty in persuading the Greeks that we had no ideas of ridding them of malaria by flying-machines. Eighteen small training planes of the U.S.A.A.F. Stearman type were used. They are single-motored with a cruising speed of about 90 m.p.h. and a landing speed of 40 m.p.h. They were flown by Royal Hellenic Air Force pilots specially trained in the flying technique and given some instruction in malariology. Ten principal bases and many subsidiary landing strips were used. The pilot made a preliminary ground and air survey of his section with the local malariologist or sanitary engineer and then sprayed it when the air was calm from a minimum height of 10 feet. The density of the mist was controlled by a Venturi jet and could be estimated by an observer on the ground. The swamps of Greece lend themselves to this type of spraying. There are few if any trees and the aquatic vegetation is light. Also, during the spring and summer one can count upon fine weather. In 1946 there was no rain to speak of and the long period of drought aided us by shrinking the size of many shallow lakes and swamps. The area which we considered on the basis of larva surveys should be sprayed was 113,000 acres at the beginning of the season and by the end had shrunk to 80,000 acres.

Under ordinary conditions the pilots could spray about 17 acres per minute, but on the basis of the total flying time, including the flight to and from the base, the speed worked out at 4 acres per minute. In all, 506,356 acres were sprayed which represented a 5·3 times spraying of the average number of acres (96,000) sprayed during the season. The total cost, excluding the initial cost of the planes (£6,000) but including pilots, mechanics, labourers and watchmen, was £20,460 or 4s. 4½d. per acre.

A comparison of the cost and man-power required for the various methods of spraying is given in Table II.

TABLE II.—SHOWING CERTAIN FIGURES OF SPRAYING CAPACITY, MAN-POWER POTENTIAL, AND COSTS, WHEN USING VARIOUS METHODS AND MATERIALS FOR SPRAYING IN MALARIA CONTROL.

	Oil	Paris Green dust	Paris Green suspension	DDT planes	DDT hand Oil	DDT hand Emulsion
(1) 1,000 sq. metres requires	35 Lit.	0·2 Lit.	0·09 Lit. dust	0·012 kg. DDT 100% in Velsicol 51·0 c.c.	0·010 kg. 100% as 5%	0·012 kg. 100% as 1%
(2) One man can cover daily	1,200 sq. metres	3,700 sq. metres	3,500 sq. metres	1,100,000 sq. metres per one flying hour*		
(3) He uses for this	42 Lit.	74 Lit.	210 Lit.	56 Lit. for 1 hr. flight*	0·25 Lit. 5% per 1,000 sq. metres	1·25 Lit. 1% DDT per 1,000 sq. metres
(4) Approx. cost of treating 10,000 sq. metres	$18§ £4 10s.	$3.80§ 19s.	$2.20§ 11s. (80% larva kill)	40 cents† 2s.	$3.60‡ 18s.	$3.60 18s.

*The actual spraying time was about one-fourth total flying time.
†In proportion of two for material and one for labour (Greece, 1946).
‡In proportion of about one for material and thirteen for labour.
§Pre-war prices.
NOTE.—Cost of transport and general expenses is not included.

In fairness to the plan it has to be recorded that there were many difficulties in the use of Government-hired labour and in securing delivery of supplies to schedule. Political and administrative moves frequently threatened to break the scheme and succeeded in causing irritation and delays.

SIDE-EFFECTS OF DDT SPRAYING

In Athens in 1946, the most surprising thing was an almost entire absence of flies. In addition to the use of DDT in private houses, large garbage dumps on the end of the town were sprayed from the air at intervals during the hot weather. Air-spraying appeared to clear sandflies from the Nea Smyrna suburb of Athens. It was successfully used against the Dacus fly in olive groves and against a plague of Tene moth in pine and fruit trees. In the interests of the beekeepers care was taken not to use DDT where bees drew their sustenance.

The notifications of typhoid and dysentery in the whole of Greece (Table III) although probably not very accurate do suggest that the reduction of flies by spraying from about July onwards affected the dysentery figures. Typhoid in Greece is mainly a matter of water supply and one would not expect similar results from the eradication of flies.

TABLE III.—NOTIFICATIONS OF TYPHOID AND DYSENTERY FOR ALL GREECE

	1945		1946

EFFECT OF DDT SPRAYING ON MALARIA

Damkas and Mandekos, Rockefeller-trained malariologists who worked in Macedonia with UNRRA and the Government respectively, have supplied figures of spleen indices for a large number of places. The 1946 figures showed a consistent fall below the 1945 level and usually below any level recorded in previous years. In 13 places where no such fall was found, investigations showed that DDT residual spraying was not done (3 places), was delayed or partial (7 places) or that the technique was bad (3 places). Parasite indices in a number of places also showed a fall, but the full results will not be available for some time. Livadas and his co-workers examined in 7 villages 99 babies born after the end of the 1945 season. They were all negative for plasmodia at the end of the 1946 season. In a control non-sprayed village 1 of 11 babies was positive.

In judging the effect of the DDT campaign it is of the greatest importance to establish whether 1946 was naturally a year of low endemicity or not. There are differences of opinion on this. Livadas with his great experience of malaria control in his native land sums up as follows:

> "1946 was preceded by three years, 1943, 1944 and 1945, of comparatively high drought during which malaria remained, after the high level of 1942, at more or less low levels. The abundant rainfall of late 1945 and early 1946 created favourable hydrological conditions for anopheline breeding. It was noted that the early generations of anophelines in 1946 were more numerous than usual, and there was agreement among the experts that there would follow an increased endemicity as is usually the case in Greece every three to five years.
>
> "The ensuing drought, relatively low temperature of the summer and the steady trade winds led to the conclusion that even where no malaria control was carried out the early pessimistic views might be discounted.
>
> "However, actual investigation showed that the anopheline density was not lower than in years of average endemicity. For example, Rodonia village, unprotected from malaria, showed aside from a clear rise of malaria indices a typical local rise in parasite indices, all carriers showing *P. falciparum*. It is also noted that mosquito density in that region approached proportions of epidemic years . . . It is not right to generalize from the above observations, but the conclusions from the evidence to date may be given as follows:
>
> "(i) The level of malaria endemicity in 1946 varied substantially from area to area as is usual in Greece.
>
> "(ii) The assumption is well justified that if the epidemiological conditions of 1946 proved on the whole less favourable for the development of malaria compared with 1938 and 1942 (the more recent epidemic years in Greece) yet they were undoubtedly more favourable than the conditions prevalent during the immediately preceding years of 1943, 1944 and 1945.
>
> "This being so, the surprising improvement of the malaria condition noted in 1946 must be attributed in a very great measure to the malaria control programme, and more particularly to the extensive use of the DDT house-spray technique."

It must be mentioned that atebrin was supplied by UNRRA and distributed in large quantities through local M.O.sH. and Malaria Control Officers during the winter of 1945-46. It is thought that there was not much use of the drug though there is no good evidence either way. It is possible that the availability of atebrin to some extent masked the value of the DDT spraying. Among the UNRRA 2,000 or so personnel atebrin was issued in the spring of 1946 with a recommendation as to its use. The usual story is that some of them took it for a few weeks and then gave it up as there did not seem to be any mosquitoes; similarly with nets, which were hardly used at all. In fact we have travelled over the whole of Greece and lived in provincial small towns without being conscious of a mosquito problem. There have been no new cases of malaria amongst UNRRA personnel.

Further evidence of the success of the campaign was gained from returns by Greek Regional Health Centres when asked by the School of Hygiene for information on malaria incidence during 1946. Eleven centres described the incidence as "reduced", seven as "considerably reduced", nine as "very low", six as "surprisingly low" and four as "practically non-existent". It was noteworthy that the fall in morbidity corresponded with the extent of the campaign in each prefecture. Four health centres reported a small epidemic incidence in non-protected areas and all others no local epidemic incidence whatever. Information from hospitals showed generally a satisfactory fall in numbers of patients treated. It will require a further year or two of intensive effort before the reduction in malaria will be noticeable among the population in general.

Livadas and the School of Hygiene estimate that some 3,600,000 persons were protected; that is about 80% of the total population at risk. The cost per capita was 2s., i.e. the present price of two tablets of quinine, or very much less than one-fifth of the cost of a single intramuscular injection by a private doctor. The total proposed as the budget for 1947 is, however, in the region of £300,000 and it is a very real problem to produce it. The aeroplanes and the DDT have been UNRRA gifts, as have most of the transport vehicles which after a season on the roads of Greece are not in such good shape as they were. The biggest expense is the hire of labour for spraying, and it is the opinion of many of us that this work can be carried out by voluntary or locally paid labour in the villages themselves without drawing on central Government funds. A staff of peripatetic inspectors could instruct and supervise.

It will be interesting to follow the 1947 effort. On the credit side there is the experience gained in 1946 both in headquarters and among the ranks in the field. There is ample DDT of all kinds in Greece now, whereas last year we did not get enough until well on into the summer. Against this, we start with the country in a terribly disturbed condition. Many key men, professional and technical, have been discharged for political reasons. There is a pitiful number of malariologists available, a hopelessly inadequate force. Transport is a greater problem than last year and may well modify the whole plan. There are only two as against seven or eight imported engineers for help and supervision and the essential reliable reporting service. There is, however, one advantage which must be mentioned. Amongst the people of Greece of all classes there are now no sceptics as to the value of this method of fighting malaria and dealing with other insect pests.

We feel that a vigorous effort must be made this year and perhaps for one or two more seasons. After that we think that a careful watch by the Malaria Service of the School of Hygiene and a relatively small action group on an insignificant budget should be sufficient to control this plague, always assuming that there will be something of a continual effort by the population itself to use DDT for the other reasons stressed in this paper. The mosquito will not be eradicated in Greece. While there are anopheles and the odd carrier of malaria there will always be the danger, as in other countries not excepting parts of England. But that it is capable of control to relative unimportance we think is well within the realms of possibility.

I should like to pay tribute to the services of Professor Gregory Livadas and the staff of the Athens School of Hygiene for their work and their co-operation in this campaign. They carried a great burden in organization and their enthusiasm and energy were maintained throughout the season, under the most difficult conditions, both political and economic. I should also like to thank Colonel D. E. Wright, Rockefeller Foundation and during 1946 Chief Sanitary Engineer of the UNRRA Greece Mission, for the great work he carried out, for the keenness and energy he brought to the problem, and for the willing assistance he gave me in the preparation of this paper.

ADDENDUM.—During the months which have elapsed between the presentation of Dr. Vine's paper and its publication further data and conclusions from the 1946 Campaign became available and Dr. Vine, writing from Athens in October 1947, requested us to add the following observations which bear upon the material of his original paper. More mature

considerations of the operation in 1946 have led to certain conclusions and principles, some of which have been incorporated into the 1947 Campaign:

(1) The supreme importance of available and up-to-date complete data with regard to the biological, sociological, geographical, meteorological and entomological conditions of the areas to be dealt with, before the operation is planned. The above were all available to us but the War and Occupation had, to some extent, limited continuous clinical observations.

(2) The almost equal importance of establishing full understanding and co-operation between all sections engaged in the operation. This means both central and local government, malariologists, sanitary engineers and inspectors, supply and transport staff, finance officers and finally, and very important, the local population. The Campaign must be planned on the lines of a military operation with the complication of the civilian element in the forefront. Our own plans were worked out on such lines and we had full co-operation.

(3) In connexion with the above, the public must know what is going on and must be advised by leaflets and through the popular press and wireless broadcasts. We used all the above methods with satisfactory results.

(4) The timing of the different phases subject to anopheline habits presents problems in organization. Thus in Greece, *A. superpictus* can be overlooked until June-July, whereas *A. elutus* and *A. maculipennis* must be attacked in April.

(5) If at all possible, bloods, spleens and baby rates should be investigated over typical "bad" malaria areas, both before and immediately after the season. Baby rates are of a special value and we have much valuable information from this in certain areas, especially Northern Greece.

(6) It is advantageous to make a final onslaught on known breeding sites, particularly marshes, at the end of the season, with the object of diminishing the number of potential fat-bearing hibernators.

(7) With regard to bees, we found that where DDT is used after blossom time there was little or no mortality and this observation compares favourably with the mortality from other forms of insect control drugs on fruit, and vegetables, e.g. arsenic in molasses. On the other hand, we confirm that DDT used in a house where silkworms are breeding inevitably causes death of the worms. Draughts and vibration free the crystals from the sprayed surfaces and these are carried to other parts of the house.

(8) In our experience of 6,000 labourers over a period of six summer months, the toxic effect of DDT on humans is negligible. The effect, however, of kerosene and oil on the skin has to be considered and the appropriate precautions put into force.

We also suggest that in the use of DDT there are several important "unknowns" amongst which are the following:

(*a*) The full answers to the questions: "How does DDT in the area quantities and concentrations used affect the adult anopheline?" and "What is the contact-time element of 100% effectiveness of different concentrations per area of DDT residual spraying?"

(*b*) What are the relative values of larvicidal methods as against house spraying and as against a combination of both? The answer depends, of course, on local conditions but it has to be found for each campaign. In Greece we favour a combination of both and ideally we would propose completion of the first house-spraying before the first brood of larvæ develops.

(*c*) We believe there is room for further investigation by manufacturers as to the most effective agents in preparing emulsions of DDT. There are also problems of the optimum *para-para* content of technical grades of DDT. Similarly the effect of prolonged atmospheric heat and bad storage and the optimum container material for DDT are subjects, no doubt, under investigation, and requiring elucidation. Also, as DDT is readily saleable privately, care must be taken that solutions and emulsions made up in the field contain their ingredients in the proper amounts.

(*d*) Finally, it is clear that much experimental work, both technical and entomological, must be done before the most satisfactory and economic use of DDT in malaria control on the grand scale is determined.

Section of Laryngology with Section of Otology

COMBINED SUMMER MEETING HELD IN BRIGHTON

LARYNGOLOGICAL SESSION

Chairman—NORMAN PATTERSON
(President of the Section of Laryngology)

Certain Anatomical and Physiological Considerations in Paralysis of the Larynx

By V. E. NEGUS

THERE is considerable confusion in descriptions of laryngeal paralysis, and this confusion seems to arise from different causes. The first difference of opinion concerns the nerve supply of the laryngeal muscles, the second their mode of action, and the third the appearances and description of the results of disturbances of innervation. It will be best, therefore, to discuss the question under various headings.

Nerve supply.—I have obtained from Dr. G. Weddell the correct interpretation of the derivation of the motor fibres supplying the intrinsic muscles of the larynx; it is stated that they are localized in the lower part of the nucleus ambiguus, which belongs to the spinal accessory nerve [1]. The fibres arising from these motor cells leave the cranium in the eleventh nerve, which then divides into an internal and external branch. The former joins the ganglion nodosum of the vagus nerve, in which the fibres travel to reach the larynx, either through the superior laryngeal branch or through the recurrent laryngeal nerve. There is no particular clinical significance in this observation, as lesions at the jugular foramen, such as a new growth, fracture or other injury, would, in all probability, involve both the tenth and eleventh nerves, and any lesion in the medulla of any wide extent would probably involve the motor nuclei of both the tenth and eleventh nerves. It is, however, best for the sake of accuracy to decide this point, and this seems to represent the modern opinion.

The second point concerns the supply of the intrinsic laryngeal muscles. It is agreed that the crico-arytenoideus posticus and the sphincteric group, made up of lateral crico-arytenoid and thyro-arytenoid muscles, together with the interarytenoid, are all supplied by the recurrent laryngeal nerve. The interarytenoid has, of course, a bilateral supply. What is in dispute is the function of the superior laryngeal, which through its external branch gives innervation to the crico-thyroid muscles. It has been thought by some that the interarytenoid was also supplied by this nerve, but this view, according to Lemere and others, is incorrect [2, 3]. It should be accepted that the superior laryngeal nerve supplies the crico-thyroid muscle only and the recurrent, the intrinsic abductor and adductor muscles.

considerations of the operation in 1946 have led to certain conclusions and principles, some of which have been incorporated into the 1947 Campaign:

(1) The supreme importance of available and up-to-date complete data with regard to the biological, sociological, geographical, meteorological and entomological conditions of the areas to be dealt with, before the operation is planned. The above were all available to us but the War and Occupation had, to some extent, limited continuous clinical observations.

(2) The almost equal importance of establishing full understanding and co-operation between all sections engaged in the operation. This means both central and local government, malariologists, sanitary engineers and inspectors, supply and transport staff, finance officers and finally, and very important, the local population. The Campaign must be planned on the lines of a military operation with the complication of the civilian element in the forefront. Our own plans were worked out on such lines and we had full co-operation.

(3) In connexion with the above, the public must know what is going on and must be advised by leaflets and through the popular press and wireless broadcasts. We used all the above methods with satisfactory results.

(4) The timing of the different phases subject to anopheline habits presents problems in organization. Thus in Greece, *A. superpictus* can be overlooked until June-July, whereas *A. elutus* and *A. maculipennis* must be attacked in April.

(5) If at all possible, bloods, spleens and baby rates should be investigated over typical "bad" malaria areas, both before and immediately after the season. Baby rates are of a special value and we have much valuable information from this in certain areas, especially Northern Greece.

(6) It is advantageous to make a final onslaught on known breeding sites, particularly marshes, at the end of the season, with the object of diminishing the number of potential fat-bearing hibernators.

(7) With regard to bees, we found that where DDT is used after blossom time there was little or no mortality and this observation compares favourably with the mortality from other forms of insect control drugs on fruit, and vegetables, e.g. arsenic in molasses. On the other hand, we confirm that DDT used in a house where silkworms are breeding inevitably causes death of the worms. Draughts and vibration free the crystals from the sprayed surfaces and these are carried to other parts of the house.

(8) In our experience of 6,000 labourers over a period of six summer months, the toxic effect of DDT on humans is negligible. The effect, however, of kerosene and oil on the skin has to be considered and the appropriate precautions put into force.

We also suggest that in the use of DDT there are several important "unknowns" amongst which are the following:

(*a*) The full answers to the questions: "How does DDT in the area quantities and concentrations used affect the adult anopheline?" and "What is the contact-time element of 100% effectiveness of different concentrations per area of DDT residual spraying?"

(*b*) What are the relative values of larvicidal methods as against house spraying and as against a combination of both? The answer depends, of course, on local conditions but it has to be found for each campaign. In Greece we favour a combination of both and ideally we would propose completion of the first house-spraying before the first brood of larvæ develops.

(*c*) We believe there is room for further investigation by manufacturers as to the most effective agents in preparing emulsions of DDT. There are also problems of the optimum *para-para* content of technical grades of DDT. Similarly the effect of prolonged atmospheric heat and bad storage and the optimum container material for DDT are subjects, no doubt, under investigation, and requiring elucidation. Also, as DDT is readily saleable privately, care must be taken that solutions and emulsions made up in the field contain their ingredients in the proper amounts.

(*d*) Finally, it is clear that much experimental work, both technical and entomological, must be done before the most satisfactory and economic use of DDT in malaria control on the grand scale is determined.

(8) In our experience of 6,000 labourers over a period of six summer months, the toxic effect of DDT on humans is negligible. The effect, however, of kerosene and oil on the skin has to be considered and the appropriate precautions put into force.

We also suggest that in the use of DDT there are several important "unknowns" amongst which are the following:

(*a*) The full answers to the questions: "How does DDT in the area quantities and concentrations used affect the adult anopheline?" and "What is the contact-time element of 100% effectiveness of different concentrations per area of DDT residual spraying?"

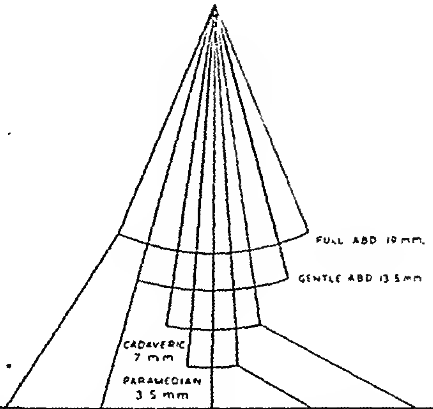
(*b*) What are the relative values of larvicidal methods as against house spraying and as against a combination of both? The answer depends, of course, on local conditions but it has to be found for each campaign. In Greece we favour a combination of both and ideally we would propose completion of the first house-spraying before the first brood of larvæ develops.

(*c*) We believe there is room for further investigation by manufacturers as to the most effective agents in preparing emulsions of DDT. There are also problems of the optimum *para-para* content of technical grades of DDT. Similarly the effect of prolonged atmospheric heat and bad storage and the optimum container material for DDT are subjects, no doubt, under investigation, and requiring elucidation. Also, as DDT is readily saleable privately, care must be taken that solutions and emulsions made up in the field contain their ingredients in the proper amounts.

(*d*) Finally, it is clear that much experimental work, both technical and entomological, must be done before the most satisfactory and economic use of DDT in malaria control on the grand scale is determined.

lengthened, and the Wrisberg cartilage may lie further back than on the unaffected side. In the aryepiglottic fold there are, on the outer side of the Wrisberg cartilage, muscular fibres continuous with the interarytenoid which have an active function in closing the aperture of the larynx during swallowing. It is common to find, therefore, that in recurrent laryngeal paralysis, with a partial loss of the protective action of the aryepiglottic folds, liquids tend to overflow into the larynx, as in the case of bulbar paralysis, thus causing considerable coughing and distress to the patient.

Positions of the vocal cords.—There has been in the past some confusion in describing the positions of the vocal cords, and it would be well to reach agreement as to nomenclature. An excellent paper by Clerf and Suehs is of particular value in clarifying this problem [3]. There are six positions to be described (fig. 1).



POSITION	FULL ABDUCTION	GENTLE ABDUCTION	MEDIAN	PARAMEDIAN	INTERMEDIATE
FUNCTION	DEEP INSPIRATION	QUIET RESPIRATION	PHONATION	STRONG WHISPER	CADAVERIC
ACTIVE MUSCLES	ALL	ABDUCTORS	ADDUCTORS	EXTERNAL ADDUCTORS	NONE
SOMETIMES PARALYSED	NONE	INTERNAL ADDUCTORS	ABDUCTORS	INTERNAL ADDUCTORS	ALL

FIG. 1.—Diagram to illustrate positions assumed by the vocal cords in health and disease. In addition to the five illustrated, a sixth, the "glottic chink," is assumed in some cases of double abductor paralysis.

Starting at the middle, there is the *median* position, which is adopted during phonation, under the action of the external and internal adductors. The median position can be taken up in cases of paralysis of the abductors when, according to Semon's law, the latter alone are paralysed.

The second position may be known as the abductor or *glottic chink*; it appears in cases of double abductor paralysis. Although, in this condition, the external and internal adductors bring the cords together, the lack of bracing back of the arytenoid cartilages by the posticus muscles allows the margins of the cords to separate very slightly during inspiration and more still during expiration [4]. If there were not this chink, the patient would be asphyxiated, and in point of fact he may be near this condition in certain early cases of double abductor paralysis.

The third position is the *paramedian* [2, 3], which leaves a posterior space of about 3·5 mm. between the cords. It is the position used in certain forms of strong whisper, and in pathological states it is taken up in cases of complete paralysis of the recurrent laryngeal nerve, when both the abductors and the internal adductor muscles are out of action. The cords are brought into the paramedian position by the influence of the crico-thyroid muscles, which act as external adductors and rotators of the arytenoid cartilages, and thus as tensors of the vocal cords [2, 3, 5]. It is incorrect to say that in cases of complete recurrent paralysis the cadaveric position is taken up.

The fourth position is the *cadaveric*, in which the posterior arm of the glottic triangle measures about 7 mm. It is the position of complete muscular relaxation and is assumed by virtue of the elasticity of the capsule forming the crico-arytenoid joint. It is only assumed when all the muscles controlling the glottic margins are paralysed, that is, the internal and

Action of intrinsic laryngeal muscles.—In considering paralysis of the larynx, the function of the *crico-thyroid muscle* is of considerable importance. By narrowing the gap between the cricoid and thyroid cartilages and by sliding the thyroid forward in relation to the cricoid, the distance between the crico-arytenoid joint and the inner surface of the thyroid alæ is lengthened. This means that the crico-thyroid in its contraction is an external tensor of the vocal cords. The same action has a rotatory effect which tends to bring the vocal processes of the arytenoids closer to one another. It should therefore be agreed that the crico-thyroid muscles act as external tensors and adductors of the vocal cords. As to which moves on the other, cricoid on thyroid, or vice versa, there is also disagreement. I believe the correct explanation is that during phonation the cricoid cartilage is held immovably against the front of the vertebral column by the action of the crico-pharyngeal sphincter and that when the crico-thyroid muscles contract, they rotate the thyroid on the stationary cricoid. During swallowing, on the other hand, the crico-pharyngeus relaxes and allows the cricoid cartilage to be tilted forward during closure of the laryngeal aperture. These are minor points, but of some interest.

The second observation, in the interest of clarity, concerns the action of the *crico-arytenoideus posticus*. The action of this muscle is of two types. In the first place the posterior fibres, attached to the muscular process of the arytenoid, rotate the latter and separate the vocal or glottic processes of the cartilages. In the second place, there are lateral fibres of the posticus muscle arising from the outer surface of the cricoid cartilage, to gain attachment to the body of the arytenoid; they slide the whole of the latter outwards on its lax joint, thus separating the bodies of the arytenoids. By this dual action, the posticus muscle opens the glottis, making it of a triangular shape, but if the usual description were correct, and rotation by traction on the muscular processes were the only action, then the glottis would be diamond-shaped when open.

Another action of the posticus muscle is to brace back the arytenoid cartilage during phonation. If this were not so, contraction of the sphincteric group of muscles would pull the arytenoid forward and there would be no possibility of obtaining tension in the margins of the glottis. As it is, the counteraction of the posticus allows the thyro-arytenoid muscles to provide elasticity to the glottic margins, the degree of elasticity varying with the pitch required, becoming greater as the pitch rises. During raising of the pitch, the increasing tension of the thyro-arytenoid muscles tends to shorten the vocal cords, a point disputed by some.

In a case of partial recurrent laryngeal paralysis, where the abductor muscle alone is paralysed, the arytenoid cartilage is allowed to slide forwards and inwards and will therefore approach the thyroid ala and will drop to a lower level. This action is increased if the internal adductors and tensors are still functioning. If there is, however, complete recurrent laryngeal paralysis, the forward and shortened position will still be taken up (fig. 2, diagrams 3 and 5). A fourth function of the posticus muscle will be considered later.

Control of the aryepiglottic fold.—It is a habit to speak of "paralysis of the cord", but in certain cases the cord itself is invisible, as it is overhung and obscured by the aryepiglottic fold. It is therefore necessary to consider the function of the latter. It is a fold designed to provide a lateral food channel, which leads down from the side of the epiglottis through the pyriform fossa to the mouth of the œsophagus. Small quantities of liquid are able to travel past the larynx even if the latter is open, and in herbivorous animals and in many Cetaceans the use of this lateral channel is the habitual manner of swallowing. In man, with his herbivorous ancestry, the fold is high, and use is made of it, particularly in infancy. The fold is attached anteriorly to the lateral border of the epiglottic cartilage and posteriorly to the body of the arytenoid and to the anterior surface of the cartilage of Santorini. The fold is kept more or less tense by the backward pull of the posticus muscle, which so braces it that it remains upstanding; but the upright position is also facilitated by the cartilage of Wrisberg, which acts as a passive prop. If the posticus muscle is paralysed, the arytenoid cartilage is no longer braced back, and the aryepiglottic fold falls forwards and inwards, overlying the laryngeal aperture. It is easy to see, in a case of recurrent laryngeal paralysis, this alteration in position of the aryepiglottic fold, which is particularly indicated by the falling forwards and inwards of the cartilage of Wrisberg. The latter lies in an anterior position in relation to its normal fellow of the opposite side. One can therefore see that there is an abductor, or a complete recurrent laryngeal paralysis, by observing the Wrisberg cartilage, even if the vocal cord is invisible. During phonation, the action of the internal tensors and adductors brings the vocal cord of the opposite side towards the mid-line and shortens it. In this action, the Wrisberg cartilage of the healthy side passes in front of that of the paralysed side (fig. 2, diagrams 3 and 5). This movement and difference of position is of considerable value in a differential diagnosis between paralytic and mechanical fixation of a vocal cord. In fact, when the crico-arytenoid joint is affected, the aryepiglottic fold appears

The points of importance suggested for consideration are the necessity for clear expression regarding the paramedian and cadaveric positions, and the differentiation between recurrent laryngeal paralysis and what I would suggest should be called combined paralysis, when both branches of the vagus are involved.

external adductors and the abductors. It can therefore only come about in cases of vagus paralysis, where both the superior laryngeal nerve and the recurrent nerve are out of action. It is not a position adopted in cases of recurrent laryngeal paralysis without involvement of the superior branch. The cadaveric is sometimes known as the *intermediate* position [3], as it lies roughly half-way between the mid-line and the fifth position of *quiet respiration.* The latter is the position of gentle abduction and is seen during peaceful respiration, the glottic space measuring about 13·5 mm. transversely. The cords are maintained in this position under the influence of the abductors. It is also the position assumed in functional aphonia, but not because of any organic paralysis. It could not, in fact, be assumed in any organic lesion, because it necessitates activity of the posticus muscle.

The sixth position is that of *full abduction*, assumed during deep respiration under the influence of the abductor muscles, with some opposing action of the adductors. In this position it is obvious that there can be no paralysis of either abductors or adductors, according to Semon's law.

Types of laryngeal paralysis.—Theoretically there might be a large variety of paralytic lesions of the larynx but, in point of fact, those encountered are relatively few. There seems no reason to doubt the truth of Semon's law, in spite of some criticisms of its accuracy. If it is accepted that the abductors are paralysed before the adductors, because they are more vulnerable, it follows that organic lesions of the adductors cannot occur as an isolated condition. Functional aphonia is merely a disordered action of the larynx, and not a form of paralysis, since the cords move well on arm efforts and during cough. Then again, there are described instances of paralysis affecting individual muscles—the thyro-arytenoid, the crico-arytenoideus lateralis and the interarytenoid—but these, if they occur, must be extremely rare, and in my experience none has appeared. There may, of course, be weakness of some of the sphincteric group, as in cases of tuberculosis, when the cords are bowed on phonation, but this is not an instance of paralysis, nor is the posterior gap sometimes left between the arytenoids paralytic, as it is merely the result of disordered phonation and can be corrected by re-education of the voice.

There remain to be considered, therefore, instances of paralysis of the recurrent laryngeal nerve, affecting either the abductors alone or all of the intrinsic group, and secondly cases where the crico-thyroid muscles are also involved. *Unilateral abductor paralysis* is frequently seen, and requires no particular comment, except to note the position of the aryepiglottic fold, and particularly the Wrisberg cartilage, which has sometimes been mistaken for a neoplasm, owing to its unusual bulbous appearance [6]. The affected vocal cord takes up a median position; during phonation the glottis is well closed, the healthy cord coming in to the mid-line, with the Wrisberg cartilage of the unaffected side passing in front of its paralysed neighbour (fig. 2, diagram 3). *Bilateral abductor paralysis* has already been referred to as leaving a glottic chink, but on inspiration there is naturally distressing dyspnœa, owing to the valvular nature of the glottic margins, which leads to their indrawing during inspiration (fig. 2, diagram 4). In *complete paralysis of the recurrent nerve* the paramedian position is taken up under the influence of the crico-thyroids. There is, therefore, a slight gap during phonation when the healthy cord comes to the mid-line, but, later, overaction of the unaffected cord may restore the voice almost to normal. *Complete bilateral recurrent paralysis,* leaving both cords in the paramedian position, allows air to pass with little distress through the narrowed glottis. The margins of the cords are still regular, although bowing outwards on expiration (fig. 2, diagrams 5 and 6).

Unilateral paralysis of the superior laryngeal nerve may follow operative injury or involvement in a new growth; it leads to lack of tension in the affected cord. *Bilateral paralysis* affecting these nerves is very rare.

When the *superior laryngeal nerve* is involved as well as the recurrent, *in combined paralysis,* the cadaveric position is taken up, as already described [3]; the margin of the affected vocal cord is irregular and wavy owing to flaccidity of the thyro-arytenoid muscles supporting it. There is naturally a sufficiently wide glottis for respiration, but during phonation there is feebleness of the voice owing to air waste, through the inability of the unaffected cord to close the glottis (fig. 2, diagram 7). Such a paralysis may follow a variety of causes, either in the basal nuclei, at the jugular foramen, or in the neck. I have seen instances due to many varying conditions, such as thrombosis of the posterior inferior cerebellar artery, fracture at the base of the skull with involvement of the jugular foramen, a tumour growing from the nasopharynx, and hæmorrhage in the neck following a bomb wound. Owing to the situation of the lesion, there is usually involvement of other nerves—the ninth, eleventh or twelfth—according to the location of the cause in the nuclei, at the base of the skull, or in the parapharyngeal space.

Bilateral combined paralysis is most unlikely to be seen, as a lesion involving the vagus on both sides is difficult to imagine.

The points of importance suggested for consideration are the necessity for clear expression regarding the paramedian and cadaveric positions, and the differentiation between recurrent laryngeal paralysis and what I would suggest should be called combined paralysis, when both branches of the vagus are involved.

The Treatment of Subacute Maxillary Sinusitis Especially in Children

By G. E. ARCHER

SUBACUTE maxillary sinusitis may be defined as the prolongation of an acute infection of the maxillary sinus which has either not been treated or failed to yield to conservative treatment.

The idea that drainage from this cavity is by gravity and that the ostium is situated in a most unsuitable position for this purpose has largely influenced our thinking and surgical procedures have mostly been designed to provide gravitational drainage. Research has shown that gravity is probably not the most important factor in the removal of fluid from the sinus. Lowndes Yates, Proetz and others [1] have shown that the action of the ciliated mucous membrane within the sinus is probably the most important factor in removing secretion. Also that the ciliary action always works towards the natural ostium.

In 1933 O'Malley [2] demonstrated the importance of the ventilation of the maxillary sinus and showed that air pressures within the sinus rise and fall with inspiration and expiration. These pressure variations can be demonstrated not only in normal sinuses but in conditions of acute and chronic sinusitis. The rise and fall of pressure within the maxillary antrum synchronizes with the rise and fall of pressure within the nasal chambers, but would appear to be further emphasized by the middle turbinate overlying the maxillary ostium, thus a condition of affairs comparable to the Sprengel pump is produced so that during expiration the expired air passing forward through the nose will assist in evacuating the air from the maxillary sinus. Simon [3] published some investigations on this question and found that with the presence of a large ostium or accessory ostium the pressure readings in the antrum tended to equal those of the corresponding nasal fossa. From this it would appear that the making of a permanent ostium from the maxillary sinus into the inferior meatus of the nose will interfere with the normal variations of the pressures and with the ventilation of the sinus, and also (except when gross amounts of fluid are present in the sinus) the opening in the inferior meatus would appear unnecessary as the ciliary action will remove the fluid via the natural ostium.

It may be asked then is it necessary, or even desirable, to make a new permanent ostium from the inferior meatus into the antrum?

The generally accepted treatment for subacute sinusitis is repeated sinus lavage. In Jacksons' book [4] the condition is dismissed in one paragraph:

"Subacute maxillary sinusitis: This condition is a prolongation of an acute infection, and treatment is similar to that in the acute infection. If, after a few weeks, there is no improvement, it may be assumed that drainage from the sinuses is inadequate. These cases usually clear up following intranasal antrotomy in the inferior meatal wall".

In their book [5] StClair Thomson and Negus inform us that treatment by lavage is worth a trial; this three times a week for three weeks is suggested, but to discontinue if there is no decided improvement after six treatments, and that it is rarely curative in cases of more than six months' duration. My view is that most of us would now be inclined to persevere with antral lavage for considerably more than three weeks. One must admit that repeated antral puncture becomes irksome to the patient and he presses for a more rapid cure of his troubles.

Various other treatments (with or without antral lavage) have at different times been recommended. Proetz displacement therapy when first introduced was thought to be a great step forward, and it seemed as if this would solve the problem of curing the less tractable acute or subacute sinusitis. My own experience of this has resulted in only moderate success. Bauwens [6] made claims for the resolution of sinusitis by treatment with short-wave diathermy but it seems to me to be particularly difficult to assess the value of this treatment. My impression is that in some cases recovery may have been hastened but I feel that recovery might have resulted without short-wave treatment. The introduction of penicillin into the sinuses has been recommended. Angell James [7] suggested the use of penicillin paste. Hunt Williams [8] suggested the technique whereby an indiarubber ureteric catheter was introduced into the maxillary antrum through which perfusion of the sinus with penicillin could be carried out.

Some ten years ago I commenced the treatment of cases of maxillary sinus suppuration (especially in children) by the introduction of an indwelling rubber catheter (of the de Pezzer type) into the maxillary sinus from the inferior meatus of the nose. Through this the sinus was irrigated with normal saline two or three times a day for seven to ten days, and when repeated washings were returned clear the catheter was removed. I was greatly interested therefore when some time later I discovered an article in the *Archives of Otolaryngology* of 1926 by Alden [9] describing a similar procedure to the one I had adopted. He used short rubber tubes with a flange made for the purpose; irrigation was made with a bulb syringe, and the antrum was flushed with 1% mercurochrome or 2% silver nitrate solution. He recommended this daily irrigation until the sinus was free from secretion, usually a period of from ten to fourteen days. But I can find no evidence that this treatment was generally adopted. In 1937 Asherson [10] recommended in cases of acute maxillary sinusitis leaving a cannula in the antrum and projecting from the nose, through which repeated perfusion with saline was made.

The small operation I recommend is most satisfactorily performed under local anæsthesia except in the case of young children when a short general anæsthetic is advisable. After cocainizing the nose, a Killian's speculum is introduced under the inferior turbinate, which is gently elevated until a good view of the naso-antral wall is obtained. Thornwaldt's trephine is placed in the position in which an antral puncture is made where the bone is thinnest. After one or two turns the trephine slips into the antrum. The trephine is then withdrawn and a de Pezzer catheter of suitable size is introduced through the hole so made. It is rarely necessary to enlarge this opening. The catheter is fixed to the cheek with adhesive tape and its free end buried in a gauze pad to absorb any fluid seeping up from the antrum. The whole procedure is completed in one or two minutes. The following day irrigation with warm normal saline is commenced by attaching the Watson-Williams syringe to the catheter and allowing the fluid to flow out through the ostium. After several irrigations the washings are returned clear and then the catheter is withdrawn, after which the hole closes in a few days and the normal anatomy and physiology of the sinus are restored.

The only mishaps encountered have been in three cases where the end of the catheter broke in the antrum (probably due to old and perished indiarubber as new catheters were not easily obtained during the war years). In two of the cases no difficulty was experienced in removing the broken-off portion via the nose. In one case, a small child, it was necessary to open the antrum from the canine fossa.

The patients find this treatment in no way irksome and young children tolerate it perfectly well. Of course, in addition to this procedure, attention must be paid to other factors which may contribute to the chronicity of the condition. Any dental root infection must have attention, and in children, if there is a large adenoid mass interfering with efficient nasal respiration or harbouring infection, removal is indicated. In adults, if there is marked deflection of the septum towards the side of the diseased antrum, a submucous resection operation may be required. In these circumstances infraction of the middle turbinate would appear to be necessary in most cases.

Regarding diagnosis of the condition, the presence of pus demonstrated in the sinus washings would appear to be sufficient, always bearing in mind the possible pitfall that we may be dealing with a so-called pyosinus which is acting as a reservoir for pus draining from an infection of the upper sinuses.

By this method I have treated about 150 cases. The record submitted does not include Service patients treated in E.M.S. Hospitals as it is quite impossible to trace them all. The 100 cases analysed are those treated in private practice (39 cases), at the Manchester Northern Hospital (34 cases), and at Stockport Infirmary (27 cases) up to the early part of this year (1947). The more recent cases are not included as it is too soon to assess results. A questionnaire (viz. "Are you cured?" "Improved?" "Left the same?" "Made worse?") was sent to the first 100 patients. Ninety-five replied and all except three have been examined within the last month. Five have not been traced, or have not replied and therefore have not been examined.

TABLE I.—AGE AND SEX DISTRIBUTION

Age (years)	M.	F.	Total
Under 10.. ..	3	3	6
10–15	8	10	18
15–20	5	7	12

Unknown	Uncomplicated	1	3	—	1
	Complicated	2	—	1	—
Totals		61	28	6	5

*28 (18 deflected nasal septum: submucous resection; 10 nasal polypi removed).

†11 (2 deflected nasal septum: submucous resection; 7 nasal polypi removed; 2 asthma, bronchiectasis).

The numbers are far too small to make positive deductions but some of the results seem to be significant.

(i) In uncomplicated cases: Up to one year's duration, 14 cured, 2 improved; over one year's duration, 9 cured, 7 improved.

(ii) Cases of over one year's duration complicated by deflected septum: 18 cured; complicated with polypi, 10 cured.

Twenty-eight cases of maxillary sinus suppuration of over one year's duration, after submucous resection operation on the septum and infraction of the middle turbinal, or after removal of polypi from the middle meatus, in order to allow the sinus to drain by its ostium, were cured without any counter-drainage opening having been made. This seems to emphasize the importance of making certain that the normal ostium is patent and capable of allowing the secretion to pass out from the antrum into the middle meatus of the nose.

Have we underestimated the powers of recovery of the ciliated mucosa of the antrum, and would it not appear that the more frequent washing out of the purulent secretion so that the ciliary action may start again with as little delay as possible is one of the secrets of securing a good result? I feel that the findings justify further trial.

The period of treatment may be considerably shortened as most uncomplicated cases of maxillary suppuration will clear up in seven to ten days and the patient spared repeated antral puncture three or more times a week for a period of some weeks. This is particularly useful in children and adolescents where only one short anæsthetic is required. My experience is that even in quite young children antral puncture can be carried out without an anæsthetic, but if repeated the child, although not hurt, becomes apprehensive and suffers some degree of mental strain.

This treatment may dispense with the necessity of an intranasal antrostomy, particularly to be avoided in a child. A child's nose is very small and with the limited space available the operation is not easy. It is not uncommon to find adhesions between the turbinates and the septum after any operative procedure in a child's nose. My own view is that even if a permanent intranasal antrostomy has to be performed the inferior turbinate should be retained entire, but how often does one see the anterior portion sacrificed with subsequent hypertrophy of the posterior remaining part.

The disadvantages that may be urged against this treatment are: (i) That it is necessary to admit the patient to hospital. There may be reasons against this in the case of an adult, but surely it is far better to do so in the case of a child.

(ii) The condition of affairs within the antrum cannot be determined by vision. This does not seem so necessary in a child, but it must be admitted that it is desirable in any intractable case in an adult, especially if the condition is unilateral.

The ideal should surely be to cure the disease and restore the normal anatomy and physiology of the part. By this method no mucous membrane is sacrificed and the normal anatomy and physiology of the nose are maintained or restored.

The President said that he was all in favour of repeated puncture and the avoidance when possible of an operation. If the condition could be cured by such means it was a great advantage, and if by substituting Mr. Archer's method less distress was occasioned to the patient that also was all to the good. The line of treatment recommended was to his mind quite reasonable.

Mr. James Crooks said that during the twelve months to the end of May last 570 children under 12 years of age—new patients—were referred to his department at Great Ormond Street with X-ray films showing opacity of the antrum. They were all washed out under local anæsthesia, and of the 570, as many as 230 were clear at their first washing. The other 340 had mucopus in the antra, and went on to repeated washing. They continued this lavage ten or twelve times before they dreamed of doing anything else apart from local treatment. In going over the figures the other day his registrar told him that out of the 340 children only 9 were referred for operative treatment—that is to say, anything more radical than lavage. That did not mean that the 331 were all cured, but certainly the vast majority of them were cured on antral washing. It would be quite safe to

say that 250 of those 330 children with antral infection were cured by washing alone. That being so, he would be very loth indeed to adopt anything more radical, even making an opening large enough to take a de Pezza catheter, as had been suggested. It would be always advantageous not to take away the bone or mucosa, and he would think that washing was the right treatment for these children.

When he was forced to do more than lavage he had done the Caldwell-Luc operation, and he had been most depressed to find that in these young children—all under 12, many of them only 6 or 7 years of age—the changes in the mucosa were in no way inferior to the changes found in the adult with chronic suppuration. One was left with the impression on looking at the mucosa that nothing short of removal would have effected improvement. The children were a great deal better after the Caldwell-Luc operation, and that was an important point, because more than half these children had bronchiectasis or other chronic lung conditions. Of the 61 children who underwent the Caldwell-Luc operation, on 53 of whom the bilateral operation was performed, bronchiectasis was present in 34.

He mentioned that he had on occasion inserted a ureteric catheter through the ordinary cannula after puncture of the antrum, keeping it there for ten days, and running in penicillin to the antrum. He had not found it beneficial, nor had he found it helpful to give massive doses of systemic penicillin. The right thing to do for a child with subacute sinus infection was to send him to a seaside resort for a month with shrinking drops for the nose, and then, if the antrum still gave trouble, to wash it out. He would wash out the antrum twelve times before he did anything else—and then he thought he would wait six months and wash it out again. After that he might be persuaded into doing the Caldwell-Luc operation. Lavage alone would cure the vast majority of these children who had had sinusitis for a month or two.

Mr. Scott Stevenson deprecated the notion of washing out the nose with saline, which within his knowledge often caused otitis media. He had tried many years ago to cure cases of so-called nasal catarrh by washing out the nose and antra with antiseptics or saline, and putting in silver nitrate and similar preparations. But for years past he had done the Caldwell-Luc operation for chronic maxillary sinusitis, with no after-treatment at all, and this often, though not always, cleared up infection of the frontal and other sinuses by removing the chief focus of disease.

His chief criticism of the paper related to Mr. Archer's term the "subacute" case, but as he mentioned pus and polypi he himself would call such cases chronic. He had never yet found a case of maxillary sinusitis in a child in whom adenoids were not present, even when they were supposed to have been removed. He certainly would not like to wash out a child's antrum under local anæsthetics ten or twelve times, as Mr. Crooks did. What he had always carried out was thorough lavage of the antrum once at the time of operation with removal of adenoids, and he firmly believed that the removal of adenoids was what cleared up the sinusitis whether one did lavage or not.

Mr. G. E. Archer, in reply, said that Mr. Crooks had had a very wide experience and one must take notice of what he had said but it was particularly to avoid the repeated antral washings that Mr. Crooks advocated that he (Mr. Archer) had suggested putting in the self-retaining catheter. Some children would tolerate repeated antral puncture perfectly well but they had all seen the child who is extremely nervous and apprehensive and who resents repeated washings. He did not think the procedure he had recommended destroyed any more mucous membrane or any more bone than doing the antral puncture and one could wash out three or four times a day for three or more days and the case would clear up.

In replying to Mr. Scott Stevenson he said he had purposely called the cases subacute because the fact remained that some of these cases, although they had continued for a year or even more, had eventually been cured without a Caldwell-Luc operation being performed, and this was why he had felt justified in calling them subacute.

Film: "Bronchial Neoplasms", by PAUL H. HOLINGER, Chicago (shown by G. H. BATEMAN).

The film first shows endoscopic views of the normal larynx and tracheobronchial tree. It then shows various neoplastic disorders of the trachea and bronchi and correlates them with radiographs of the chest and associated disorders of the larynx. It finishes with an endoscopic view of a carcinoma of the mid-œsophagus and shows the bronchoscopic view of this same neoplasm invading the left main bronchus. The photography and colour are excellent and the film provides a perfect example of the bronchoscopist's view of typical bronchial neoplasms.

The Normal Temporal Horn and Its Deformities by Tumours in the Middle Cerebral Fossa. [*Abstract*][1]

By ERIK LINDGREN, M.D.

(*From the Roentgen Department, Serafimer Hospital, Stockholm*)

IN the medial portion of the temporal lobe lies the inferior, or temporal, horn. It roughly follows the curve of the hippocampus and ends about 2·5 cm. from the tip of the lobe. The anterior part of the horn is directed medially. The floor of the horn is mainly formed by the hippocampus and laterally by the collateral eminence. A small part of the roof is formed by the tail of the caudate nucleus. In its neighbourhood is the optic radiation.

Childe and Penfield divide the horn in two parts, one above the hippocampus, which they call the supracornual cleft, and one lateral, which they call the body, but which I prefer to call the lateral cleft. In the supracornual cleft lies the choroid plexus. The lateral and supracornual cleft join each other at the tip of the horn. Very occasionally, a more or less thin membrane passes between the supracornual and the lateral cleft to the lateral part of the hippocampus. In the three cases observed by the author, this septum appeared only in the anterior part of the horn.

For pneumographic examinations of the temporal horn there are two methods for filling the horn with gas. In a lateral X-ray picture, taken with the patient lying down and with the head turned to the side, the upper temporal horn is usually easily recognized, if sufficient gas is present. In 1934, Torkildsen and Pirie modified this technique. They first placed the patient in the position described and then they lowered the top of the head a little and turned the face upwards at an angle of 30 degrees. In our opinion, the essential demands on positioning in radiology are, first, that the position must be an easy one to assume, secondly that it is easy to reproduce and thirdly that it gives a true picture of the anatomy. The positions just mentioned are not satisfactory in these respects, as it is impossible to be quite sure that there is sufficient gas in the horn, even if there is a large amount of gas in the ventricles, and because the anatomical details will be only partly visible. We have therefore adopted another method for filling the horn (demonstrated by cinematography at the lecture) and we use a different radiographic technique. Pictures taken with the different methods are not directly comparable, as is seen in fig. 1 (overleaf). With the head in sideway position, the air is in the lateral uppermost part of the horn and the cerebrospinal fluid in the lowermost part, i.e. the gas occupies chiefly the lateral cleft. With the patient in supine position, the horn gets completely filled with gas, if sufficient is present. On the side view, taken with the patient in supine position, the supracornual cleft is seen as a darker strip on the film, as the rays have gone through a deeper layer of gas. Below the supracornual cleft is a thinner layer of gas, representing the lateral cleft. The point where the supracornual cleft starts to bend down over pes hippocampus to join the lateral cleft I call the "knee". I have given it a special name, because in certain pathological conditions this knee is more or less accentuated and it might be the only demonstrable radiological change. The inclination of the horn is dependent on the shape of the skull. With a short skull the inclination is sharper than in a long skull. When we regard the horn obliquely from above (on a picture taken with 25–35 degrees inclination) it has the shape of a spoon, the shaft of which is formed by the lateral cleft.

On an anteroposterior picture the lateral cleft is always the easiest to observe and very sharply defined. If the picture is taken with the chin higher up than usual, we get a more axial view of the horn. In this projection, the picture is more like an ordinary frontal section through the brain. This projection is the best one for a close study of the anatomical details.

[1] The complete report of this investigation will appear as a supplement to *Acta Radialogica*, 1948.

say that 250 of those 330 children with antral infection were cured by washing alone. That being so, he would be very loth indeed to adopt anything more radical, even making an opening large enough to take a de Pezza catheter, as had been suggested. It would be always advantageous not to take away the bone or mucosa, and he would think that washing was the right treatment for these children.

When he was forced to do more than lavage he had done the Caldwell-Luc operation, and he had been most depressed to find that in these young children—all under 12, many of them only 6 or 7 years of age—the changes in the mucosa were in no way inferior to the changes found in the adult with chronic suppuration. One was left with the impression on looking at the mucosa that nothing short of removal would have effected improvement. The children were a great deal better after the Caldwell-Luc operation, and that was an important point, because more than half these children had bronchiectasis or other chronic lung conditions. Of the 61 children who underwent the Caldwell-Luc operation, on 53 of whom the bilateral operation was performed, bronchiectasis was present in 34.

He mentioned that he had on occasion inserted a ureteric catheter through the ordinary cannula after puncture of the antrum, keeping it there for ten days, and running in penicillin to the antrum. He had not found it beneficial, nor had he found it helpful to give massive doses of systemic penicillin. The right thing to do for a child with subacute sinus infection was to send him to a seaside resort for a month with shrinking drops for the nose, and then, if the antrum still gave trouble, to wash it out. He would wash out the antrum twelve times before he did anything else—and then he thought he would wait six months and wash it out again. After that he might be persuaded into doing the Caldwell-Luc operation. Lavage alone would cure the vast majority of these children who had had sinusitis for a month or two.

Mr. Scott Stevenson deprecated the notion of washing out the nose with saline, which within his knowledge often caused otitis media. He had tried many years ago to cure cases of so-called nasal catarrh by washing out the nose and antra with antiseptics or saline, and putting in silver nitrate and similar preparations. But for years past he had done the Caldwell-Luc operation for chronic maxillary sinusitis, with no after-treatment at all, and this often, though not always, cleared up infection of the frontal and other sinuses by removing the chief focus of disease.

His chief criticism of the paper related to Mr. Archer's term the "subacute" case, but as he mentioned pus and polypi he himself would call such cases chronic. He had never yet found a case of maxillary sinusitis in a child in whom adenoids were not present, even when they were supposed to have been removed. He certainly would not like to wash out a child's antrum under local anæsthetics ten or twelve times, as Mr. Crooks did. What he had always carried out was thorough lavage of the antrum once at the time of operation with removal of adenoids, and he firmly believed that the removal of adenoids was what cleared up the sinusitis whether one did lavage or not.

Mr. G. E. Archer, in reply, said that Mr. Crooks had had a very wide experience and one must take notice of what he had said but it was particularly to avoid the repeated antral washings that Mr. Crooks advocated that he (Mr. Archer) had suggested putting in the self-retaining catheter. Some children would tolerate repeated antral puncture perfectly well but they had all seen the child who is extremely nervous and apprehensive and who resents repeated washings. He did not think the procedure he had recommended destroyed any more mucous membrane or any more bone than doing the antral puncture and one could wash out three or four times a day for three or more days and the case would clear up.

In replying to Mr. Scott Stevenson he said he had purposely called the cases subacute because the fact remained that some of these cases, although they had continued for a year or even more, had eventually been cured without a Caldwell-Luc operation being performed, and this was why he had felt justified in calling them subacute.

Film: "Bronchial Neoplasms", by PAUL H. HOLINGER, Chicago (shown by G. H. BATEMAN).

The film first shows endoscopic views of the normal larynx and tracheobronchial tree. It then shows various neoplastic disorders of the trachea and bronchi and correlates them with radiographs of the chest and associated disorders of the larynx. It finishes with an endoscopic view of a carcinoma of the mid-œsophagus and shows the bronchoscopic view of this same neoplasm invading the left main bronchus. The photography and colour are excellent and the film provides a perfect example of the bronchoscopist's view of typical bronchial neoplasms.

[The Otological Session of the Summer Meeting will appear in the January issue of the "Proceedings".]

the sphenoidal ridge and from the brain itself—the temporal lobe. The material forming the basis for this study consists of 104 cases. Of these 9 are basilar tumours, 6 meningiomas and 3 neurinomas. In the last 3 cases there was no dislocation of the septum pellucidum, or any general deformity of the ventricular system.

The temporal horn in all these cases was dislocated upwards. In the neurinomas there was a concavity directed downwards and medially (fig. 6) while in the meningiomas the horn was directed more straight downwards. If a glioma is situated in the temporal lobe, entirely below the horn, it is possible to differentiate from an extracerebral tumour only if the glioma has caused considerable irregularities of the floor of the horn.

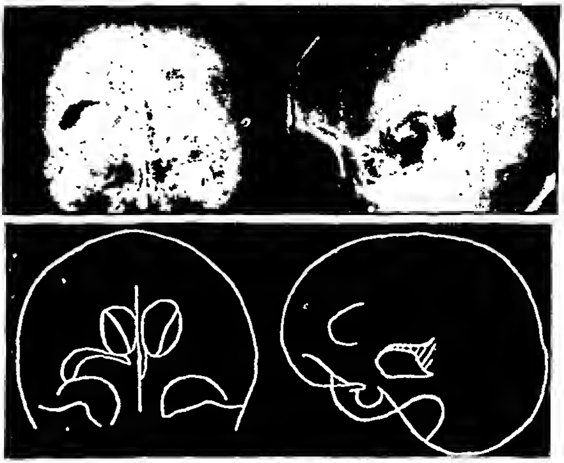

FIG. 6.—Neurinoma from the gasserian ganglion.

Tumours from the sphenoidal ridge are usually divided into three types: the clinoidal or deep type, tumours from the middle part and those from the lateral part and pterion. From the radiological standpoint, the pterion type is not uniform, as it is possible to distinguish between different types of deformities depending on how much of the tumour is situated in the middle cerebral fossa and how much above the sphenoidal ridge. The largest group consists of the type where most of the tumour lies in the middle cerebral fossa—in this material 22 out of 30 cases. It is characterized by a displacement medially of the anterior part of the temporal horn with compression of the lateral cleft (fig. 7). The other type (8 cases) has only a straightening out of the knee (fig. 8). The tumours which grow "en plaque" produce hyperostosis. The only deformity is a compression of the temporal horn from the front. The knee is more clearly distinguished than normally. Out of 4 cases, 1 had no general dislocation of the ventricular system and no visible change of the temporal horn on an antero-posterior picture.

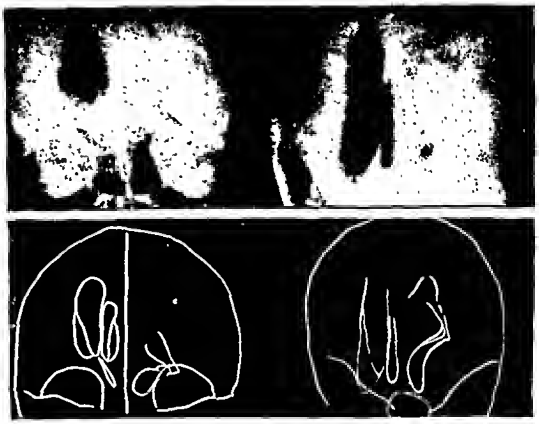

FIG. 7.—Meningioma from pterion (lower type).

Tumours from the middle part of the ridge compress the bowl of the spoon from the front, displace it backwards and give it a concave anterior border directed straight forward. The deformity is best seen on the half-axial view.

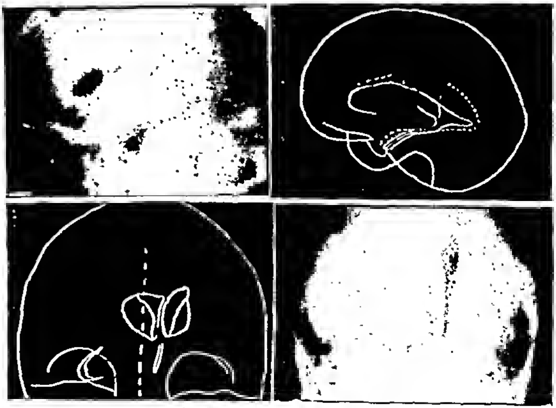

FIG. 8.—Meningioma from pterion (higher type).

The deep type are tumours from the medial part of the lesser sphenoidal wing and the anterior clinoid process. Out of 6 such cases, 1 has been localized entirely to the middle cerebral fossa. In this case the temporal horn has been pushed backwards and on the

The radiological diagnosis of a tumour in the middle cerebral fossa usually seems to be based on a general dislocation and deformity of the ventricular system and not on a thorough analysis of the shape of the temporal horn, with the result that in many cases we can only suspect the presence of a tumour. The exact pre-operative localization of a tumour which is so essential is not possible without a thorough examination of the temporal horn. Again, there may be large tumours in the middle cerebral fossa with no general dislocation of the ventricular system at all, only with a deformity of the temporal horn. Most tumours above the tentorium can produce a deformity of the temporal horn and a study of the shape of the horn makes a differentiation of the main deformities possible. The half-schematic drawings in figs. 2-5 illustrate this. Generally, the tumour is localized on the basis of the more obvious changes of the ventricular system. In some cases, the shape of the temporal horn gives valuable supplementary information, but for an exact localization of a tumour in the middle cerebral fossa, the shape of the temporal horn is of decisive importance.

Tumours in the middle cerebral fossa may be divided into tumours from the floor, from

The Importance of Statistics in Psychiatry

By L. S. Penrose, M.D.

Galton Professor of Eugenics, University College, London

Abstract.—The paper gives an outline, with examples, of various statistical methods which may be of special use in psychiatry.

(1) *Actuarial data.*—The simple accumulation of accurate figures on the ages of patients, their diagnoses and length of stay in hospital or under treatment for mental illness is of great value in understanding the scope of psychiatric problems. The age and sex incidences which correspond to different disease groups are very characteristic. Such material has value in the estimation of the results of therapeutic experiments but special methods have to be devised, as there is no exact prototype in standard vital statistics or in work on therapeutic trials.

(2) *Biametric techniques.*—Knowledge of ordinary statistical practice guards against elementary errors and aids in establishing significance or otherwise of metrical deviations from the normal found in mentally ill subjects. Also the range of variations may be much more marked in abnormal than in normal groups. Furthermore, abnormal reactions in themselves may be characterized by either too much or too little variety, i.e. by scatter or by stereotypy.

Discrimination between normal and abnormal reaction can be based on a single quantitative measurement, on difference in variance or on a compound measurement, i.e. pattern or profile. The discriminative approach has advantages over other methods because in this approach the initial factors are concrete and based on known classes such as males and females, children and adults, special clinical types, &c.

(3) *Genetical analysis.*—Actuarial data can be useful in genetic studies by leading to estimation of population frequency of genes and consanguinity rates. Moreover, combined clinical and genetical observations can reveal the existence of new clinical entities.

Résumé.—Cet article expose dans ses grandes lignes les diverses méthodes statistiques qui peuvent être utiles en psychiatrie, avec quelques exemples.

(1) *Données actuarielles.*—La simple accumulation de données numériques exactes sur l'âge des malades, les diagnostics et la durée de leur séjour à l'hôpital ou de leur traitement pour une maladie mentale a une grande valeur en faisant comprendre la portée des problèmes psychiatriques. Les incidences selon l'âge et le sexe des différents groupes de maladies sont très caractéristiques. Un tel matériel est utile pour l'évaluation des résultats des essais thérapeutiques, mais il faut trouver de nouvelles méthodes, car il n'existe pas de prototype exact dans les statistiques vitales générales, ni de travail sur les essais thérapeutiques.

(2) *Techniques biamétriques.*—Une connaissance de la pratique statistique ordinaire permet d'éviter les erreurs élémentaires, et aide à reconnaître si une déviation de la normale chez un malade mental est significative ou non. Il est aussi possible que l'étendue des variations soit beaucoup plus grande dans les groupes anormaux que dans les groupes normaux. De plus, les réactions anormales elles-mêmes peuvent être caractérisées par trop ou trop peu de variété, c'est à dire par la dispersion ou par la stéréotypie.

La distinction entre les réactions normales et anormales peut être basée sur une seule mesure quantitative, sur une différence de variation ou sur une mesure composée, c'est à dire un groupement ou un profil.

La méthode différentielle a l'avantage sur les autres méthodes que les facteurs initiaux sont concrets et basés sur une classe connue, telle que hommes ou femmes, enfants ou adultes, types cliniques spéciaux, etc.

(3) *Analyse génétique.*—Les données actuarielles peuvent être utiles dans les études génétiques, en menant à l'estimation de la fréquence des gènes et de la consanguinité dans une population. En outre, la combinaison des observations cliniques et génétiques peut démontrer l'existence de nouvelles entités cliniques.

АБСТРАКТ.—Лекция дает отчет и примеры различных статистических методов специально применимых в психиатрии

1. Статистические данные.—Простое накопление точных чисел возрастов больных, их диагнозов и длительности пребывания в госпитале или же лечения душевной болезни, имеет большое значение в понимании целей психиатрических проблем. Отношение возраста и пола к разным группам болезней очень характерно. Такой материал очень важен для оценки результатов терапевтических опытов, но нужно найти специальные методы, так как нет точного прототипа в стандарте жизненных статистик или в работе над терапевтическими опытами.

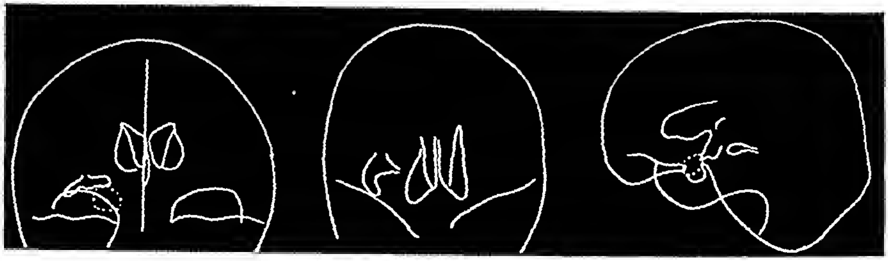

FIG. 9.—Meningioma of the clinoidal type, only in the middle cerebral fossa (dotted: bone sclerosis).

half-axial view there is a filling defect in the medial part of the spoon (fig. 9). In the other cases, the tumours extended into the anterior fossa, thereby causing the same deformity of the anterior horn as by subfrontal tumours and, besides, a straightening out of the knee of the temporal horn.

The tumours in the temporal lobe, gliomas, cause the most varying deformities of the horn, depending on their position in the lobe. In this material, we have 3 cases with no dislocation of the septum. No changes would have been established to allow a tumour diagnosis had the temporal horn not been examined. If a glioma is situated in the same place as is described for meningiomas, the pictures may be alike. In some cases it is therefore impossible to distinguish a meningioma from a glioma radiologically and we must content ourselves with localizing the tumour only. Generally speaking, all deformities which do not agree with those described, may be assumed to be caused by gliomas. In this material there are 42 gliomas. We could make the diagnosis of glioma in 23 cases. In 2 cases it was impossible to fill the horn and in 17 cases we could not state what kind of tumour had caused the changes.

Four cases of cholesteatomas have quite a characteristic appearance. The gas is lying distributed in larger or smaller irregular spots (fig. 10).

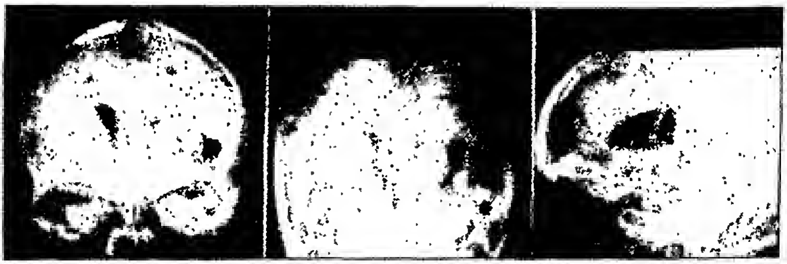

FIG. 10.—Cholesteatoma in the temporal horn.

During the last 14 years, we have had 4 cases where we could find no sign of a tumour in the temporal lobe by pneumographic examination, but where a tumour was revealed by arteriography or by calcification visible on the plain films. On the other hand, we have 2 cases where pneumography gave us the diagnosis but where the angiography failed. It is not yet possible to decide which method is the more reliable, but it seems to me that the answer is that one method may be used as a complement to the other.

Even the most thorough analysis of the anatomical details may sometimes fail. The more spreading a lesion is, the easier it is to observe; the more infiltrative, the harder to recognize. When tumours have reached such a size that they produce clinical symptoms, they are as a rule big enough to be discovered at a closer radiological examination. To get the best results, however, a pneumographic examination must be performed by an experienced radiologist.

We radiologists have, as it were, the opportunity of cutting sections *in vivo*. We must, however, extract the right sections. Just as pathologists will fail to arrive at the truth at autopsy, if they cut too few sections—or the incorrect sections—so will the radiologist fail by taking short cuts in his examination or, worse still, by relying only on the standard projections of a technician. When making use of X-rays, the radiologist has to choose appropriate projections for presenting the various anatomical details in each case, and this must be dependent upon the kind of deformities and the shape of the skull. If a lesion has not been brought out at the examination, an interpretation of the picture later will not succeed in exposing it, however thorough the study may be.

available, and came to the conclusion that the amount of attention paid to mental health was inversely proportional to the amount of serious crime (Penrose, 1939). Very roughly, two beds in a mental hospital made one prison cell unnecessary. As prisons cost twice as much as mental hospitals per inmate, there is approximate economical equivalence but social advantage is presumably with the hospital beds.

In the case of mental deficiency much could be learned if we knew the age grouping and intelligence distribution of all institutional cases. Table I shows a rough estimate of the distribution based on surveys of general and institutional populations. One can say that probably one-third of all idiots in the country are under institutional care, one-sixth of all imbeciles but only one-twentieth of all feeble-minded; and of the borderline cases only an extremely small fraction. It is evident that some very strong selective mechanisms determine just which cases shall be cared for and which left in the community. Undoubtedly, those whose families are in poor circumstances contribute an undue proportion of cases and, furthermore, patients with behaviour disorder added to defect are concentrated in the institutional group.

TABLE I.—DEFECTIVES OF ALL TYPES: ESTIMATED NUMBERS IN ENGLAND AND WALES

Grade	Total in general population	Institutional cases	Proportion in institutions
Borderline ..	?	5,000	1/....
Feeble-minded	300,000	15,000	1/20
Imbecile ..	80,000	13,000	1/6
Idiot	20,000	7,000	1/3
Total	400,000	40,000	1/10

Turning to the mentally ill, an elementary example of the value of actuarial data is the difference found in proportions of diagnoses according to whether we consider first admissions or resident populations. The trends are shown in Table II (Duncan *et al.*, 1936). The longer a patient stays in hospital the more likely is he to be a diagnosed schizophrenic, even if he did not start with this diagnosis. In general, diagnosis in psychiatry is so elusive that the age and sex of patients on first admission, which is a very good guide, cannot be neglected. The cases fall naturally into four classes, which have their maximum frequencies in the four double decades 0 to 20, 20 to 40, 40 to 60, 60 to 80. The classes are, mental defect, schizophrenia, affective psychosis and organic psychosis. Fig. 1 (p. 866) shows the relationship of diagnosis and age in 9,821 patients first admitted to the Ontario mental hospitals during the years 1939 to 1942. For simplicity here, epilepsy has been grouped with mental defect and some miscellaneous diagnoses have been included with the organic. Specifying sex gives further information. There are relatively more male cases of early onset and of late onset than female cases, who, in their turn, are more frequent in the central period, 30 years to 50 years. Classification according to both diagnosis and sex helps to explain this phenomenon. Schizophrenia (like mental defect) is more severe in males than in females as shown by its earlier onset in the male sex. Malzberg's (1935) survey of admissions to New York State Mental Hospitals is typical of all large bodies of data in this respect. He found that the mean first admission age for male cases of dementia præcox was 31·8 years, significantly lower than that for female cases, 36·5 years. With affective psychoses the relationship is reversed; the female cases are more abundant, at least those of early onset. In the same data of Malzberg, male first admissions with manic-depressive psychosis were significantly older than corresponding female cases. Table III shows the details.

TABLE II.—RESIDENT POPULATION ANALYSED ACCORDING TO LENGTH OF TIME SINCE ADMISSION (SEVERALLS MENTAL HOSPITAL)

Type of disorder	First admissions (1934)	0–5 yrs.	5–10 yrs.	10–15 yrs.	15–20 yrs.	20 years+
	%	%	%	%	%	%
Schizophrenia ..	33·3	45·3	53·5	55·0	57·4	69·8
Organic	40·8	32·3	23·4	12·9	8·8	8·0
Manic-depressive	17·5	14·8	13·6	16·2	13·9	7·4
Epileptic	4·3	4·6	6·9	6·8	11·1	2·2
No psychosis (mostly defective)	4·1	3·0	2·6	9·1	8·8	12·6
Total number	463	899	346	309	216	364

2. Биометрическая техника.—*Знание обыкновенной статистики предохраняет от элементарных ошибок и помогает установить важность или незначительность метрических отклонений от нормы среди психиатрических больных. Также и число вариаций может быть более точно определено в ненормальных, чем в нормальных группах. Кроме того, ненормальные реакции сами по себе отличаются большей или меньшей разновидностью, т. е. они или слишком разбросаны или же слишком стереотипны.*

Распознование нормальных или ненормальных реакций может быть основано на единичном количественном измерении, на разнице изменения, или же на сложном измерении, т. е. образец или профиль. Распозновательный подход имеет преимущество над другими методами, так как в таком подходе начальные факторы более конкретны и основаны на известных классах, как то—мужчины и женщины, дети и взрослые, специальные клинические типы и т. д.

3. Генетические анализ.—*Статистические данные могут быть полезны и в изучении генетики, а именно в исчислении многократности народонаселения гена и степени единокровности. Сверх того, соединенные клинические и генетические наблюдения могут обнаружить присутствие новых клинических сущностей.*

RESUMEN.—El artículo presenta un sumario, con ejemplos, de los varios métodos estadísticos que pueden tener una aplicacion específica en la psiquiatría.

(1) *Datos actuarios.*—Para concebír el alcance de las problemas psiquiatricas es de gran servicio la simple acumulación de cálculos seguros sobre las edades de los enfermos, sus diagnosis, duración de detención en hospital o bajo tratamiento para enfermedad psiquiatrica. Son muy caracteristicos la edad y el sexo de incidencia correspondiendo a varios grupos de enfermedades. Tales datos tienen valor en el aprecio de los resultados de experimentos terapéuticos pero métodos especiales se tienen que proyectar, pues no hai un prototipo exacto en la estadística demográfica normal o en los estudios sobre pruebas terapéuticas.

(2) *Técnicas biométricas.*—El entendimiento de los métodos estadísticos corrientes previene los errores elementales y asiste en establecer la significación o no de desviaciónes métricas de la normal que se encuentran en los casos psiquiatricos. Tambien puede ser mucho mas marcado el grado de variaciónes en los grupos anormales que en los normales. Además, las reacciónes anormales pueden ser si mismas caracterizadas por demasiados o de menos variedades, i.e. por dispersar o por estereotipar.

El discernimiento entre la reacción normal y anormal puede ser basado sobre una sola medida cuantitativa, sobre diferencia en variación o sobre una medida compound, i.e. un ejemplar o un perfil. El acercamiento discriminador lleva la ventaja sobre otros metodos que en este los factores iniciales son concretos y basados sobre categorias conocidas como varónes y hembras, niños y adultos, tipos clínicos especiales, etc.

(3) *Análisis genésico.*—Los datos actuarios pueden ser útiles en los estudios genesicos conduciendo a el cálculo de la frequencia de los genes y la proporción de consanguinidad en la población. Además, observaciónes clinicas y genésicas pueden juntas descubrir la existencia de neuvas entidas clinicas.

(1) *Actuarial data.*—It is a standard practice in medicine to inquire into the age and sex of every patient, to ascertain the time of onset of the disease and to record previous attacks. In psychiatry, the onset of symptoms is often very difficult to determine but there are two mitigating circumstances. Since mental illness often lasts many years—or a large part of a lifetime—the exact date of onset is of less importance than the epoch of life in which it commences. Furthermore, in serious illness, which necessitates hospital treatment, exact dates of admission and discharge are capable of being recorded automatically. It is surprising how little use has been made in the scientific study of psychiatry of the simple actuarial material relating to mental illness. Reports of the Board of Control forty or fifty years ago were full of interesting information about the ages of patients admitted to mental institutions but presumably this was thought to be of insufficient value more recently and has been dropped. Especially in his early editions, Stoddart (1926) discussed such statistics at length; few more modern texts, however, give any space to them. The elementary accountancy of numbers of patients under hospital care (or under treatment at clinics) is of great sociological as well as of clinical interest. I propose to cite examples of this and other statistical points in connexion with psychiatric problems and I must apologize if most of them are drawn from my own observations: such examples are naturally most easily available to me.

It is a matter of common knowledge that only a small proportion of the mentally ill or defective persons in the general community are actually certified. The proportion so dealt with depends upon the degree of development of the mental health services. Some years ago I compared statistics from all countries in the world for which figures were available, and came to the conclusion that the amount of attention paid to mental health was inversely proportional to the amount of serious crime (Penrose, 1939). Very roughly, two beds in a mental hospital made one prison cell unnecessary. As prisons cost twice as much as mental hospitals per inmate, there is approximate economical equivalence but social advantage is presumably with the hospital beds.

In the case of mental deficiency much could be learned if we knew the age grouping and intelligence distribution of all institutional cases. Table I shows a rough estimate of the distribution based on surveys of general and institutional populations. One can say that probably one-third of all idiots in the country are under institutional care, one-sixth of all imbeciles but only one-twentieth of all feeble-minded; and of the borderline cases only an extremely small fraction. It is evident that some very strong selective mechanisms determine just which cases shall be cared for and which left in the community. Undoubtedly, those whose families are in poor circumstances contribute an undue proportion of cases and, furthermore, patients with behaviour disorder added to defect are concentrated in the institutional group.

TABLE I.—DEFECTIVES OF ALL TYPES: ESTIMATED NUMBERS IN ENGLAND AND WALES

Grade	Total in general population	Institutional cases	Proportion in institutions

Total number	463	899	346	309	216	364

TABLE III.—FIRST ADMISSION AGES (MALZBERG, 1935)

Diagnosis	Sex	Number of cases	Mean of first admission age in years	Standard deviation of first admission age in years
Dementia Præcox	Male	4,163	31·8	10·5
	Female	3,376	36·5	11·6
Manic-depressive psychosis	Male	1,530	38·3	13·7
	Female	2,316	36·2	12·4

The use of statistics in estimating effects of toxins, drugs or therapeutic procedures has produced a considerable level of accuracy in animal experiments but in medical practice the problem of finding adequate control populations often prevents reliable conclusions from being reached. About 1930, Park suggested a method of assessing the value of pneumonia antisera by making out standard tables of recovery rates in pneumonia, taking into consideration a variety of important points such as age and sex of patient, length of illness, temperature fluctuations, cyanosis, blood picture and so on. Very large numbers of cases are needed in such a control group to match every significant peculiarity of a specially treated case and, in the treatment of mental illness, the problems are even more difficult.

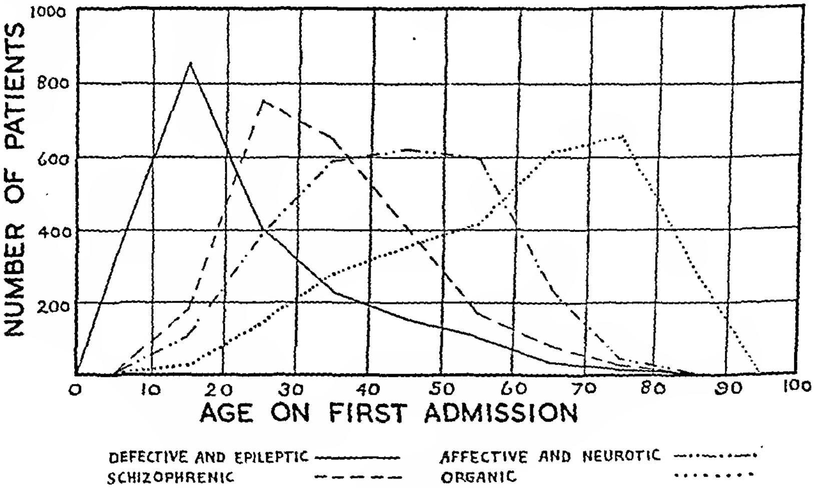

FIG. 1.

In one respect, however, we are lucky, because, as I have tried to demonstrate, age of onset, which is closely correlated with age on first admission, is a good index of diagnosis. We can, if we have good statistical records, find out the chances that a patient, first admitted at any given age, will be found on the books of a mental hospital at any subsequent point in time. The calculation of this chance has no prototype in vital statistics because the patients are frequently discharged and subsequently readmitted—often to a different hospital. Only a central register can take care of this circumstance. Tables which were prepared in the Ontario Department of Health to establish the chances of remaining in hospital for all types of patients (Penrose and Marr, 1943) were, to my mind, extremely interesting. A summary of the most important results is given in Table IV. The method involved one

TABLE IV.—PERCENTAGES OF PATIENTS ON HOSPITAL BOOKS* AFTER A GIVEN LAPSE OF TIME

	Lapse of time since first admission					
	1 year		5 years		25 years	
Age on first admission	Male %	Female %	Male %	Female %	Male %	Female %
0–19	65	76	38	53	28	30
20–39	58	50	32	29	25	27
40–59	50	48	17	24	13	16
60–79	43	66	9	20	1	2

All ages—both sexes ..	55		26		19	

*Some patients represented here will have been continuously in hospital all the time since first admission and others readmitted to hospital.

serious omission, in that there was no exact way of allowing for the difference in mortality rate of psychotic and non-psychotic subjects outside the hospital. As they stand, these norms of expected chances of remaining in hospital are, I believe, accurate, but one cannot tell from them, when a patient has not returned after a period of time, whether this is because he has been cured or because he has died. Thus, while comparisons could be made between expected and observed cases in hospital after treatments of various kinds, if a treatment should tend to shorten patients' lives, this would appear on the favourable side of the ledger. Fortunately, examination of known individual cases did not suggest that this was a source of error of any significant magnitude in comparing treated cases with the control population. The comparison of observed and expected numbers of specially treated cases could be made, after separate tables had been compiled for different intervals between first admission and beginning of treatment for both sexes. The types of readings finally obtained are shown in Table V. First admission age, sex, interval between first admission and special treatment and interval since such treatment was observed in each member of the special treatment group (*a*) and was matched in the control group (*b*). The figures indicate clearly that quite good results were obtained after three to four years by shock therapy in cases of psychosis with late onset but no appreciable effect was obtained by all the vast amount of work with coma or convulsion therapy done on the cases of early onset, the majority of whom were diagnosed schizophrenia. Some careful observers have considered these results too pessimistic (Freudenberg, 1947; Mayer-Gross and Slater, 1947). The main point of difference between the method described here and those in general use is the discarding of diagnosis for purposes of matching in favour of unbiased facts about dates and ages of patients.

TABLE V.—CASES TREATED DURING 1939 TO 1941 IN ONTARIO MENTAL HOSPITALS BY COMA OR CONVULSION THERAPY: STATUS IN NOVEMBER 1943

First admission age-group	Number of cases	(*a*) Observed number still on books	(*b*) Expected number still on books	Difference (*a*)−(*b*)
0–19	155	71	71·46	− 0·46
20–29	621	319	330·77	−11·77
30–39	458	197	231·44	−34·44

50 and over	140	31	61·29	−30·29
All cases	1600	703	799·40	−96·40

First admission age-group	% of cases	(*a*) Observed % on books	(*b*) Expected % on books	Difference (*a*)−(*b*)
0–19	100·0	45·8	46·1	− 0·3
20–29	100·0	51·4	53·3	− 1·9
30–39	100·0	43·0	50·5	− 7·5
40–49	100·0	37·6	46·2	− 8·6
50 and over	100·0	22·1	43·8	−21·7
All cases	100·0	43·9	50·0	− 6·1

(2) *Biometric techniques.*—The scientific study of mental disorder is partly a matter of recognizing qualities of ideas and of behaviour in patients, which we call pathological. As in other branches of medicine, we also recognize physical disturbances and, in so far as psychiatry is concerned, especially those bodily disturbances which are accompanied by mental changes, e.g. G.P.I., mongolism, hypothyroidism, &c. When the difference between the normal and the pathological is gross, no difficulty is experienced in making decisions but, unfortunately, many signs are only slight and merely give indications of trends. Moreover, one sign is not usually enough to determine the presence of a disease process and we need to add up the evidence from a variety of observations and weigh it before coming to a decision. It is sometimes convenient not to rely upon "all or none" qualitative judgments of presence or absence of signs but to use characters which are capable of being arranged in an ordered series and, in the extreme case, to take actual measurements. Thus, we may estimate the basal metabolism, the blood cholesterol or bromide content or the length of a set of numbers which can be repeated from memory. For example, mental defect is defined as social failure but a main symptom is failure on intelligence tests. The normals and abnormals overlap but, as Pearson first showed, physical measurements give much poorer discrimination.

To distinguish the limits of normal on the basis of distributions is typical of modern statistical teaching and it is of course done by ascertaining the probability against such

TABLE III.—FIRST ADMISSION AGES (MALZBERG, 1935)

Diagnosis	Sex	Number of cases	Mean of first admission age in years	Standard deviation of first admission age in years
Dementia Præcox	Male	4,163	31·8	10·5
	Female	3,376	36·5	11·6
Manic-depressive psychosis	Male	1,530	38·3	13·7
	Female	2,316	36·2	12·4

The use of statistics in estimating effects of toxins, drugs or therapeutic procedures has produced a considerable level of accuracy in animal experiments but in medical practice the problem of finding adequate control populations often prevents reliable conclusions from being reached. About 1930, Park suggested a method of assessing the value of pneumonia antisera by making out standard tables of recovery rates in pneumonia, taking into consideration a variety of important points such as age and sex of patient, length of illness, temperature fluctuations, cyanosis, blood picture and so on. Very large numbers of cases are needed in such a control group to match every significant peculiarity of a specially treated case and, in the treatment of mental illness, the problems are even more difficult.

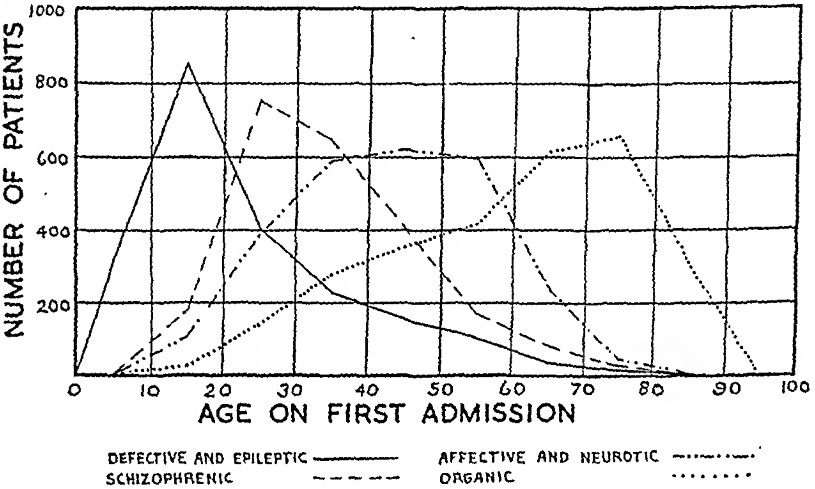

FIG. 1.

In one respect, however, we are lucky, because, as I have tried to demonstrate, age of onset, which is closely correlated with age on first admission, is a good index of diagnosis. We can, if we have good statistical records, find out the chances that a patient, first admitted at any given age, will be found on the books of a mental hospital at any subsequent point in time. The calculation of this chance has no prototype in vital statistics because the patients are frequently discharged and subsequently readmitted—often to a different hospital. Only a central register can take care of this circumstance. Tables which were prepared in the Ontario Department of Health to establish the chances of remaining in hospital for all types of patients (Penrose and Marr, 1943) were, to my mind, extremely interesting. A summary of the most important results is given in Table IV. The method involved one

*Some patients represented here will have been continuously in hospital all the time since first admission and others readmitted to hospital.

serious omission, in that there was no exact way of allowing for the difference in mortality rate of psychotic and non-psychotic subjects outside the hospital. As they stand, these norms of expected chances of remaining in hospital are, I believe, accurate, but one cannot tell from them, when a patient has not returned after a period of time, whether this is because he has been cured or because he has died. Thus, while comparisons could be made between expected and observed cases in hospital after treatments of various kinds, if a treatment should tend to shorten patients' lives, this would appear on the favourable side of the ledger. Fortunately, examination of known individual cases did not suggest that this was a source of error of any significant magnitude in comparing treated cases with the control population. The comparison of observed and expected numbers of specially treated cases could be made, after separate tables had been compiled for different intervals between first admission and beginning of treatment for both sexes. (2) *Biometric techniques.*—The scientific study of mental disorder is partly a matter of recognizing qualities of ideas and of behaviour in patients, which we call pathological. As in other branches of medicine, we also recognize physical disturbances and, in so far as psychiatry is concerned, especially those bodily disturbances which are accompanied by mental changes, e.g. G.P.I., mongolism, hypothyroidism, &c. When the difference between the normal and the pathological is gross, no difficulty is experienced in making decisions but, unfortunately, many signs are only slight and merely give indications of trends. Moreover, one sign is not usually enough to determine the presence of a disease process and we need to add up the evidence from a variety of observations and weigh it before coming to a decision. It is sometimes convenient not to rely upon "all or none" qualitative judgments of presence or absence of signs but to use characters which are capable of being arranged in an ordered series and, in the extreme case, to take actual measurements. Thus, we may estimate the basal metabolism, the blood cholesterol or bromide content or the length of a set of numbers which can be repeated from memory. For example, mental defect is defined as social failure but a main symptom is failure on intelligence tests. The normals and abnormals overlap but, as Pearson first showed, physical measurements give much poorer discrimination.

To distinguish the limits of normal on the basis of distributions is typical of modern statistical teaching and it is of course done by ascertaining the probability against such and such a deviation being due to a chance fluctuation. I need not exemplify this point, since the theory of statistical estimation and calculation of sampling error is fully dealt with in standard works. It is perhaps worth noting how necessary it has become for even psychiatrists to have a passing acquaintance with these fundamental principles. Elementary calculations enable the probable significance of the difference in the mean admission ages of males and females in Table III to be established.

I wish, however, to draw attention to some peculiarities common in psychiatric data, which require special care in their statistical treatment and to which few academic statisticians have paid much attention. The problem arises in connexion with certain characteristics of the psychotic state. It was observed by Jung and others that, whereas normally, stimulus words led to reaction words which had a limited degree of variation, abnormal subjects gave bizarre responses, repeated the stimulus word or failed to respond altogether. Kent and Rosanoff (1910) attempted to classify word responses by their improbability and to score unusual words as abnormal. But it is also true that too obvious a reply may be abnormal, e.g. the repetition of the stimulus word. The stereotyped response, due to a tendency to perseveration or whatever it may be called, is just as important as the tendency to extreme dispersion. That is to say, in statistical terms, in mental disorder the variance of the reactions is usually increased but also it may be diminished. Increased variance is well known in the tendency for neurotic children to show "scattering" in intelligence test scores (e.g. the Binet). In reaction time measurements, while it has been shown that many mental illnesses lengthen the time between stimulus and response, extreme anxiety to do the test properly can produce abnormally rapid reactions, which can even precede the expected stimulus. The same statistical picture arises in an even more general form, when we consider the Freudian hypothesis, that repression may give rise either to overreaction or to failure of reaction. These characteristics of the disordered mental state lead to problems of statistical estimation of a very interesting type and, if they are not carefully watched, may cause investigators to neglect important information. For example, on the results of personality tests of the questionnaire variety and even on those with more elaborate techniques like the Rorschach, many abnormal subjects and often just those whom we desire especially to detect, give normal scores. Perhaps some of these scores are just a little *too* normal and this underreaction tendency can rarely be detected by the usual methods of scoring.

To illustrate the point concretely I take an example of a simple test given to a few normal and psychotic subjects. Each subject was required to tap as quickly as possible (for twenty-five seconds) on a metal plate. The taps were electrically recorded on a revolving drum and each hand was given a trial. The scores were plotted as shown in fig. 2 and are summarized in Table VI. Unquestionably the patients as a group were slower than the normals but some were quite within the normal limits. However, the range of speeds among the patients was much wider than among the normals. Each individual record was also analysed for

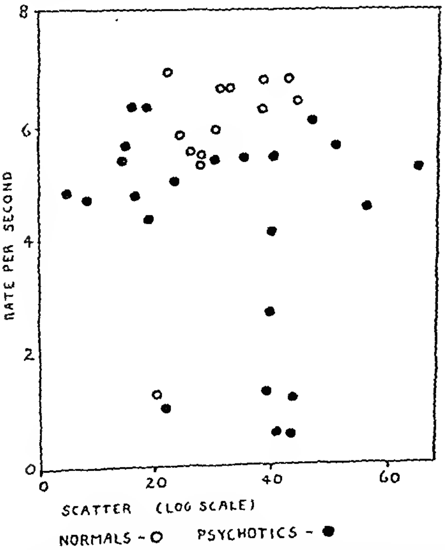

FIG. 2.—Tapping speed. *Unpractised adult subjects.*

TABLE VI.—TAPPING TEST:

NUMBER OF TAPS PER SECOND FOR 25 SECONDS

Group of subjects	Speed, i.e. number of taps per second		Measure of scatter in response	
	Mean	Standard deviation	Mean	Standard deviation
12 normals	6·18	0·57	32·08	6·88
24 psychotics	4·07	1·95	31·04	15·58

(The variability of both the speeds and the scatter is greater in the psychotic group. The mean speeds for normals and psychotics differ significantly.)

irregularity or scatter. Normally, there is a certain amount of irregularity due to fatigue and other causes, which can be estimated by finding the degree of variation from second to second in the ordinary way by a mean square method. When the same analysis was made for abnormals it was found that, though the average amount of scatter was the same as before, the range of scatter was much wider. To obtain the greatest possible diagnostic advantage out of such a test we need a function which will measure the distance in all directions from the centre of the normal group. Thus, records with slow rates and records with too little or too much variation are all suspected of being abnormal. If we try to distinguish between normal and abnormal subjects in such data as these, by ordinary methods, no use can be made of the fact that two groups differ in range. It is, however, easy to devise methods which will do so efficiently (Penrose, 1947).

A great deal of work has been done recently on the analysis of measurements of all kinds in psychiatric work. On the physical side, the stimulus of Kretschmer is still felt. It is now realized, however, that neither the mentally ill nor the normal can be clearly divided into two or more types. The distributions of all measurements or of their combinations tend to be continuous. The present fashion is to search for factors rather than types but analysis by the Spearman-Thurstone method does not necessarily lead to the discovery of factors which are of clinical or genetical interest. As Thomson has pointed out, the factors obtained are determined by the tests and any three tests will produce a general factor of some sort. All the argument about the existence or otherwise of "g" would be avoided if we started with a definition of intelligence as that which normals have and defectives lack. Then each test of intelligence would stand or fall by its ability to discriminate defectives from normals. A good test then can be used with known precision as part of our clinical armoury to diagnose and investigate cases as they arise in practice. From the point of view of research, it is always advisable to proceed from the known to the unknown and, thus, to start with known differences, e.g. between normals and defectives, between the sexes, between normals and neurotics or between different types of diseases. We can then apply the discriminating qualities extracted from these known types to unknown conditions. It is perhaps a good thing that we do not have to rely upon the results of factor analysis for the diagnosis of syphilis.

Terman and Miles (1936) have set up an ingenious test which discriminates quite well between male and female normal reaction types. There are several parts to the test; one part is a "controlled association" test which uses ink blots. Males score significantly more than females if the answers given by normal males are considered to be the correct ones. By applying the same standardized test to any subject we can measure the degree of maleness or femaleness in the reaction. Such tests may have considerable value in psychiatry where homosexual overt or latent tendencies are extremely important in symptomatology. Almost any mental or physical measurement can be used to some degree as a discriminator between different types. For example, the Canadian Army M-test is a battery of 8 sub-tests; picture absurdities, paper form board, mechanical information, arithmetic and verbal tests are included. Normal males did better in some parts of this test and normal females in others. A combination of the weighted scores on four of the sub-tests gave quite a good separation of males and females (Beall, 1945), either by using Fisher's complete solution method or by a simpler method, which reduces a system of any number of measurements to two factors which can be called *size* and *profile*.

Similarly, the M-test, like any mixed battery, could be scored for psychosis *versus* normals by suitable weighting of sub-test scores. The profile of success and failure of mentally ill subjects showed all the well-known features. Tests involving uncritical reproduction of past experience, vocabulary and arithmetic, were fairly well done but absurdities were found very difficult for such subjects to detect (Penrose, 1945). Direct weighting of sub-test scores on the basis of this profile led to a fair discrimination. A *profile* is here defined, for statistical purposes, as any set of weights (applied to test scores expressed in terms of their sigmas) which add up to zero. More critical discrimination can be obtained if the fact is used that the general scoring level in psychotic subjects is usually diminished below the normal. But there are some advantages in considering profile and intelligence level (or size) separately. These are two compound characters which can be used for discriminative purposes separately or in combination. Another type of test, a verbal controlled association test, was tried out in a similar way by Neal (1942). There were 30 items and a complete Fisher solution, such as was used successfully by P. Slater (Bennett and Slater, 1945) on a battery of questionnaires, would have been impracticable. However, scoring level (the size measurement) and profile weighting both gave good differentiation in normal and abnormal subjects and Smith (1947) showed how differences in variances could also be used in combining the two factors.

Discriminative measurements, of course, need not be compound tests like those derived from profiles but can be single measurements like stature, weight, and so on, or ratios and such a deviation being due to a chance fluctuation. I need not exemplify this point, since the theory of statistical estimation and calculation of sampling error is fully dealt with in standard works. It is perhaps worth noting how necessary it has become for even psychiatrists to have a passing acquaintance with these fundamental principles. Elementary calculations enable the probable significance of the difference in the mean admission ages of males and females in Table III to be established.

I wish, however, to draw attention to some peculiarities common in psychiatric data, which require special care in their statistical treatment and to which few academic statisticians have paid much attention. The problem arises in connexion with certain characteristics of the psychotic state. It was observed by Jung and others that, whereas normally, stimulus words led to reaction words which had a limited degree of variation, abnormal subjects gave bizarre responses, repeated the stimulus word or failed to respond altogether. Kent and Rosanoff (1910) attempted to classify word responses by their improbability and to score unusual words as abnormal. But it is also true that too obvious a reply may be abnormal, e.g. the repetition of the stimulus word. The stereotyped response, due to a tendency to perseveration or whatever it may be called, is just as important as the tendency to extreme dispersion. That is to say, in statistical terms, in mental disorder the variance of the reactions is usually increased but also it may be diminished. Increased variance is well known in the tendency for neurotic children to show "scattering" in intelligence test scores (e.g. the Binet). In reaction time measurements, while it has been shown that many mental illnesses lengthen the time between stimulus and response, extreme anxiety to do the test properly can produce abnormally rapid reactions, which can even precede the expected stimulus. The same statistical picture arises in an even more general form, when we consider the Freudian hypothesis, that repression may give rise either to overreaction or to failure of reaction. These characteristics of the disordered mental state lead to problems of statistical estimation of a very interesting type and, if they are not carefully watched, may cause investigators to neglect important information. [*March* 12, 1947, *concluded*]

Specimen of Colon Removed on Account of Severe Pyoderma from a Long-Standing Case of Chronic Ulcerative Colitis.—Rupert S. Corbett, M.Ch.

The specimen was removed from a female aged 46, suffering for twelve years from chronic ulcerative colitis.

On account of recurrent attacks of colicky pain, with vomiting, loss of weight associated with fever and a reduction in the hæmoglobin to 42%, a terminal ileostomy was performed. This led to a very great improvement in her general health; she could eat anything and the rectal discharge diminished considerably. Weight increased and the Hb went up to 66%.

It was noted that the rectal discharge persisted from 2 to 4 oz. daily and was offensive mucopus. In addition she developed large superficial areas of ulceration on the thigh and calf of the right lower extremity. The skin condition was diagnosed as pyoderma.

It was decided to perform a subtotal colectomy. This has resulted in a very great improvement to her general health and no recurrence of the skin lesion.

I wish to emphasize the importance of this skin complication as an indication for colectomy. Other authorities have referred to the common association of erythema nodosum which often breaks down to the condition of pyoderma gangrenosum.

The X-ray film shows the condition of the colon prior to excision and the photograph shows the condition of the specimen after removal.

Pathological report (Dr. C. E. Dukes).—Colon removed by right subtotal colectomy 21.11.46.

The specimen consisted of the cæcum, ascending colon, transverse and descending colon and also about 3 in. (7·6 cm.) of the ileum. The whole colon was much thickened and contracted down and embedded in tough fibrous fatty tissue. Dissection showed the

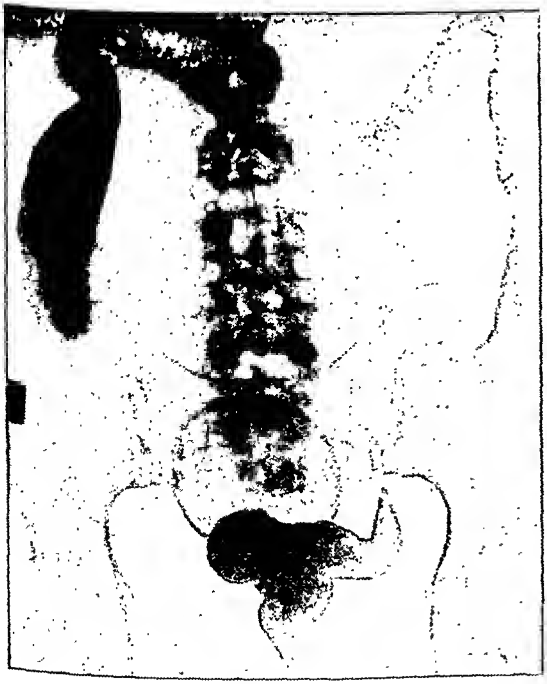

Fig. 1.

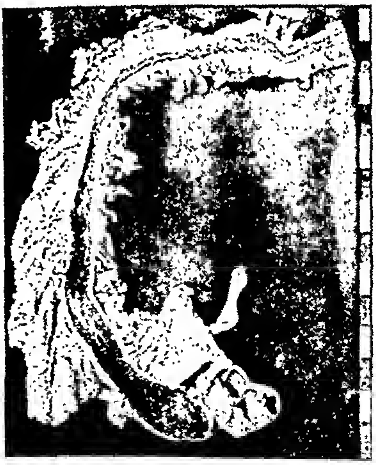

Fig. 2.

Fig. 2.—Specimen, inside view.

like cephalic index or stature divided by chest diameter (Rees and Eysenck, 1945). Having ascertained that they differentiate two groups well, we can then measure any person and inquire to which end of the scale he has the greater affinity. When a male–female test has been set up, we can test a patient and find whether he deviates in any direction from the normal for his sex. Very tentative experiments with the sex profile of the M-test, used as a discriminant between males and females, gave somewhat surprising results. This led me to a theory which I should like to see tested further. It seems that schizophrenics are fundamentally too feminine. Looked at in another way, cases of relatively early onset have intersexual tendency and those of late onset perhaps normal sexuality or supersexual tendency.

(3) *Genetical analysis.*—In conclusion I would like to draw attention to the value of statistical inquiry in the elucidation of the genetical background of psychiatric phenomena. With genetical characters it is of the utmost interest to know their frequencies in the population, since different frequencies involve different properties. It is desirable to know the frequency of cases of Huntington's chorea, for example, and, in addition, subsequent inquiry, case by case, could elicit how many cases were sporadic and in how many cases a parent was affected. From such data an estimate of mutation frequency could ultimately be made.

Diseases due to rare recessive genes can be detected by finding an increased consanguinity rate in the patients' parents. Inquiries have been carried out by Bell (1940) on data from general hospital admissions and by Munro (1938) on mental hospital admissions. Among the mentally defective patients the incidence of consanguinity in parents is particularly illuminating and indicates that some types of cerebral diplegia and microcephaly are due to single recessive genes (Duff and Dingee, 1941).

As previously mentioned, an objection to the method of factor analysis is that the entities which are deduced do not necessarily agree with clinical or genetical factors. Having established a factor, one can, of course, test it genetically by examining families. It is methodologically much more direct first to measure the same trait or set of traits in sibs or other relations and to find out by genetical analysis which traits are likely to be of significance. In its most elementary form the method would involve finding how far disease types are constant in different members of the same family. It would be useful to take, for example, instead of a random sample of men, a random sample of brothers. Genetical likeness, which can be observed in persons who have blood relationship, can be used as a means of grouping disease entities in psychiatry. Genetical differences are factors which should be used as the basis of discrimination between types.

Fig. 2.—Specimen, inside view.

mucosal surface of the colon to be dark brown in colour and covered with ridges and small polypoid tumours, mostly about the size of a pinhead. These ceased abruptly at the ileocæcal valve and the mucous surface of the small intestine was normal in appearance.

Microscopic structure.—Sections show extensive ulceration of the mucous membrane with only small surviving patches of mucosa. In the bare areas the submucosa is occupied by very vascular granulation tissue containing large numbers of lymphoid cells, plasma cells and eosinophils. In some regions there appears to be hyperplasia of the lymphoid tissue and the dark colour is due to blood pigment, of which there is a considerable quantity in the submucosa. There is no sign of any form of malignancy.

Associated Carcinoma of Colon and Rectum

Report of Two Cases

By Frank Forty, M.B., B.S., F.R.C.S.
(*Surgeon, Redhill County Hospital, Edgware*)

The occurrence of multiple primary carcinomata is not one of the great rarities of surgical pathology.

Few such tumours, however, have been recorded as affecting exclusively the colon and rectum. The majority occur in unrelated systems or organs.

Cokkinis, reviewing the literature in 1934, found that only 29 authentic cases of multiple tumours confined to the large bowel had been recorded up till that date.

Norbury (1931), in his Presidential Address to this Section on "Multiple Primary Malignant Growths, with Special Reference to the Colon and Rectum", reported several cases and stressed the practical importance of a thorough search for multiple tumours before planning any radical operation, or the placing of a colostomy. He also discussed the difficult question of the ætiology of multiple tumours, with regard to the possibilities of their arising independently, in areas of diffuse polyposis, or as implants of detached portions of one growth into another part of the bowel. Consideration was also given to the possibility that a familial or hereditary susceptibility might favour the development of multiple carcinomata, but this influence would not appear to operate with any greater frequency in cases of multiple, than in those of single primary malignant growths.

Case I.—Mrs. E. T., aged 61, was first seen in May 1945.

History.—Bleeding *per rectum* on defæcation for past three months. Bowels regular but with passage of excessive flatus. No mucous discharge. No abdominal pain. Some loss of weight.

Examination.—A carcinoma was palpable in the upper third of the rectum. *Per abdomen*, a mass was palpable in the right upper quadrant which moved up and down with respiration and which was suggestive of an enlargement of the liver. This was thought to be probably due to metastases from the carcinoma in her rectum.

First operation (5.6.45).—*Exploration*: The mass which had been felt on examination of the abdomen was found to be an annular carcinoma in the ascending colon 1½ in. (3·8 cm.) beyond the ileocæcal junction. There were no local attachments and no glandular metastases, nor secondary deposits in the liver or elsewhere. The presence of a mobile carcinomatous ulcer at the rectosigmoid junction was confirmed. There was no gross intestinal obstruction.

Operative procedure: Right hemicolectomy for adenocarcinoma of cæcum, completed by the Paul-Mikulicz method. Post-operative progress uneventful.

Second operation (10.7.45).—One-stage abdomino-perineal excision of the rectum for adenocarcinoma of rectosigmoid junction.

Post-operative progress again uneventful until signs of small-gut obstruction developed on the tenth day.

Third operation (23.7.45).—The abdomen was reopened and two narrow peritoneal bands, associated with the last parietal incision, were found obstructing a loop of small intestine, and were easily divided.

Although very ill at this time the patient made a good recovery.

On October 10 a small polypus was found presenting at the stoma of the terminal colostomy and excised. Microscopically, this showed a columnar-cell adenocarcinoma.

Fourth operation (16.4.46)—*Extraperitoneal closure of ileocolostomy.* The patient was finally discharged from hospital on May 3, 1946, in good health, and has remained well and free from recurrence.

Case II.—Mrs. C. W., aged 38, was admitted to hospital on July 31, 1943.

History.—Bleeding from rectum on the day before admission, preceded by slight pain "like wind".

Past history.—No previous bowel symptoms nor any previous ill-health.

On examination.—Small hard swelling below right costal margin. No other physical signs.

Investigation.—Barium enema—large filling defect at hepatic flexure suggestive of carcinoma.

First operotion (31.8.43).—*Findings*: Annular carcinoma at right side of transverse colon. Mobile. No secondaries. *Procedure*: Excision by Paul-Mikulicz method. *Microscopical report*: Adenocarcinoma of colon.

Second operation (24.10.44).—Extraperitoneal closure of colostomy. A hard nodule excised from the abdominal wall just above the colostomy showed adenocarcinoma.

First readmission (14.5.45).—*History*: Abdominal enlargement and discomfort for three months. Vaginal discharge three weeks.

On exomination: General condition good. Abdomen—large elastic swelling arising out of pelvis nearly to umbilicus. No ascites. *Per vaginam*—cervix displaced forwards. Mass filling pouch of Douglas continuous with abdominal swelling.

Third operotion (16.5.45) (Mr. E. ap I. Rosser).—*Findings*: Bilateral papilliferous cysts of both ovaries. *Procedure*: Subtotal hysterectomy with removal of both ovaries. At this laparotomy the colon showed no recurrence of growth and the abdomen was free from adhesions. *Microscopical examination of ovarion tumours*: "Section shows secondary carcinoma. Structure would fit well with colonic primary."

Second readmission (12.1.47).—*History*: Bleeding *per rectum*, onset two weeks previously. Bowels rather constipated.

On exominotion: Hard nodule present in the lower mid-line laparotomy scar. No intraperitoneal mass palpable. *Per rectum* indurated ulcer with raised edges on left anterior wall.

Investigations: Barium enema ascended to cæcum without delay or difficulty. Insufflation revealed no soft tissue masses. No neoplasm was detected. Sigmoidoscopy revealed a low sessile papillomatous ulcer on the anterior wall of the rectum situated about 4 or 5 in. (10 or 12·5 cm.) from the anus.

Fourth operotion (30.1.47).—*Exploration*: Liver contained no secondaries. No primary or secondary growth discovered in abdominal cavity except for a small nodule in the omentum which was removed. There were several enlarged glands in the pelvic mesocolon and subperitoneal growth was spreading from the rectum along the bottom of the pouch of Douglas, causing some fixation to the left pelvic wall.

Procedure: One-stage abdomino-perineal excision of rectum. A nodule of growth was also removed from the region of the right round ligament and the portion of the mid-line scar containing a nodule of recurrent growth was excised.

Specimen: A papillomatous ulcer, 1½ in. (3·8 cm.) in diameter, 5 in. (12·5 cm.) above the anus, with massive invasion of perirectal tissues.

Microscopical examination: Adenocarcinoma of rectum. Omentum, abdominal wall and right round ligament all show secondary adenocarcinoma. Post-operative progress uneventful.

DISCUSSION

A few points of general interest or significance from the case-histories of these two patients invite comment.

From the practical aspect, Case I exemplifies the point stressed by Norbury in his Presidential Address and by many other writers, namely the importance of suspecting, and searching for, other primary growths when one has been discovered.

The palpable tumour in the right side of the abdomen did somewhat closely simulate an enlargement of the liver, and it would have been unfortunate if this assumption had been accepted without verification.

Secondly, the completion of the right hemicolectomy by a Paul-Mikulicz procedure appeared particularly appropriate in the presence of a second carcinoma at the rectosigmoid junction, which, as a potential cause of obstruction, might have seriously added to the risks of an immediate ileocolic anastomosis.

Furthermore, the temporary ileocolostomy served the useful purpose of isolating and decompressing the distal colon and rectum as a preliminary to the abdomino-perineal excision.

From the theoretical point of view, a tentative opinion that, in both cases, the associated carcinoma in the rectum arose as an implant of a detached fragment from the colonic growth is suggested by the following evidence:

(1) In neither of these patients was there a generalized polyposis. The growths in both excised rectums were solitary; in both cases, palpation of the colon at laparotomy revealed no polypi; and in the second case, a barium enema with air contrast films, specially done to reveal possible multiple polypi, gave a negative result.

(2) The adenocarcinomatous polypus, which formed at the stoma of the left iliac colostomy in Case I, was evidently an implant from the growth in the ascending colon. A similar implant in the rectum therefore seems a likely explanation of the origin of the carcinoma in this situation.

(3) In Case II, the fact that rather profuse hæmorrhage was the first symptom of both the colonic and rectal carcinomata may be an indication of a similarity in the type of growth

and, furthermore, the occurrence of implants in the abdominal wall after each of the first two laparotomies suggests a particular proneness to this manner of spread.

On the basis of these assumptions, the rectal carcinoma would be readily explained as an implant derived from the growth at the hepatic flexure. This, however, implies a very slow rate of growth of the rectal carcinoma in view of the lapse of three years and four months between removal of the colonic tumour and the first appearance of rectal symptoms.

Carcinoma of the Cæcum associated with Carcinoid Tumour of the Small Intestine.—C. NAUNTON MORGAN, F.R.C.S.

S. B., male, aged 65. Musician.

Attended St. Mark's Hospital, complaining of rectal bleeding for years.

On examination.—An ill-looking man; mucous membranes pale; smooth tongue with atrophy of the mucosa. Chest: poor expansion; fine and coarse rhonchi over both lungs. B.P. 80/60 mm.Hg. Abdomen: a large, tender, hard and irregular mass was found in the right iliac fossa, which appeared to be slightly fixed. Rectum showed large third degree internal hæmorrhoids which would account for the bleeding. Sigmoidoscopy to 25 cm. revealed nothing abnormal. Diagnosis: Carcinoma of the cæcum.

Barium enema suggested that the abdominal mass was probably an appendix abscess, there being no definite evidence of a new growth. Hæmoglobin was found to be 66% and white blood-count 13,000 (polymorphonuclear leucocytosis). Patient ran a swinging temperature up to 102/103° F. (38·9/39·5° C.) for the first week and during that time he was given 3 pints (1·7 litres) of blood and one pint (0·57 litre) of serum. Hæmoglobin now was 70%.

For ten pre-operative days he was given phthalylsulphathiazole 10 grammes daily, and his temperature settled soon after its commencement.

Operation was performed twelve days after admission under spinal anæsthesia and continuous drip pentothal. The abdomen was opened by a long right oblique incision and a large mobile carcinoma was found in the cæcum, there being one large palpable gland in the mesentery of the small intestine.

On routine exploration of the abdomen the liver was found to be free of any palpable deposit, but a small hard contracting mass was palpated in the small intestine, which on delivery was found to be an ileal intussusception actually developing. After reduction, a small puckered hard mass was felt in the wall of the ileum and there was a hard gland about 3 in. (7·6 cm.) away in the mesentery. This second growth was thought to be another carcinoma. The whole of the small intestine was examined for other tumours but none was found. The tumour was situated approximately 6 ft. (183 cm.) from the ileocæcal valve.

A right hemicolectomy including approximately 6 ft. of ileum with its mesentery was performed; the apex of the excised mesenteric field being about 1 in. (2·5 cm.) below the duodenum.

The proximal end of the ileum was closed and also the end of the colon just distal to the hepatic angle. A side-to-side anastomosis was performed and the mesenteric defect repaired. The retroperitoneal area in the right loin was drained with Penrose drains. The patient made an uninterrupted recovery and, fifteen days later, his hæmorrhoids were ligatured and excised.

Pathologist's report (21.2.47) (Dr. C. E. Dukes).—*Gross characters.*—The specimen consisted of the cæcum, ascending colon and 9 ft. (2·75 m.) of small intestine. A huge fungating tumour completely encircled the ileocæcal valve and protruded into the cæcum (A). A hard nodule was found in the small intestine causing some constriction of the lumen. This was situated about 5 ft. (152 cm.) from the ileocæcal valve (fig. 1, B).

Microscopic structure.—The growth in the cæcum is an adenocarcinoma of a low grade of malignancy. The tumour in the small intestine is a carcinoid tumour.

Methods of spread.—(1) *By direct continuity*: The cæcal growth had spread into the pericolic fat to a moderate extent. The carcinoid tumour had begun to invade the muscle coat. (2) *Venous spread*: There was no sign of venous spread. (3) *Lymphatic spread*: The glands from the ileocæcal angle were all free from metastases (fifteen glands examined) but of five glands removed from the mesentery of the small intestine in the vicinity of the carcinoid tumour three contained metastases from this growth (fig. 2).

Classification.—Carcinoid tumour of the small intestine with three lymphatic metastases associated with adenocarcinoma of the cæcum free from metastases.

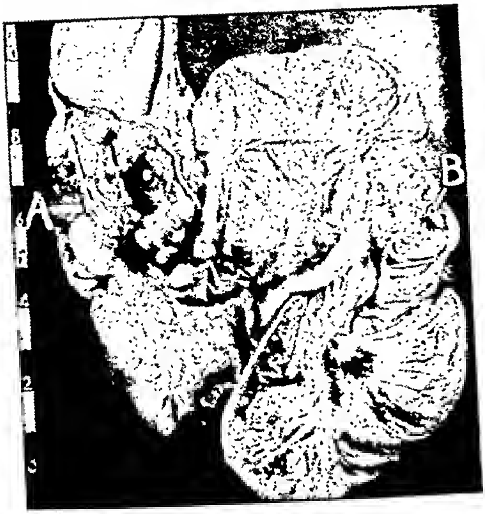

FIG. 1.

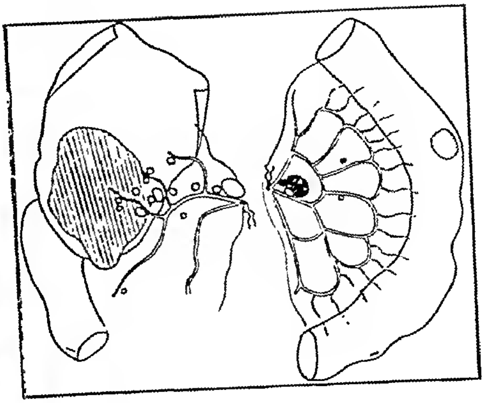

FIG. 2.

The association of a carcinoma with a carcinoid tumour is a very rare occurrence. Carcinoid tumours of the small intestine metastasize more frequently than those of the appendix.

Carcinoma of the Rectum with a Single Secondary in the Liver. Synchronous Combined Excision and Left Hepatectomy.—O. V. LLOYD-DAVIES, M.S.

F. T., male, aged 50.

He attended St. Mark's Hospital in June 1943 with a large carcinoma of the rectum.

At operation 30.6.43 a large single secondary was found in the left lobe of the liver, the right lobe being apparently free from metastases; the primary growth was locally operable and a synchronous combined excision was performed. The rectal growth specimen was classified as a C1 case, only two out of eighteen glands being involved, and from that aspect it was considered that the man had a reasonable chance of a five-year cure.

In the hope that the deposit in the left lobe of the liver might be the only one the left lobe was removed three weeks later 21.7.43 (fig. 1).

The patient made an uninterrupted recovery and returned to his work as a farm labourer in Lincolnshire. On August 26, 1945, he developed an attack of acute intestinal obstruction; he was admitted to

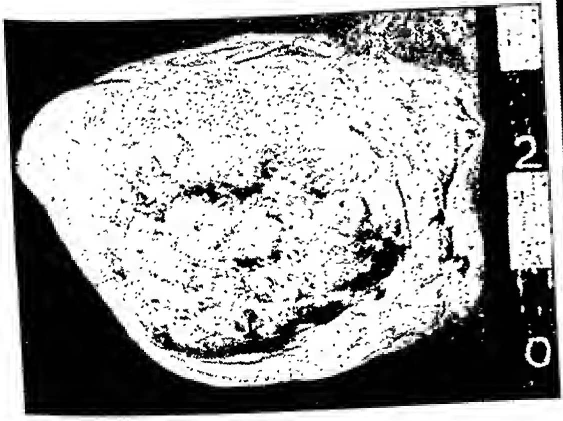

FIG. 1.

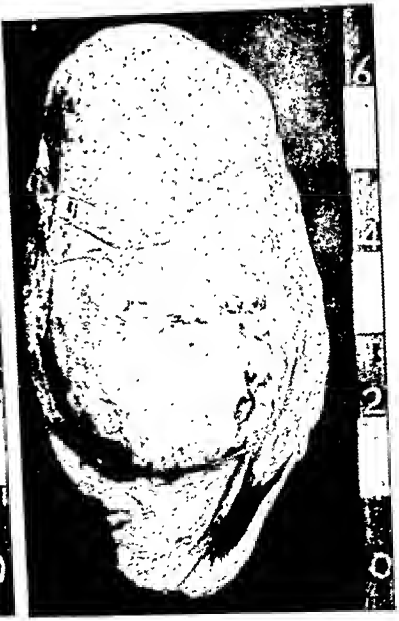

FIG. 2.

his local hospital. Unfortunately the assumption was made that the obstruction was probably due to secondary deposits and there was a forty-eight-hour delay before operation.

At operation it was found that a loop of the small intestine had become adherent to a Meckel's diverticulum; this was relieved, but the patient did not recover and died two days later. At post-mortem no evidence of any other secondaries could be found.

Fig. 2 is another case of a single secondary in the left lobe of the liver removed in June 1946 three and a half years after a resection for a carcinoma of the colon. The progress of this case is being watched with interest.

Partial Hepatectomy and Right Hemicolectomy for Carcinoma of the Hepatic Flexure of the Colon.—RONALD W. RAVEN, O.B.E., F.R.C.S.

Male, aged 38, was admitted to the Royal Cancer Hospital with symptoms extending over one year. Two months before admission another surgeon performed an exploratory laparotomy and found a carcinoma of the hepatic flexure of the colon invading extensively the right lobe of the liver. This was considered inoperable and a palliative ileo-transverse colostomy was performed. The patient's condition was deteriorating rapidly, he was wasted and had severe secondary anæmia—R.B.C. 1,900,000 per c.mm., Hb 28 %. The patient and his wife urged that an attempt should be made to eradicate the tumour and after careful preparation, including the transfusion of large amounts of blood, operation was performed. A large part of the right lobe of the liver, including the gall-bladder and the right half of the colon, was excised. No evidence of secondary carcinoma, apart from the liver extension, was found. Patient made an excellent recovery from the operation.

(A full report of this case appeared in the *British Medical Journal*, 1947 (ii), 249.)

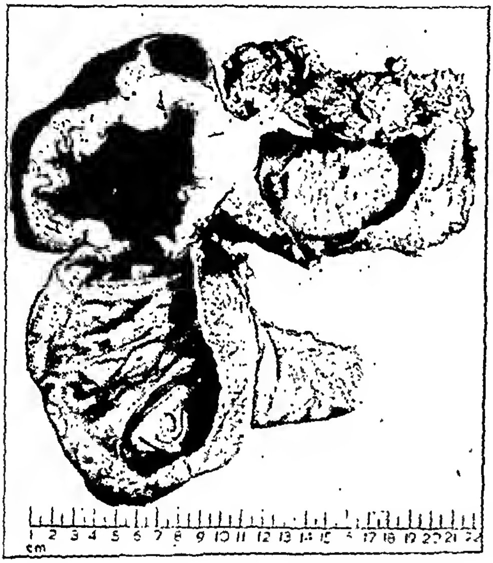

FIG. 1.
Specimen removed at operation showing a part of the right lobe of the liver, gall-bladder and right half of the colon. A large carcinoma of the hepatic flexure of the colon is invading extensively the right lobe of the liver.

DISCUSSION ON
CONGENITAL ANOMALIES OF THE ANORECTAL REGION

Professor John Kirk: *A résumé of the developmental anatomy of the rectum and anal canal.*—The portion of the embryonic gut supplied by the inferior mesenteric artery extends from the distal part of the transverse colon to the junction of the upper two-thirds with the lower third of the anal canal and is termed the "hind-gut". At an early stage it gives off a ventral diverticulum, the allantois, which, passing forwards and upwards into the umbilical stalk, carries with it the two allantoic vessels which will become the umbilical arteries of the placenta. Immediately proximal to the base of the allantois two lateral ridges form on the inner surface of the gut wall and by meeting and fusing in the mid-line form a urorectal septum. This extends caudalwards in a coronal plane and divides the gut-tube at first partially, but finally completely, into a ventral (urogenital) and a dorsal (rectal) compartment.

The genital ducts and the ureters retain their connexion with the urogenital compartment and behind it are embedded in the septum. At first both compartments are shut off from the surface by the cloacal membrane. On the external aspect of this two shallow depressions are discernible; the anterior of these represents the future urogenital cleft and the posterior one (the proctodæum) is destined to form the lower half-inch of the anal canal.

In the eighth week the membrane breaks down and the two passages open on the perineum. They are separated by a condensation of mesoderm, the perineal body, which forms at the point where the septum first makes contact with the membrane. The ectodermal proctodæum is thus brought into continuity with the entodermal gut-tube and the junctional zone becomes a critical landmark in the anatomy, physiology and pathology of the anal canal. Should the anal membrane fail to break down, a form of imperforate anus results.

Fate of the urorectal septum.—The septum is at first solid mesoderm but later becomes excavated by an extension into it of the cœlomic (peritoneal) cavity. Thus is formed the rectovesical pouch in the male, containing in its anterior wall the derivatives of the Wolffian ducts—the vasa deferentia and vesiculæ seminales—as well as the prostate and bladder. In the female, the pouch is further divided by the derivatives of the Müllerian ducts—the uterus, tubes and vaginal canal. The broad ligaments with their parametric tissue are the remains of the urorectal septum itself. In the female there is thus formed both a uterovesical and a uterorectal pouch. At the bottom of the latter the recto-anal flexure is in close contact with the vaginal wall, and beyond it the vaginal and anal canals are separated only by the perineal body.

In the male at birth the rectovesical pouch extends to the perineal body on a level with the apex of the prostate and base of the perineal membrane (triangular ligament). Later, however, this peritoneal pouch is obliterated by the adhesion of its walls. A double sheet of fascia is all that remains (the fascia of Denonvilliers) to separate the prostate, seminal vesicles, and trigone of the bladder in front from the ampulla of the rectum behind.

It is not surprising, therefore, that the commonest site of a congenital communication between the rectum and the urogenital passage, due to a defect in the septum, is found, in the male, to lie in the prostatic urethra just distal to the uterus masculinus, and in the female at a corresponding point, i.e. in the floor of the vestibule just external to the hymen.

In those rare cases where the whole of the rectum as well as the anal canal is absent, the defect is obviously due to an abnormal growth of the urorectal septum which, instead of producing a partition, proceeds to fill up and obliterate the dorsal compartment of the gut cavity and only the patent urogenital sinus remains.

Normally a small and temporary diverticulum of the rectal compartment forms just above and behind the cloacal membrane. This is the post-anal gut. It soon disintegrates and disappears but some remnant may remain to give rise to a dermoid tumour in the anococcygeal region.

PRACTICAL CONSIDERATIONS

The anorectal junction in the adult of both sexes is approximately 1½ in. (3·8 cm.) from the anus and is clearly identified as the point where the ampulla of the rectum suddenly narrows and takes a knuckle-bend downwards and backwards to form the anal canal. Here the puborectalis fibres of the pubo-coccygeus muscle form a sling which loops round the gut on its posterior and lateral aspects to make an anorectal ring of great functional value. The fibres of the iliococcygeus, descending from the lateral pelvic wall, undercut this part of the levator ani and pass downwards alongside the gut as far as the peri-anal skin. *En route* these fibres mingle with the longitudinal coat of the bowel and with the internal and external sphincter muscles. The upper two-thirds of the anal canal is true gut lined by entoderm; the lower third (not more than ½ in. (1·3 cm.) long in the adult) is formed from the proctodæum and its mucous membrane is, therefore, ectodermal in origin.

At the junction of these two zones the columnar epithelium of the one shades off into the stratified squamous epithelium of the other, and the area has been aptly termed the "pecten" or "pectinate line" because its upper limit is the line of the anal valves found at the distal ends of the grooves lying between the anal columns of Morgagni. These columns and grooves are not to be confused with the longitudinal folds and furrows often seen in the lower cutaneous portion of the canal and which correspond to the territory of the superficial part of the external sphincter muscle. The columns of Morgagni are frequently, but erroneously, referred to as "rectal" but they are truly anal in position and, moreover, were originally described as such ("ani columnæ") by Morgagni in 1741.

Just distal to the corrugated line of valvules is the mucocutaneous junction indicated to the naked-eye by the "white line" of John Hilton. In the living subject the line is more often bluish-pink in colour and is best seen in the dark races.

Here in the early embryo was attached the cloacal membrane and here is the boundary line between the splanchnic and somatic territories of the anal canal. Above the pecten the smooth involuntary internal sphincter grips the canal and the nerve supply of the gut, both motor and sensory, belongs to the autonomic system and therefore has a high threshold for pain, touch and temperature stimuli. Its lymphatic drainage is intrapelvic.

his local hospital. Unfortunately the assumption was made that the obstruction was probably due to secondary deposits and there was a forty-eight-hour delay before operation.

At operation it was found that a loop of the small intestine had become adherent to a Meckel's diverticulum; this was relieved, but the patient did not recover and died two days later. At post-mortem no evidence of any other secondaries could be found.

Fig. 2 is another case of a single secondary in the left lobe of the liver removed in June 1946 three and a half years after a resection for a carcinoma of the colon. The progress of this case is being watched with interest.

Partial Hepatectomy and Right Hemicolectomy for Carcinoma of the Hepatic Flexure of the Colon.—RONALD W. RAVEN, O.B.E., F.R.C.S.

Male, aged 38, was admitted to the Royal Cancer Hospital with symptoms extending over one year. Two months before admission another surgeon performed an exploratory laparotomy and found a carcinoma of the hepatic flexure of the colon invading extensively the right lobe of the liver. This was considered inoperable and a palliative ileo-transverse colostomy was performed. The patient's condition was deteriorating rapidly, he was wasted and had severe secondary anæmia—R.B.C. 1,900,000 per c.mm., Hb 28 %. The patient and his wife urged that an attempt should be made to eradicate the tumour and after careful preparation, including the transfusion of large amounts of blood, operation was performed. A large part of the right lobe of the liver, including the gall-bladder and the right half of the colon, was excised. No evidence of secondary carcinoma, apart from the liver extension, was found. Patient made an excellent recovery from the operation.

DISCUSSION ON

CONGENITAL ANOMALIES OF THE ANORECTAL REGION

Professor John Kirk: *A résumé of the developmental anatomy of the rectum and anal canal.*—The portion of the embryonic gut supplied by the inferior mesenteric artery extends from the distal part of the transverse colon to the junction of the upper two-thirds with the lower third of the anal canal and is termed the "hind-gut". At an early stage it gives off a ventral diverticulum, the allantois, which, passing forwards and upwards into the umbilical stalk, carries with it the two allantoic vessels which will become the umbilical arteries of the placenta. Immediately proximal to the base of the allantois two lateral ridges form on the inner surface of the gut wall and by meeting and fusing in the mid-line form a urorectal septum. This extends caudalwards in a coronal plane and divides the gut-tube at first partially, but finally completely, into a ventral (urogenital) and a dorsal (rectal) compartment.

The genital ducts and the ureters retain their connexion with the urogenital compartment and behind it are embedded in the septum. At first both compartments are shut off from the surface by the cloacal membrane. On the external aspect of this two shallow depressions are discernible; the anterior of these represents the future urogenital cleft and the posterior one (the proctodæum) is destined to form the lower half-inch of the anal canal.

In the eighth week the membrane breaks down and the two passages open on the

In the frog both bladder and rectum open into a common cloacal outlet and the genital ducts (which in the male function both as ureters and vasa deferentia) have their separate openings into the same passage a little more distally. In the female the Wolffian ducts act solely as ureters and they, as well as the oviducts, open separately into the cloacal chamber.

In reptiles, on the other hand, while there is still a common cloacal outlet for bladder and rectum, the two passages are now partially separated by a short septum into a ventral (urogenital) and a dorsal (rectal) compartment. In the male the ureters are distinct for a short distance only and unite with the vasa deferentia before opening into the cloaca. In the female the ureters and the oviducts open into the chamber separately.

In the monotremes—those primitive oviparous mammals represented by the platypus and the echidna—the division of the cloaca, though still incomplete, is carried a stage further. The vasa deferentia of the male are now completely separated from the ureters and all four channels open on the floor of the urogenital sinus which has become elongated to form a urethra.

In the marsupial mammals yet another stage is reached. The urorectal septum is almost, but not quite, complete and the rectum and urogenital passages still communicate with each other close to the perineum. A common sphincter muscle, however, surrounds the anal and urogenital openings which lie just within the cloacal aperture.

In the higher mammals we find for the first time the formation of a perineal body with complete separation of the anal and urogenital passages.

All these successive stages can be seen taking place in the developing human embryo. In the fifth week the rectum ends as in the frog; in the sixth week the condition is similar to that found in the monotremes, and early in the seventh week the urorectal septum is complete and the perineal body is formed. At this date, however, the cloacal membrane is still intact but on its external surface two shallow depressions are discernible, the anterior one representing the future urogenital cleft and the posterior one (the proctodæum) destined to form the anal opening and lower third of the anal canal.

Early in the eighth week the membrane breaks down and the anal canal is complete. There is thus enacted a drama of progressive development presenting a transition from amphibian, reptilian, and primitive mammalian anatomy to its perfection in the human perineum. It is worth noting that at this same time in the embryological calendar the development of the human face reaches completion by the fusion of its several processes.

A study of congenital malformations of the rectum and anus in man becomes an open book to those who remember those simple but salient facts in the embryology and comparative anatomy of this region.

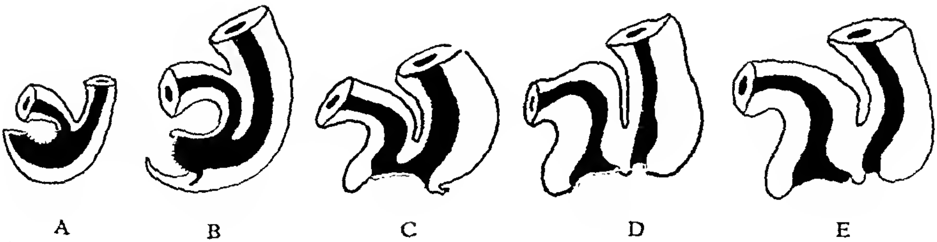

FIG. 2.—Hind-gut of human embryo: A, at four weeks; B, at five weeks; C, at six weeks; D, at seven weeks; E, at eight weeks.

Professor R. A. Willis: *Comments on Sacrococcygeal Teratomas.*—

I. Distinction of Teratomas from other Regional Malformations

A teratoma is a true tumour containing multiple tissues foreign to the part. The presacral teratomas should be distinguished sharply from the following three kinds of malformations, with which they have been confused but to which they are unrelated:

The lower area distal to the pecten, however, is supplied by *somatic nerves* (the *inferior* hæmorrhoidal branch of the pudendal nerve and the perineal branch of the fourth sacral). Its muscle ring—the external sphincter—is striped and voluntary, and its mucous membrane is exquisitely sensitive. Its lymphatic vessels drain with the peri-anal skin to the superficial set of subinguinal glands. As far as vascular supply is concerned the same embryonic line demarcates the anastomosis of the arterial stream from the superior hæmorrhoidal artery of the pelvis with the inferior hæmorrhoidal artery of the ischiorectal fossa. It is rare to find a middle hæmorrhoidal artery of any size. If present, its origin usually shares a common stem with the inferior vesical branch of the internal iliac. The venous drainage has a corresponding arrangement and across the boundary line there is a *freely communicating* network linking the portal and systemic venous systems.

There are three spaces in relation to the rectum and anal canal which are of embryological significance and of much practical importance. The ischiorectal fossa which lies below and external to the levator ani is divided by a layer of fascia, the tegmentum ("lunate fascia" of Elliot Smith), into an infra- and a suprategmental compartment. This fascia represents the deep fascia of other regions. On the medial wall of the fossa it is attached, as is to be expected, to the upper edge of the external sphincter, i.e. at the level of the pecten, and laterally it fuses with the fascia over the obturator internus to form a sheath for the pudendal vessels (Alcock's canal). Superficial to the tegmentum is the subcutaneous fat and loose areolar tissue of the ischiorectal fossa. In the suprategmental space the fat is less in amount and the areolar tissue has a finer texture. It is limited above and medially by the perineal surface of the levator ani covered by its anal fascia. Above the levator ani and surrounding the lower one-third of the rectum is the extraperitoneal fat and connective tissue which covers the pelvic floor. Into this perirectal space an ischiorectal abscess *may, under certain circumstances,* extend.

THE VALUE OF COMPARATIVE ANATOMY

The comparative anatomy of this region is as illuminating as its embryology and we owe much to Sir Arthur Keith [1] and Professor Wood Jones [2] for their elucidation of this subject.

In the frog both bladder and rectum open into a common cloacal outlet and the genital ducts (which in the male function both as ureters and vasa deferentia) have their separate openings into the same passage a little more distally. In the female the Wolffian ducts act solely as ureters and they, as well as the oviducts, open separately into the cloacal chamber.

In reptiles, on the other hand, while there is still a common cloacal outlet for bladder and rectum, the two passages are now partially separated by a short septum into a ventral (urogenital) and a dorsal (rectal) compartment. In the male the ureters are distinct for a short distance only and unite with the vasa deferentia before opening into the cloaca. In the female the ureters and the oviducts open into the chamber separately.

In the monotremes—those primitive oviparous mammals represented by the platypus and the echidna—the division of the cloaca, though still incomplete, is carried a stage further. The vasa deferentia of the male are now completely separated from the ureters and all four channels open on the floor of the urogenital sinus which has become elongated to form a urethra.

In the marsupial mammals yet another stage is reached. The urorectal septum is almost, but not quite, complete and the rectum and urogenital passages still communicate with each other close to the perineum. A common sphincter muscle, however, surrounds the anal and urogenital openings which lie just within the cloacal aperture.

In the higher mammals we find for the first time the formation of a perineal body with complete separation of the anal and urogenital passages.

All these successive stages can be seen taking place in the developing human embryo. In the fifth week the rectum ends as in the frog; in the sixth week the condition is similar to that found in the monotremes, and early in the seventh week the urorectal septum is complete and the perineal body is formed. At this date, however, the cloacal membrane is still intact but on its external surface two shallow depressions are discernible, the anterior one representing the future urogenital cleft and the posterior one (the proctodæum) destined to form the anal opening and lower third of the anal canal.

Early in the eighth week the membrane breaks down and the anal canal is complete. There is thus enacted a drama of progressive development presenting a transition from amphibian, reptilian, and primitive mammalian anatomy to its perfection in the human perineum. It is worth noting that at this same time in the embryological calendar the development of the human face reaches completion by the fusion of its several processes.

A study of congenital malformations of the rectum and anus in man becomes an open book to those who remember those simple but salient facts in the embryology and comparative anatomy of this region.

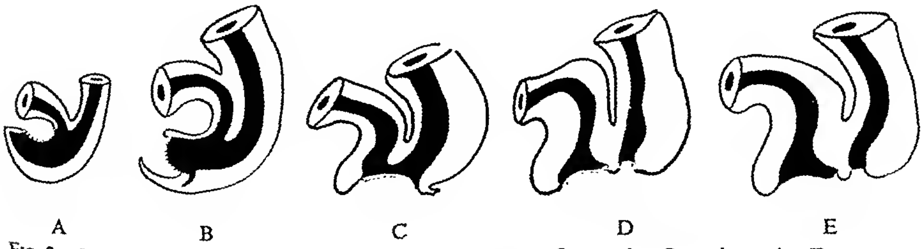

FIG. 2.—Hind-gut of human embryo: A, at four weeks; B, at five weeks; C, at six weeks; D, at seven weeks; E, at eight weeks.

Professor R. A. Willis: *Comments on Sacrococcygeal Teratomas.*—

I. Distinction of Teratomas from other Regional Malformations

A teratoma is a true tumour containing multiple tissues foreign to the part. The presacral teratomas should be distinguished sharply from the following three kinds of malformations, with which they have been confused but to which they are unrelated:

(*a*) *Caudally attached twins:* Reconstructional studies show that teratomas never contain a vertebral axis nor show orderly regional distribution of parts.

(*b*) *Supernumerary limbs:* These are always externally attached and they contain only limb structures. Teratomas sometimes contain well-developed digits and perhaps other parts of limbs, but these are internal ingredients of the teratoma itself and are always accompanied by other kinds of tissues.

(*c*) *Residues of post-anal gut or neural canal:* The suggestion of Meyer and others that teratomas arise from such residues can be rejected; this is purely speculative, ignores the obvious fact that the presacral teratomas are essentially similar to the retroperitoneal teratomas in general, and of course fails to account for the many other tissues which they contain.

II. Structure of Presacral Teratomas

Skin, respiratory and alimentary epithelium, choroid plexus, neuroglial tissue, nerves and nerve ganglia, pancreatic or gastric tissue, skeletal and smooth muscle, bone and cartilage are all common components. Highly organized structures, such as digits or coils of intestine, are not unusual; they have often misled pathologists into interpreting teratomas as reduced fœtuses. Malignancy in sacral teratomas often involves papillary glandular components, possibly of the nature of choroid plexus; and malignant change may occur at an early age, even in infancy.

III. The Nature of Teratomas

Structural studies alone suffice to disprove the still prevalent view that teratomas represent included fœtuses. Their explanation is to be sought rather in disturbances of the chemistry of early embryonic growth, disturbances resulting in partial isolation or release of foci of embryonic tissue from the action of the primary organizer, and at the same time their neoplastic conversion. The early age at which teratomas are present—especially obvious with the presacral group—and their distribution in parts of the body derived from median or paramedian prevertebral structures, accord with this concept.

Technique and Value of Tattooing in Plastic Surgery

By D. N. MATTHEWS, O.B.E., M.Ch., F.R.C.S.

TATTOOING is a very ancient art. It has been practised through all ages all over the world. Primitive tribes used thorns with tree-gum soot as the tattooing medium, whilst Egyptian craftsmen designed fine gold rakes and gold hammers with which to drive in an infinite variety of coloured pigments. The modern apparatus consists of a needle connected to a vibrator electrically driven.

Dangers.—In the past infection was a common sequel to tattooing and not infrequently caused death. Transmission of syphilis occurred so often that tattooing was declared illegal by the Army authorities of many nations. But with strict adherence to modern aseptic technique, these risks are completely eliminated. The possible toxicity of the dyes is the only danger to-day, and it is wise to make several small test tattoos of any new dye before accepting it into general use.

Dyes.—These must be relatively insoluble, stable to light and unaffected by tissue reaction. The reaction they excite must be slight and only transient and they must have no toxic systemic action. I have used ochres, which are oxides of iron, in shades of brown and red supplied to me by Imperial Chemical Industries. I have also used cadmium selenides, supplied by the Blythe Colour Works, in nine shades ranging from tangerine, through yellow and pink to brick red. I have not used mercuric sulphide (cinnabar) since it can cause severe mercurial poisoning, although it has been recommended by tattooists for cosmetic purposes and is used by dermatologists in the treatment of pruritus. I.C.I. and the Blythe Colour Works naturally disclaimed all responsibility for any toxic or other untoward effect the injection of these pigments might produce, but gave me all possible assistance.

Tattooing instrument.—My tattooing machine is an adaptation of one I bought from a professional. It consists of a simple electric "make and break" vibrator working against a small spring load with a 3 mm. travel. A four-volt battery or rheostat control from the electric light drives it. The head of the vibrator contains nine needles set close and arranged to give an even track of punctures (fig. 1).

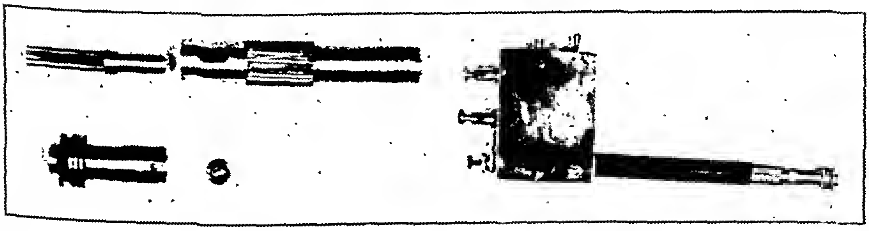

FIG. 1.—Tattooing machine (designed by author) with detachable head, containing nine needles. Driven by 4 volt current.

Technique.—Authentic medical literature is scanty and in the few articles published the technique recommended is to obtain the requisite shade by mixing the dyes with a white base. Zinc oxide and barium sulphate have both been advocated for the purpose. But in my experience such mixtures always give an ugly, blotchy appearance when tattooed, despite an excellent colour match *in vitro*. This was so whether the powders were mixed dry or with alcohol. It seemed that the only way to get a good result was to possess a large enough variety of shades for all requirements, (*a*) *Caudally attached twins*: Reconstructional studies show that teratomas never contain a vertebral axis nor show orderly regional distribution of parts.

(*b*) *Supernumerary limbs*: These are always externally attached and they contain only limb structures. Teratomas sometimes contain well-developed digits and perhaps other parts of limbs, but these are internal ingredients of the teratoma itself and are always accompanied by other kinds of tissues.

(*c*) *Residues of post-anal gut or neural canal*: The suggestion of Meyer and others that teratomas arise from such residues can be rejected; this is purely speculative, ignores the obvious fact that the presacral teratomas are essentially similar to the retroperitoneal teratomas in general, and of course fails to account for the many other tissues which they contain.

II. Structure of Presacral Teratomas

Skin, respiratory and alimentary epithelium, choroid plexus, neuroglial tissue, nerves and nerve ganglia, pancreatic or gastric tissue, skeletal and smooth muscle, bone and cartilage are all common components. Highly organized structures, such as digits or coils of intestine, are not unusual; they have often misled pathologists into interpreting teratomas as reduced fœtuses. Malignancy in sacral teratomas often involves papillary glandular components, possibly of the nature of choroid plexus; and malignant change may occur at an early age, even in infancy.

III. The Nature of Teratomas

Structural studies alone suffice to disprove the still prevalent view that teratomas represent included fœtuses. Their explanation is to be sought rather in disturbances of the chemistry of early embryonic growth, disturbances resulting in partial isolation or release of foci of embryonic tissue from the action of the primary organizer, and at the same time their neoplastic conversion. The early age at which teratomas are present—especially obvious with the presacral group—and their distribution in parts of the body derived from median or paramedian prevertebral structures, accord with this concept.

reverse of any published recommendations I have been able to find. If placed superficially as has been advocated, the scarred epithelium blisters and the dye is lost.

Finally two patients were tattooed with a light shade of pink in an attempt to hide the pigmentation left by burns. These were failures as the pigment was so superficially placed that it was impossible to cover it. The dye always went too deep.

Mr. D. C. Bodenham: What is the best particle size to select in powders used for tattooing: and has Mr. Matthews any further information on the tattooing of dark areas with light colours?

Mr. D. N. Matthews (in reply): The smaller the particle size the better. I am at present trying to replace the pigmented areas with white, using zinc oxide and then colouring the white base as required. It is too early to say whether this is going to prove satisfactory. Technically it is difficult.

MEETING HELD AT THE ROYAL HOSPITAL, SHEFFIELD

Some Dermatological Complications of Open Wounds

By I. B. SNEDDON, M.B., Ch.B., M.R.C.P.

THE dermatitis which may complicate open wounds, and by that I mean any granulating surface whatever the cause, is an important type, not from the numbers of cases which occur, but because many of the cases may be prevented. It is often affirmed that dermatitis cannot be cured and there is an element of truth in this. So many of our chronics could have got through life without trouble if it had not been for a precipitating cause, therefore any method of prevention is valuable.

If dermatitis does occur it may prolong unduly the treatment of a simple surgical case by delaying later surgical procedures. Dermatitis after amputations may make an otherwise satisfactory stump useless. The pathology of dermatitis consists essentially of the formation of vesicles in the epidermis by a combination of extracellular œdema and destruction of the cells by intracellular œdema. The vesicles rupture, leaving a moist, weeping surface which later becomes crusted.

The types of dermatitis which may affect the skin surrounding a granulating surface may be classified as:

(1) Traumatic.
(2) Sensitization. — (*a*) Chemical.
(*b*) Bacterial.

(1) *Traumatic dermatitis.*—This is caused by the direct physico-chemical action of agents, such as acids and alkalis, and the stronger antiseptics, such as iodine and picric acid. The mechanism of this type of eruption is obvious and its prevention simple.

(2) *Sensitization dermatitis.* (*a*) *Chemical.*—To produce this the chemical agent has to act for some time on epithelial cells which eventually become sensitized. At this stage further contact with the agent causes dermatitis. The classical experiments of Cranston Low, who made a group of individuals sensitive to primula leaves, illustrate this mechanism. Bloch showed that idiosyncrasy was only a matter of degree and that everyone could be sensitized if concentration and time of application were increased. Granulating surfaces are particularly prone to become sensitized as the epithelial cells are exposed to closer contact with external agents than in intact skin. The site of a wound is also important. Where the blood supply is poor the epidermis is more prone to sensitization, owing to the longer time of healing and also the poorer nutrition of the cells.

Of the popular applications which may give rise to dermatitis the following are of topical interest:

(i) *Acridines.*—Acriflavine is a common cause of dermatitis, much more common than the literature would suggest. During the last ten years only two cases have been published, by Beare (1947) and Young and Hawking (1938). Acriflavine also has the effect of lighting up sulphonamide dermatitis and Russell and Beck (1944) showed that proflavine and sulphonamide mixtures were more lethal to tissues than either substance singly.

and to tattoo each separately where it was needed. This method has proved satisfactory. The colour of normal skin consists of brown and pink in varying proportions and shades with the superadded stubble of the hirsute areas in men.

My practice has been to tattoo the brown colour first, matching the amounts and shades to the opposite side of the face if present. A little overlapping softens the change from one colour to another provided a considerable reduction is made in the quantity of both dyes used in the overlap; otherwise the overlap is too dark.

Areas can be marked off in Bonney's blue and tattooed, and the spaces between them blended by overlapping. Owing to a diffusion of the points of colour, they become more apparent after a few weeks. All areas should therefore be slightly undercoloured especially when beard and moustache stubble are being tattooed. This diffusion is probably due to entry of the dye into the tracks of the hair follicles and sweat ducts. An interval of one month should be made between brown and pink tattooing and again before hair stubble is added. For this, dark brown dye is more satisfactory than black as the latter looks dirty.

The procedure is carried out with full aseptic theatre routine and sterilization of the skin and detachable parts of the vibrator. The dyes are not autoclaved owing to colour changes which heat would produce. They are, however, mixed with absolute alcohol. The paste which results is painted on the surface to be tattooed and the instrument pressed into it with the needles vibrating and held at right angles to the skin. Insertion of the dye is facilitated if the skin is stretched slightly. In unsupported regions such as the cheek, a finger must be inserted into the mouth for counterpressure. The dye should be driven into the dermis and the basal layer of the epidermis. Insertion at this level causes minute pin-point hæmorrhages which are useful guides to the correct level. If it is put in the superficial layers of the epidermis there is no bleeding. Most of the dye inserted at this level is rubbed away within a few months. It is probably true that a little of the dye inserted in the dermis is ultimately deposited in the lymphatics. To avoid disfiguring lines or blurred marks, the collar of the vibrator must be so adjusted that the needles disappear behind it with each vibration; this allows a 2 to 3 mm. travel. The instrument must be moved very slowly over the skin for the same reason; no more than 1 cm. of movement should be made in one minute. It is impossible to drive dry powder into the skin, and as the alcohol evaporates rapidly it is convenient to cover only about half a square inch with the paste at a time. When each area has been traversed the excess dye is washed away with ether to assess how much has been driven in. I have not found an anæsthetic to be necessary. The pricking sensation is only uncomfortable initially. Injections of local anæsthetic prevent accurate judgment of depth. The tattooed area is covered with tulle gras, backed with sterile gauze and smeared with penicillin cream. Irritation and slight œdema sometimes occur, but disappear in forty-eight hours. The dressing is discarded a day or two later.

Uses and results.—Tattooing is a valuable adjunct to the plastic repair of facial wounds and burns. The colour match of free grafts and pedicle flaps in such cases is often poor and can be considerably improved. In addition a hirsute appearance can be given to the beard area, a missing eyebrow can be simulated and the vermilion border added to a flap replacing a lost lip. I have tattooed 21 patients. Fifteen required tinting of free grafts and flaps, and beard stubbling; this group gave the most satisfactory results. A very fair degree of normality can be restored and for them tattooing finds its greatest usefulness.

Two patients required eyebrow disguise; these were reasonably satisfactory but could have been better if tattooing had been done in lines rather than dots. This could have been effected by adjusting the needles so that they did not quite disappear behind the collar of the vibrator with each vibration. Two patients had scars left by X-rays, and were more successful than I had expected. Scar tissue is difficult to tattoo and it is necessary to drive the dye deeper than for normal skin. This is the

Recurrent Dislocation of the Elbow-Joint

By D. WAINWRIGHT, F.R.C.S.Ed.

RECURRENT dislocation occurs most commonly at the shoulder-joint but the condition does occasionally arise at the other joints, e.g. the temporomandibular joint, the sterno-clavicular joint, and the carpo-metacarpal joint of the thumb, and as a subluxation at the ankle-joint.

In the literature I have only been able to find a description of three previous cases of recurrent dislocation of the elbow-joint. The first case was described by Sorrel in 1935; in 1936 Henry Milch reported a case of bilateral recurrent dislocation and in 1943 Gosman of Wisconsin reported a unilateral case.

The following is an illustrative case:

Albert T., aged 12, was referred to the Orthopædic Hospital, Stoke-on-Trent, on 3.12.45. He first dislocated the right elbow-joint as a result of a fall when he was 10. The dislocation was reduced and the elbow immobilized in flexion with a collar-and-cuff sling for two weeks. The dislocation recurred on five subsequent occasions, each time as a result of a trivial injury—usually with the joint in a position of almost full extension—and on each occasion the dislocation was reduced under gas and oxygen anæsthesia. On the fifth occasion the elbow was immobilized in plaster for eight weeks.

The only abnormality seen on examination of the elbow at any time was a slight degree of hyperextension of the joint when compared with the normal side, and the X-ray suggested a rather shallow olecranon fossa with a little deficiency in the depth of the coronoid process.

It was decided to provide an anterior bone block by inserting a flat bone graft into the coronoid process, and on 5.12.45 this was carried out. Under anæsthesia it was possible to reproduce the dislocation by a combination of downward traction and backward thrust of the forearm.

Under a tourniquet the anterior aspect of the joint was exposed by exploring the sulcus between biceps and the brachioradialis and splitting the fibres of the brachialis anticus protecting the musculospiral nerve. The anterior part of the capsule of the joint was found to be lax and an incision was made through it over the coronoid process and, using a small osteotome, a groove was prepared in the process for reception of the graft.

(ii) *Sulphonamides.*—The danger of sulphonamide dermatitis in this country has been exaggerated, but it is so distressing that it must be avoided at all costs.

Sulphonamides taken internally are free from the danger of causing dermatitis although they may cause toxic morbilliform eruptions. Apart from the usual type of contact dermatitis caused by sulphonamides they may produce sensitivity to sunlight. For this no cure has been found as desensitization to sulphonamide does not relieve it. It is difficult to assess the incidence of sulphonamide dermatitis but Peterkin (1945), in a review of the literature, quoted that of 1,052 cases treated by sulphonamides 35 developed dermatitis.

(iii) *Penicillin.*—The local use of penicillin is remarkably safe. Michie and Baillie (1945) report only one case of penicillin sensitivity to powder in 30,000 casualties in the British Liberation Army. Vickers (1946) and Bedford (1946) also report cases.

The remaining reports in the literature are all of doctors and technicians handling penicillin in high concentration for long periods.

It certainly seems that it takes thirty to forty days for penicillin sensitivity to develop and that powder is more dangerous than cream or solution.

There is, however, a phenomenon of aggravation of the wound without definite dermatitis. It is impossible to demonstrate penicillin sensitivity by patch tests in these cases, and it appears to be a purely local sensitivity which disappears when penicillin therapy is stopped. Wright and Gross (1947) have also found no explanation for this phenomenon.

(*b*) *Bacterial sensitization.*—The skin surrounding a wound may become sensitized to the bacteria or their breakdown products. It is commonly seen around traumatic ulcers of the leg or when a purulent wound is encased in plaster of Paris. A later phenomenon is a generalized vesicular eruption on the remainder of the body after an area of dermatitis has been aggravated or encased in an occlusive dressing. This autosensitization was described by Whitfield in 1930. Recent work by Hecht *et al.* (1943) has suggested that autosensitization is due to blood-stream spread of broken-down skin proteins, combined with local staphylococcal infection.

Prevention

As a dermatologist I would say: (1) Never put anything on the skin unless it is absolutely essential. Local treatment should be limited to dry dressings, saline, tulle gras and possibly penicillin cream. Sulphonamides should not be used. (2) Pre-operative preparation of the skin should be reduced to washing with soap and water and removal of dirt by cetavlon. Iodine and biniodide should not be used. (3) If there is already a pyogenic infection of the skin it should not be enclosed in plaster of Paris. (4) Chemotherapy should be given parenterally or by mouth.

In support of this I would like to quote the conclusions of an American surgeon, Dr. C. Lyons (1947), reviewing the treatment of war wounds, who states that local chemotherapy is unnecessary and undesirable.

A paper on Treatment of Cerebral Abscess was read by Mr. James Hardman. This was based on work carried out with Professor Wilson Smith, in preparation for a joint paper.

(1) *Waldenström's Sign and the Ligamentum Teres*

Waldenström (1938) of Stockholm, described as an early sign an increased distance between the medial pole of the head and the floor of the socket. We have found Waldenström's sign very frequently and not uncommonly on the first film that showed changes in opacity. It is not very marked in the earliest stage but becomes more so in the following months if the hip is not put to rest. Then it may reach such a degree that the shadows of the femoral head and the ischial bone no longer overlap but leave a gap between them (fig. 1). Waldenström believes that his phenomenon is due to an effusion into the joint. We cannot agree with him for several reasons. The effusion found at operations was always negligible in amount and never under sufficient tension to distend the capsule, let alone displace the femoral head. An effusion under high tension would cause severe clinical symptoms. It would push the head downward as well as outward. Finally, the arthrogram would show marked pooling of contrast medium in the space in question.

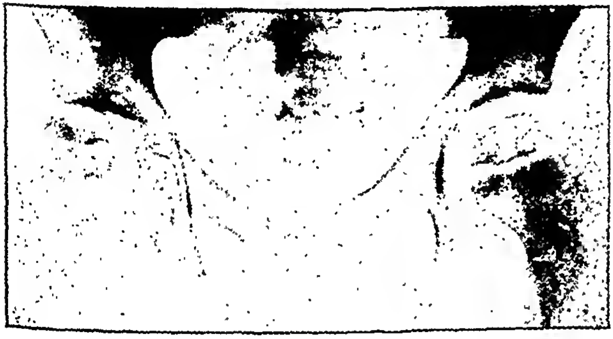

FIG. 1.

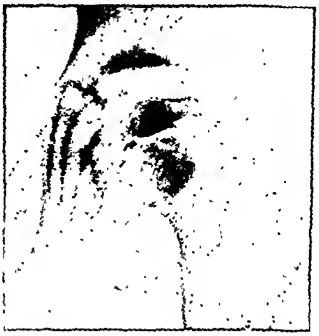

FIG. 2.

FIG. 1.—Untreated case. The shadows of femur and ischium do not overlap. Excavation of acetabular floor.

FIG. 2.—Arthrogram. No pooling of contrast medium in socket. In the lower part of the latter there are two thin deposits separated by soft parts.

The arthrogram (fig. 2) was taken before a perfect technique had been evolved but it shows clearly that there is no pooling between head and socket. There is, however, medial to the head contour, another narrow space filled with contrast medium, but between this and the surface of the head there is a translucent area. This area can only contain some soft structure. Closer scrutiny of the previous X-ray (fig. 1) reveals a feature that sheds more light on the problem. The acetabular floor is altered. It does not show the same rounded contour, continuing that of the roof, as on the other side but is hollowed out abruptly. This excavation of the acetabular floor becomes apparent very much later than Waldenström's sign but is never seen in the latter's absence. Both signs can be observed occasionally in hips with inflammatory lesions, such as tubercle.

A picture like this suggests that there is something between the bony parts, pressing the femoral head outward and the floor of the socket inward. In this situation lie the Haversian pad of fat and the round ligament. Whitman (1929), when he opened a hip-joint in a case of pseudocoxalgia, found the ligamentum teres grossly swollen and congested, and a similar observation was made in a case of the present series. The inference seems justified that it is the congested, hyperæmic, throbbing ligamentum teres that causes both Waldenström's sign and the excavation of the acetabular floor, much as an aortic aneurysm displaces the viscera and erodes the spine.

Both Milch and Gosman used a *tibial graft*; but there appeared to be no point in looking elsewhere for bone, and a flat cortical graft about ¾ in. × ½ in., and about ¼ in. thick, was taken from the subcutaneous portion of the upper end of the ulna and forced firmly into the groove. The anterior capsule was closed and reefed longitudinally, the wound closed, and the elbow immobilized in plaster at a right angle for two months.

The series of X-rays [demonstrated at the meeting] show very clearly the degree of absorption of the graft, the substitution of new bone and the process of remodelling and moulding which has taken place and which has occurred much more rapidly than one would have expected.

In spite of the prolonged immobilization, movements returned fairly rapidly and radiographically, at any rate, the bone block appears to be adequate to prevent further dislocation.

Pathology.—The underlying pathology of this condition appears to differ in the cases which have been described.

Sorrel's case was associated with a marked relaxation of the ulnar collateral ligament and in his case the dislocation was associated with an outward gliding movement of the ulna.

In the case described by Milch (which was bilateral) there appears to have been a true congenital abnormality of the greater sigmoid cavity, which was very shallow.

Gosman's case, on the other hand, showed no radiological abnormality but was associated with hypermobility of the joint and general laxity of the ligaments.

In the case just described, I think the main factor was the deficiency in depth of the coronoid process: when the joint was exposed at operation this process appeared to have a smooth, rounded beak, providing a very inefficient check to forward displacement of the lower end of the humerus. There was, in addition, some general laxity of the capsular ligaments, but this was felt to be rather a secondary result of the repeated dislocations.

Treatment.—So far as treatment is concerned there appeared to be three possible ways of tackling the problem: Reefing the collateral ligaments might have been tried but, on the whole, capsuloplasties are not very successful; or the convexity of the sigmoid notch could be modified by an osteotomy of the coronoid process.

The soundest procedure, however, appeared to be some type of bone block. An osteotomy and forward flexion of the tip of the olecranon process, to prevent full extension of the elbow, might have succeeded; but an anterior bone block appeared to be more rational. This was the method used successfully by both Milch and Gosman. Milch employed a curved, boomerang-shaped, cortical graft from the tibia to form a continuous line with the curve of the coronoid process. A rectangular graft is much simpler to cut and insert, and subsequent X-rays demonstrate clearly the remodelling which occurs during the process of absorption and substitution of new bone.

Pseudocoxalgia: (Calvé-Legg-Perthes' Disease)

The Radiographic Changes Outside the Femoral Head

By H. G. KORVIN, F.R.C.S.

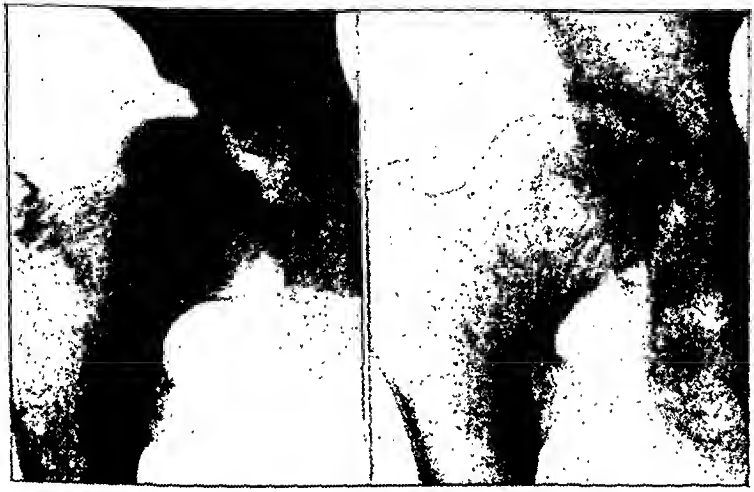
In a previous paper (Korvin, 1947) the radiographic changes in the femoral epiphysis seen in pseudocoxalgia have been discussed. The conclusion arrived at was that they conform to the pattern of ischæmic necrosis and that it is unnecessary to assume a pathological lesion not met with elsewhere in the body. The changes outside the epiphysis have generally been given less attention, but have occasionally been described as an extension of the disease process from the femoral head into the neck and acetabulum. In the following an attempt will be made to interpret these, too, in terms of recognized pathology. The conclusions are based on the study of 90 cases with 102 affected hips, seen at Biddulph Grange Orthopædic Hospital (54), Ethel Headley Hospital (26), and Manchester Royal Infirmary (10).[1]

---

[1] My thanks are due to Professor Platt and to Dr. Jean Bucknell.

definite zone of sclerosis. The acetabular roof shows three distinct areas, each the size of a pea, which are more translucent than the rest and, again, partly surrounded by a faint line of sclerosis. The anterior margin of the roof is made up of several rounded prominences protruding downward. They are more marked than normally besides being better visible because the bony epiphysis, reduced to a flat disc, no longer obscures them. Six years later not the slightest trace of the cyst-like appearance is visible.

In a boy aged 13 (fig. 5) the X-ray film showed a late stage of pseudocoxalgia. The outer half and the inner edge of the epiphysis are regenerated. To the inner side of the centre there is still a considerable defect. The edge of the acetabular roof shows a complete defect, nearly half an inch in diameter. The site of that defect corresponds to the attachment of the joint capsule, a structure known to be markedly congested in such cases. In the ischial part of the socket there is a less marked, round, very regular translucent area: an enlarged vascular foramen. Two years later, when the head was re-formed, the defect in the head of the acetabulum had disappeared except for a tiny notch. But the socket as a whole has become very much flattened during the time when it was deprived of much of its bony structure.



A. B.

FIG. 5.—Boy aged 13. A. Large defect at edge of acetabular roof. B. Two years later defect almost obliterated.

(3) *Deformity of the Femoral Neck*

The amount of deformation the necrotic femoral epiphysis undergoes before it regenerates is the main factor determining the ultimate shape of the upper end of the femur, but it is not the only factor. Often gross flattening of the epiphysis is associated with marked deformity of the femoral neck, resulting in coxa vara, anteversion, or retroversion.

A boy had been treated for pseudocoxalgia from his sixth to his eighth year. An anteroposterior radiograph taken at the age of 15 (fig. 6) shows, apart from marked flattening of the epiphysis, severe coxa vara deformity. The lateral view shows the anterior contour of the neck only slightly concave but the posterior contour almost semicircular, the metaphyseal end forming here an overhanging

There are, on the other hand, cases in which the arthrogram does show pooling of contrast medium between head and socket. A boy aged 6 had complained of pain in his left hip for three months. Three years earlier a congenital dislocation of his right hip had been reduced. The X-ray film showed the left femoral epiphysis flattened and denser than the rest of the bone, beginning absorption at its inner extremity, and an increased distance between the head and the acetabular floor. The roof of the socket was slightly but definitely sloping upward and outward. The arthrogram (fig. 3) reveals a considerable pool of contrast medium between femoral head and acetabular floor. In the right hip a similar pooling of contrast medium and marked sloping of the roof of the very shallow socket can be seen.

In this case there had been, associated with the dislocation of the right hip, subluxation or "dysplasia" on the left side. This is demonstrable as a sloping roof on X-ray films taken before the hip developed pseudocoxalgia. Owing to the subluxation there is room in the socket for contrast medium to collect. This, however, is an exceptional finding that can be fully accounted for. It thus confirms the rule that Waldenström's sign is not due to joint effusion.

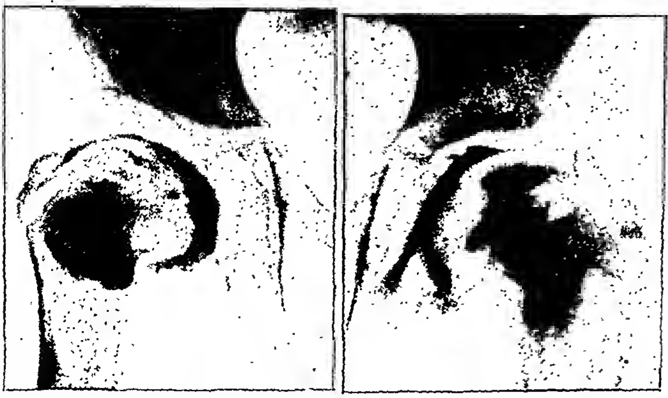


FIG. 3.—Reduced dislocation of right hip, pseudocoxalgia on left side. Both roofs sloping. Arthrograms. Pooling of contrast medium between head and socket on both sides.

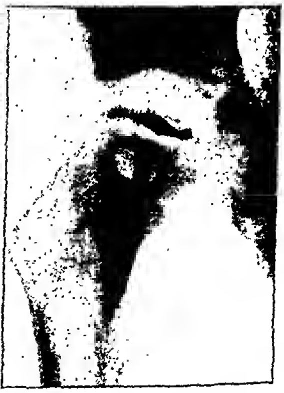

FIG. 4.—"Cyst-like spaces" in centre of neck.

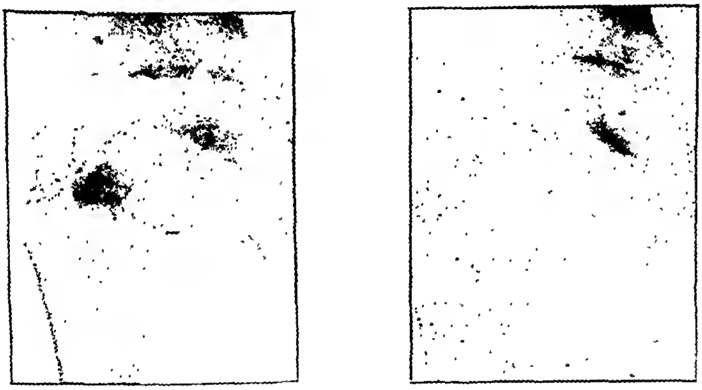
(2) *Structural Changes in the Neck and Socket*

The osteoporosis of the neck and the socket observed in the early stages is diffuse and homogeneous. In severe cases the absorption of bone becomes at a later stage more complete in some parts than in others, resulting in formation of what are often termed "cystlike spaces" and, at the edge of the bone, actual defects. These areas of absorption have been wrongly described as necroses or as an extension of that undefined process "osteochondritis" into the neck and acetabulum.

Wherever osteoporosis attains a high degree and is present for long periods, such "cystlike" spaces are found. They are met with in osteo-arthritis, rheumatoid arthritis, osteomalacia, occasionally in Paget's disease, and, most characteristically, in parathyroid disease. Where the underlying condition can be cured the "cysts" can disappear again. They disappear in pseudocoxalgia by the time the epiphysis has regained its normal texture. But any deformity the skeletal parts have acquired during and on account of this extreme bone atrophy remains permanent.

In a boy aged 4 (fig. 4) the radiograph shows severe crushing of the epiphysis. Near the centre of the neck there are two cyst-like areas, partly surrounded by a on the other side. This is due to the head having another lower border which is convex and overlaps the neck. If this line is taken as the contour the epiphysis must be described as ovoid, not crescentic. In reality it is neither. It is merely tilted and therefore not seen strictly in profile, similar to the slipped epiphysis in coxa vara. It differs from the latter in that the displacement has occurred within the substance of the neck and not at the epiphyseal line. A certain degree of coxa vara is present: on the left side a line drawn through the tip of the trochanter at right angles to the shaft bisects the epiphyseal line, while on the right it lies wholly above it.

Three months later the boy developed clinical pseudocoxalgia. A radiograph taken one year after the first shows typical changes (fig. 8A). The epiphysis is relatively dense. Its outer edge is eroded. The twofold lower contour is very conspicuous: the tilting has increased. The tip of the trochanter is now level with the summit of the head. In order to determine whether the neck had bent forward or backward, films were taken with the X-rays traversing the hip obliquely. When the angle of incidence was made 30 degrees by flexing the hip by that amount the epiphysis was seen in profile and the epiphyseal line was narrow, straight, and clear (fig. 8B). The femoral neck was, therefore, bent forward.



A. B.

Fig. 8.—Same case, one year later. A. Definite pseudocoxalgia. Tilting more marked. B. Normal relationships restored by flexing hip through 30 degrees.

This tilting of the epiphysis caused by forward bending of the neck is more obvious before any real deformity of the epiphysis itself has developed, i.e. in early cases. They constitute Legg's mushroom type, with its favourable prognosis. But the deformity of the neck is not an essential feature at this stage. It was seen in one-half of the early cases only. Although the demonstrable osteoporosis is not conspicuous it is the only factor that can be made responsible for the bending of the neck.

There remain to be discussed the changes in the articular cartilage. This is commonly regarded to be unaffected, as evidenced by the preservation of the radiographic joint space. Only many years later osteo-arthritis supervenes owing to incongruity of the articular surfaces in all but the very early treated cases. Very rarely—in 5% of the cases under review—the cartilage is lost early.

ledge. The epiphyseal line, just beginning to obliterate, is not set at right angles to the axis of the neck but tilted backward.

Deformity of the femoral neck can develop very early in the course of the disease, even before the head has become deformed. A boy of 8 was X-rayed because his twin brother suffered from pseudocoxalgia although he himself presented no symptoms. The radiograph (fig. 7) shows on the right side an epiphysis hardly flatter than that on the left and of equal translucency, but somewhat crescentic in shape, its lower border being, on the whole, a little concave. The adjacent part of the neck shows very slight irregular rarefaction. The epiphyseal line is not as clear as

Brief Note on the Contributions of the late Sir Henry Gauvain to Orthopædic Surgery

Sir Thomas Fairbank said that Sir Henry Gauvain was appointed to the Lord Mayor Treloar Hospital, Hants, in 1908; he was, from the first, an ardent advocate of conservative versus operative treatment for non-pulmonary tuberculosis, and the aspiration of tubercular abscesses instead of incision. Gauvain insisted on the paramount importance of general treatment, in addition to local, and did pioneer work in the use of heliotherapy, open air, sea-bathing and light treatment. He insisted on "lessons" and occupational therapy to fill the patients' time.

A college was opened for teaching a trade to crippled lads, and so enable them to earn a living. He advocated the use of celluloid splints, rendered non-inflammable by a special method, for selected tubercular and other cases. The plans for rebuilding the hospital were largely the result of his experience and thought. He published valuable instructions for the use of the iron lung. His test for the activity or quiescence of tubercular arthritis of the hip (*Lancet*, 1918 (ii), 666) has proved of the greatest value. Lastly his exceptional personality and its great influence on the staff and patients was referred to.

A full account will be published in the *Journal of Bone and Joint Surgery*.

Cases and Case Records Illustrating Orthopædic and Plastic Surgical Team Work

By Professor T. POMFRET KILNER, C.B.E., F.R.C.S.

IN the early twenties, Sir Henry Gauvain invited Sir Harold Gillies and me to pay occasional visits to the Lord Mayor Treloar Hospital to carry out reconstructive work on cases of lupus in which the original disease and its curative treatment had produced deformity or disfigurement.

As the incidence of lupus in children became less frequent, the call for plastic surgical treatment of this kind diminished but a wider definition was given to the word "cripple" by the Trustees and when London hospitals became unpleasant residences for children in the early days of the war I was privileged to transfer to Alton my waiting lists of all cleft lip and palate cases from St. Thomas's Hospital and the then Princess Elizabeth of York Hospital for Children, Shadwell. Many of these cases requiring secondary corrections of a non-urgent character are still waiting for treatment, for Hampshire became "cleft lip and palate minded" and we now have a County service for these conditions run by the Medical Officer of Health to whom all cases are notified and who arranges for them to be seen either at the local Orthopædic Clinics or here. The follow-up system for these cases is excellent.

More than 90% of our work now consists of such cases and can be of little interest to the orthopædic surgeon. The other 10% is concerned with the treatment of congenital and acquired defects of the limbs. In most instances we are called upon to supply skin in the form of free grafts to parts where this is congenitally missing or has been lost by trauma, or to replace unstable scarred areas by sound full-thickness flap skin to allow orthopædic procedures to be carried out in comfort and without danger of infection to deeper structures.

CASE II (fig. 2A, B).—P. W., born 26.11.39. Syndactyly, left hand and both feet.

1.8.42: Operation, Treloar Hospital, Alton. Fingers separated. Fingers splinted in abducted position. Thickish Thiersch graft from left thigh applied on stent mould to raw surfaces.

CASE III (fig. 3).—R. G., born 4.5.43. At 6 months scalded with hot-water bottle. Extensive scarring right side trunk extending to axilla, groin and outer side right thigh.

Arm abducts to less than 90 degrees. Limitation of extension of right hip.

2.9.44: Consultation at Treolar Hospital, Alton. *Advice*—X-ray therapy; later, free the contracture, and graft. Three applications X-rays at Warren Road, Guildford.

6.10.45: Operation, Treloar Hospital, Alton. Scarred area across right groin incised and margins allowed to retract. Extended position of hip produced very large raw surface. Thiersch graft in four pieces applied to raw area from same thigh. Flavine emulsion gauze graduated compress. Spica.

20.10.45: All grafts taken well.

5.1.46: Incision across axilla at upper border of scar: Thiersch graft from left thigh. Pressure dressing held by tie-over silk stitches. Crepe bandage: plaster fixation in abduction.

19.1.46: Good take of graft.

21.6.47: Child now exhibits no disability. Grafted areas are sound and supple and all movements are free..

The Brittain Method of Arthrodesis of the Hip

By H. H. LANGSTON, F.R.C.S.

THIS paper is based on a series of 28 cases in which by this method an extra-articular arthrodesis of the hip has been attempted. Apart from Brittain's own cases, the only other recorded groups of cases have been published in America by Knight and Bluhm and by Freiberg.

In 25 cases the operation was performed on patients in whom the hip-joint had been disorganized by tuberculous disease. In three cases the hip was the subject of an advanced or painful osteo-arthritis. Of the 25 T.B. cases, 4 were operated upon before their tenth birthday, 20 were between 10 and 16 years of age and one was a doctor aged 28. There were three cases only in these series for whom the operation was carried out for osteo-arthritis; all three were between 50 and 55 years of age. In two cases bony union was secured. In one case bony union was not obtained, but this patient has been seen recently—four years since operation—and has remained completely free of pain. She has 30 degrees of flexion movement.

In 22 patients sound bony arthrodesis has been obtained. In five, bony union across the hip-joint extra-articularly has not been achieved. One case is too recent for the outcome to be known.

This method of arthrodesis is attractive for the following reasons:

(1) If correctly carried out, a graft bridging the hip-joint can be inserted from femur to ischium well away from the hip-joint as a truly extra-articular procedure.

(2) The graft is also usually well away from any extension of disease from the hip into the bony pelvis as extension downwards into the ischium is less frequently encountered than upward extension of the disease in the ilium. The operation is particularly suitable for cases in which extension of disease in the ilium has produced the so-called "wandering acetabulum".

(3) The method allows of the simultaneous correction of any deformity present at the hip as the result of the disease instead of this deformity having to be corrected at a subsequent operation as is the case in the majority of ilio-femoral methods of arthrodesis.

The Brittain Method of Arthrodesis of the Hip

By H. H. LANGSTON, F.R.C.S.

THIS paper is based on a series of 28 cases in which by this method an extra-articular arthrodesis of the hip has been attempted. Apart from Brittain's own cases, the only other recorded groups of cases have been published in America by Knight and Bluhm and by Freiberg.

In 25 cases the operation was performed on patients in whom the hip-joint had been disorganized by tuberculous disease. In three cases the hip was the subject of an advanced or painful osteo-arthritis. Of the 25 T.B. cases, 4 were operated upon before their tenth birthday, 20 were between 10 and 16 years of age and one was a doctor aged 28. There were three cases only in these series for whom the operation was carried out for osteo-arthritis; all three were between 50 and 55 years of age. In two cases bony union was secured. In one case bony union was not obtained, but this patient has been seen recently—four years since operation—and has remained completely free of pain. She has 30 degrees of flexion movement.

In 22 patients sound bony arthrodesis has been obtained. In five, bony union across the hip-joint extra-articularly has not been achieved. One case is too recent for the outcome to be known.

This method of arthrodesis is attractive for the following reasons:

(1) If correctly carried out, a graft bridging the hip-joint can be inserted from femur to ischium well away from the hip-joint as a truly extra-articular procedure.

(2) The graft is also usually well away from any extension of disease from the hip into the bony pelvis as extension downwards into the ischium is less frequently encountered than upward extension of the disease in the ilium. The operation is particularly suitable for cases in which extension of disease in the ilium has produced the so-called "wandering acetabulum".

(3) The method allows of the simultaneous correction of any deformity present at the hip as the result of the disease instead of this deformity having to be corrected at a subsequent operation as is the case in the majority of ilio-femoral methods of arthrodesis.

(4) Brittain is correct in his contention that as this is a method by which a graft is inserted in compression (as opposed to the tension on the ilio-femoral graft) union in a successfully placed graft is remarkably rapid and solid. Even if bony fusion by graft fails, a satisfactory clinical result may follow from the fact that one has carried out a bifurcation osteotomy. Sir Henry Gauvain showed many years ago that a satisfactory firm fibrous ankylosis and sometimes bony ankylosis could be achieved by this osteotomy alone.

(5) The removal of the pull of the adductors on the hip by the osteotomy is a further advantage and in itself (as Wilkinson has shown) may lead to a rapid alteration and improvement in the radiological appearance of the hip. This was well illustrated in some of these cases.

(6) In this operation no extensive stripping of muscle is necessary and although hæmorrhage and shock need not be a problem in these days, in methods necessitating a Smith-Petersen approach, there is less risk of shock in this method.

(7) Although I advise waiting until a child is at least 10 years of age before carrying out this operation, it has been done with success in a somewhat puny boy of 8, whose home conditions were such that it seemed unlikely that parental care would be good, and that therefore instructions as to protective appliances might not be carried out. I think most orthopædic surgeons feel that an ilio-femoral arthrodesis under 10 to 12 is a somewhat uncertain procedure.

The operation has, however, certain practical difficulties and disadvantages which are not yet fully solved:

(1) The method of insertion of the graft into the ischium is blind. The ischium itself is never exposed and seen. X-ray control of the line of osteotomy is of assistance, but the ultimate making of the cleft in the ischium is blind, and one is entirely dependent on a sense of touch at the end of an osteotome together with such guidance as anatomical points can provide to guide one in the correct line.

(2) The sciatic nerve, lying on the posterior aspect of the obturator internus, gemelli and quadrator femoris, although in a measure protected by these muscles, is probably not much more than ½ in. behind the line which the graft and, still more important, the osteotomes, traverse on the way to the ischium. In a case in which there is any marked degree of flexion deformity present, the nerve may be in serious danger.

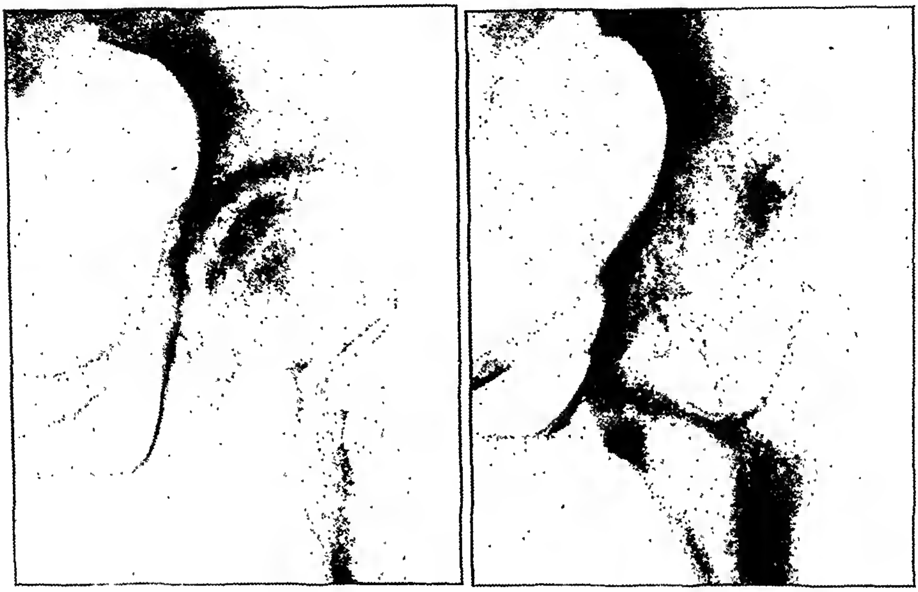
Although in this series of 28 cases there has never been the slightest suggestion of damage to the sciatic nerve, one orthopædic surgeon has told me of a personal case in which a sciatic paralysis was found the day after operation and exploration of the nerve revealed that the graft had transfixed the nerve on its way to the ischium.

(3) I have also been told of a case in which the graft was directed too far anteriorly, apparently into the ilio-pubic ramus through which it passed to perforate the external iliac artery.

(4) Although if the osteotomy is correctly planned and the femur clearly divided without splintering it is not difficult to find the ischium and drive an osteotome into it, it is often much more difficult to make the thicker and softer graft enter the cleft in the ischium, which closes like an oyster once the osteotome is removed.

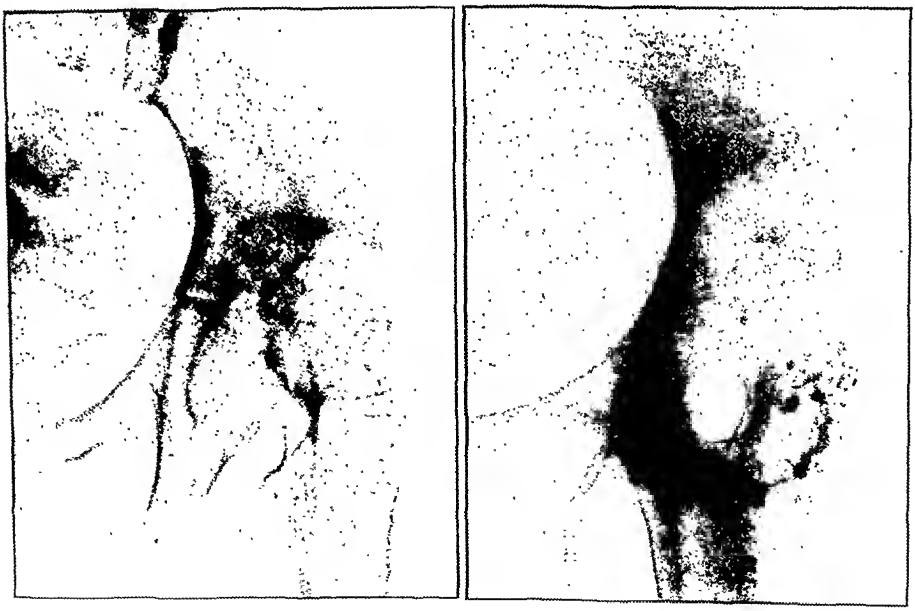
The five failures in this series were all due to this difficulty; in three the graft slipped upwards, possibly into the hip-joint, and in two the graft appears to have perforated the obturator foramen.

Special difficulty is likely to be encountered in cases of long-standing disease where growth of the pelvis has been retarded and the ischium is small and possibly obliquely placed.



A. B.

FIG. 1.—Tuberculous hip. Onset at 3 years of age, arthrodesis at 12½ years. A. Condition at 12½ years. B. Condition four years after arthrodesis.



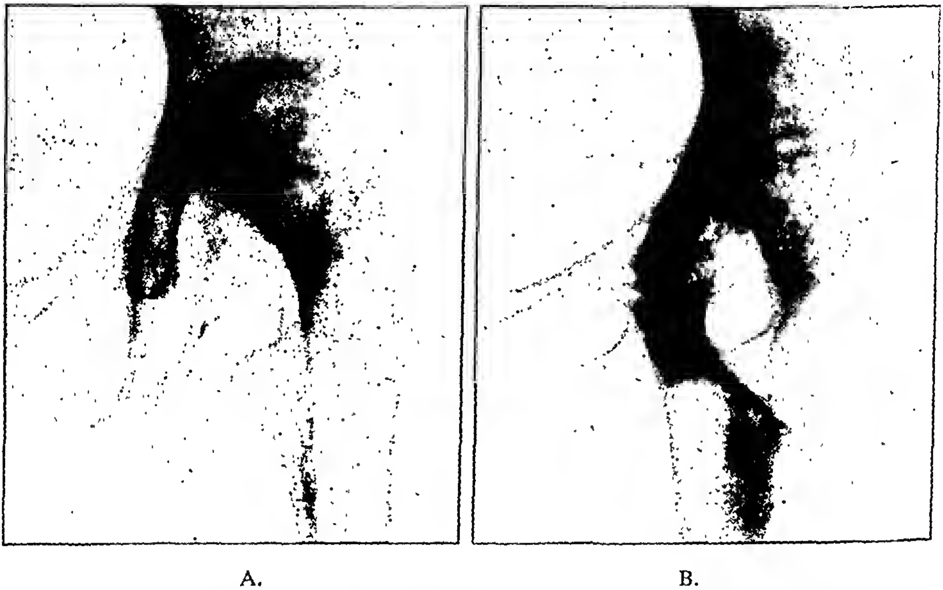
A. B.

FIG. 2.—Tuberculous hip. Onset at age of 7 years, arthrodesis at 14 years. A. Appearance before arthrodesis. B. Three years after arthrodesis.

A few points in technique seem worthy of mention:

(1) It is essential to make the osteotomy in the right line if the graft is to engage satisfactorily in the ischium. I always now therefore insert a Watson-Jones guide wire into the femur before carrying out the osteotomy, planning the line of osteotomy by the X-ray film taken of the hip immediately after insertion of the wire.

(2) The osteotomy must be an absolutely clean cut; any spike on the inner side will lead the osteotome and graft astray—usually into the hip-joint. It is wise therefore to begin one's osteotomy on the inner side, starting with a keyhole saw or the reciprocating blade of the Luck saw, and cut from within outward. This is not difficult if the incision is somewhat to the front of the femoral shaft, allowing a good view of the anterior aspect of the femur.



A. B.

FIG. 3.—Tuberculous hip. Onset at age of 8 years, arthrodesis at 13 years. A. Appearance before arthrodesis. B. Appearance three years after arthrodesis.

(3) Brittain advocates a massive graft including both the anterior and the posterior border of the femur. A wide graft is wise but I do not believe it is necessary to include the anterior and posterior borders, and although I have sometimes done so, my experience has been that it is rather more difficult to get such a graft to lodge securely in the ilium owing to its bulk.

SUMMARY

If the tibial graft can be made to engage correctly in the ischium a rapid and strong arthrodesis of the hip can be obtained by the Brittain method, and obtained at an early date. Even if arthrodesis is not obtained, a fair clinical result will follow from the fact that a bifurcation osteotomy is an essential part of the procedure. The route of approach to the ischium, however, involves risk of damage to important structures, and as far as I can see, no measure has yet been designed whereby this risk can be eliminated with any degree of certainty. The engagement of the graft in the ischium can be difficult, and failure may follow from the graft slipping upward towards the hip-joint or through the obturator foramen.

Section of Obstetrics and Gynæcology

[*June* 20, 1947]

DISCUSSION ON SOME RECENT DEVELOPMENTS IN KNOWLEDGE OF THE PHYSIOLOGY OF THE BREAST

Dr. S. Engel: *Histology of the lactating breast.*—It is common knowledge that physiological function depends on the capacity of an organ to respond to an adequate stimulus. In the case of the breast there is variability in the function of lactation; this may be due either to inadequate capacity of the breast or of lactogenic stimuli. A morphological study of a large number of breasts revealed that the breast does, in fact, show great individual variations in structure which are closely related to its functional capacity.

The methods of investigation were as follows: Sections through the whole breast were prepared, and these gave a good survey of mammary architecture. These sections were about 100μ thick. Thin sections cut from smaller blocks have been used for the investigation of finer details.

There are two features of mammary structure which have an important bearing on the capacity of individual breasts to react to hormonal influences. The first is the variation in the total amount of glandular tissue present in different breasts, and the second the degree of differentiation of this tissue.

First, the total amount of glandular tissue: Investigation of some 80 breasts showed that only 20% to 30% contained glandular tissue in the same abundance as animals such as cows, dogs, guinea-pigs, rabbits and others which were examined for comparison. 30% to 40% contained less than an average amount of glandular tissue. The remainder fell somewhere between these limits.

The percentage of breasts which anatomically appear capable of adequate lactation corresponds closely with that observed in clinical practice. The relationship is closer still when the time for which lactation is maintained is also taken into account.

The glandular tissue is chiefly concentrated at the periphery and in the base of the breast; there is seldom much in the centre.

The features I have described are more easily seen in the lactating than the resting breast as the glands are minute and difficult to study in the latter.

When the glandular tissue is deficient in quantity, the glands themselves are usually poorly differentiated.

In the resting breast, the alveolus is lined by two distinct layers of cells, whereas during lactation there is only one layer. French investigators believe that, during the transition from rest to activity, the large cells of the external layer are reduced to minute dimensions, and the cells of the internal layer become the secretory cells. They consider the reduced cells of the external layer correspond to the cells of Boll in the sweat glands. In my own experience, the external layer consists of large, pale, slightly irregular cells, and the internal layer of regular, small, columnar cells. The cells of the external layer are the precursors of the secretory cells, whereas those of the inner layer represent a kind of protective covering. This is deduced from the observation that shrinkage and desquamation of the cells of the internal layer take place at the very beginning of lactation, and the cells then appear in the colostrum. In the non-lactating breast, the protecting layer serves to retain any small amount of secretion which may occur in the resting breast during menstruation. The abundant peri-acinar lymphatics are the means by which any retained menstrual secretions are removed.

Do menstrual changes occur in the breast? Because of the natural variations in the glandular equipment of different breasts it can be said that there is no rule and menstrual changes may or may not occur.

In sections through breasts of women who died during various phases of the menstrual cycle it is seen that, when they contain an abundance of well-differentiated glands promising satisfactory lactation, there is some alveolar sprouting in the pre-menstruum. On the other hand, in breasts which contain only a few primitive glands, there is no evidence of any response to menstrual influences. Occasionally, there are islets of primitive alveoli in otherwise well-developed breasts, in these cases such islets remain unaffected, although the remainder of the breast shows quite obvious menstrual changes. There can be little doubt that the differences of opinion about the behaviour of the breast during menstruation are accounted for by individual variations in anatomy. More important, since only well-equipped breasts are capable of undergoing changes during menstruation, it is clear that consideration of the behaviour of the breast during menstruation affords an accurate means of predicting its capacity to lactate. It should be emphasized here that neither size nor palpation give any correct indication of the functional capacity of a breast.

Hormone therapy for failure of lactation.—In most cases the failure is due to the scarce and undifferentiated glandular tissue in the breast. In menstruation primitive glandular tissue does not respond to menstrual influences, and the hormones responsible for lactation cannot produce the immense amount of glands necessary for satisfactory lactation. It is, therefore, not surprising if the results of hormone therapy are not always encouraging; the most that can reasonably be expected is that, by these means, a poor breast can be made to secrete a little more for a little longer.

Finally, it has long been held that menstruation is injurious to lactation. The total daily secretion of a number of women was measured by the usual method of test-feeding, and it was found that the relationship between menstruation and lactation was exactly the reverse. Menstruation commenced only when the milk supply had already begun to fail.

Dr. S. K. Kon and Dr. Elinor Huntsman Mawson (*National Institute for Research in Dairying, University of Reading*): *Studies of certain vitamins and other constituents of human milk.*—This short paper deals with some of the salient points arising from an investigation, still unpublished, which lasted for four years and during which more than two thousand samples of milk were examined. The constituents estimated included vitamin A, carotenoids, vitamin B_1, riboflavin, ascorbic acid, fat, total solids and, in a small proportion of samples, lactose, total nitrogen, calcium and phosphorus. Particular attention was paid to the vitamins since less was known about them than about the major constituents of human milk.

The purpose of our investigation was to determine to what extent the vitamin content of milk reflects the state of nutrition of the mother with regard to these factors and to study the influence on the composition of milk of dietary changes brought about by wartime conditions. Owing to the food policy of the Government some of these changes were for better rather than for worse. Since food habits of different populations vary, as, for example, in urban and rural areas, we arranged to study the composition of milk obtained from more than one locality.

The collection of samples from large numbers of women in rural areas was obviously not feasible but Reading, a prosperous town in the centre of an agricultural area, provided a good starting point. It had the additional advantage of being close to the National Institute for Research in Dairying where the investigation was carried out. Regular collection of samples in Reading was begun in the early summer of 1941 and continued until March 1945. In April 1942 financial support from the Medical Research Council ensured continuance of the Reading investigation and enabled us to extend our activities to Shoreditch where samples were collected for us through the kindness of the Medical Officer of Health and his staff. This small section of a great urban area provided a good contrast to Reading. The population of Shoreditch is essentially of the working class, whereas in Reading samples were obtained from most sections of the community—from the wives of business and professional men as well as from those of industrial workers and of some farmers and agricultural labourers. The husbands of many women in both areas were, of course, in the armed forces. During the war Shoreditch was exposed to enemy attack to a much greater degree than Reading.

To compare results it was necessary to learn to what extent the composition of milk was influenced by factors other than diet. Such factors include the time of day, the stage of lactation, milk yield, the age and parity of the mother.

To study the composition of milk in early lactation a special series of samples was obtained from Paddington Hospital through the kindness of Dr. G. M. Gray and Professor

W. C. W. Nixon. We can mention only very briefly those aspects of these findings relating to work which we will describe in greater detail.

FAT

The fat content is particularly difficult to determine on account of the sampling errors to which it is subject. Those who have obtained human milk by manual expression will have noticed that at first it is blue and watery but as the breast is emptied it becomes more and more creamy in appearance. Chemical analyses confirm that the first milk is poor in fat while the strippings are very rich. When samples are to be examined for fat all the milk in the breast should be obtained but in practice it is not always easy to determine whether or not the breast has been completely emptied.

The fat content of milk is also influenced by the interval elapsing since the baby's last feed. It is obvious that samples taken immediately after feeding will be very rich in fat. As the interval after feeding increases the fat content decreases. Thus the fat content of samples taken at 6 a.m. is less than that of samples taken during the rest of the day. Studies of fat content would be best carried out on a complete expression of all milk secreted during twenty-four hours but as this is rarely practicable we have used a standard procedure of obtaining milk during the morning from breasts used four to six hours previously. We realize, however, that, owing to the difficulty of ensuring complete emptying of the breast, our results are not free from sampling errors.

The fat content of Shoreditch samples proved less than that of Reading samples. We are unable to give an explanation for this but in view of the difficulties just discussed it is doubtful whether the difference is of nutritional significance.

VITAMIN A AND CAROTENOIDS

Results obtained for vitamin A and carotenoids, which are fat-soluble, naturally vary with the fat content and when this is in error they will also be incorrect. In considering results for groups of women we have therefore preferred to express our values for these constituents in terms of concentration in the milk fat. This cannot be done for individual women, however, on account of individual variations in fat content.

In early lactation the vitamin-A and carotenoid content of milk fat, high at first, decreases rapidly. This is well known, especially for carotenoids since it can be observed visually. In later lactation the carotenoids soon reach a steady level but the vitamin A continues to decrease though more slowly. As our samples were taken at different stages of lactation it was necessary to introduce a correction for this before making comparisons. This was done in calculating the yearly mean values for Reading and Shoreditch. During the course of our investigation the vitamin-A content of the fat of milk samples from Reading remained unchanged. From a dietary point of view this was expected since the amount of preformed vitamin A available for consumption by nursing mothers did not alter greatly during this time. A special cod-liver oil supplement was given to pregnant women early in 1943 but this did not affect the vitamin-A content of the milk they later produced. On the other hand, the mean vitamin-A content of the milk fat of 41 Reading women who took supplements of vitamin A during lactation was significantly higher than that of all samples examined. The vitamin-A content of milk fat from Shoreditch women in 1942–3 and 1943–4 agreed well with that found at Reading but in 1944–5 there was a very appreciable drop for which we have been unable to find a dietary explanation. At the same time there was a less marked fall in carotenoids.

It should be mentioned that the carotenoids of human milk consist largely of xanthophylls and other pigments with little or no vitamin-A activity so that from a nutritional point of view they are almost negligible.

Those who are familiar with the marked seasonal variation in the vitamin-A content of cow's milk may be interested to know that no comparable change took place in our experience with human milk. There was, however, a seasonal difference in carotenoid content.

VITAMIN B_1

The vitamin-B_1 content of milk undergoes a marked change in early lactation. It is very low to start with and increases rapidly to the fifth week after which it remains more or less steady. It is obvious that results for early lactation samples cannot be compared with those for mature milk and in making comparisons we have used only samples taken from the fifth week onward.

In 1941 when our Reading investigation was begun, white bread was still on the market and it was not until April 1942 that the national wheatmeal loaf superseded it. The increase in the amount of vitamin B_1 in the national diet resulting from this change was accompanied by a proportionately smaller though significant increase in the vitamin-B_1

content of Reading milk samples. Unfortunately there were no Shoreditch results for the period in which white bread was consumed but the mean values for subsequent years were similar to those from Reading.

RIBOFLAVIN

The riboflavin content of milk, like the fat content, is subject to sampling errors. This is because the ingestion of riboflavin by the mother is rapidly followed by a rise in the riboflavin content of the milk. Samples taken at 6 a.m. give a low result because they are little influenced by meals and higher results are found for samples taken later in the day. Collection of all milk secreted during twenty-four hours, if possible, would be most suitable for the measurement of riboflavin but even then it would be important to ensure that on the day of the test no food rich in riboflavin and not normally consumed is included in the diet. As samples taken at 10 a.m. from breasts used four hours earlier give results which are roughly the same as the mean for the whole day we have used this procedure as the only possible one for making our comparisons.

The riboflavin content of milk from Reading and Shoreditch women remained almost constant during three years. The Reading values were consistently higher than the Shoreditch ones but the difference, although statistically significant, was not very marked. We prefer not to lay too much stress on it since the possibility cannot be excluded that the riboflavin content of breakfasts at Reading was higher than at Shoreditch and that Shoreditch women may have made up for this later in the day.

VITAMIN C

Before our investigation was begun there was already a considerable amount of published information about the vitamin C of human milk—almost all of it from other countries. We have confirmed previous findings that a high proportion of a mother's intake of vitamin C is secreted into her milk and that consequently lactation makes a considerable drain on her reserves. Just how seriously this should be regarded depends on one's views concerning the requirement of adults for vitamin C. At any rate Nature has made ample provision for the child and there seems to be little need for giving extra vitamin C to the breast-fed infant unless the mother is very poorly supplied with it, and even then the need of the mother will probably be greater than that of the child.

In July 1941 the vitamin-C content of milk from Reading was low but it rose rapidly and remained more or less at the higher level until December after which a marked fall occurred. The same trends were repeated at both Reading and Shoreditch in the following year. During these two years the country was largely dependent on native fruits and vegetables for vitamin C and the low values (2 to 3 mg./100 ml.) in January, February and March can be explained by a shortage of green vegetables and the seasonal decline in the vitamin-C content of potatoes. Oranges became available in March 1943 at Shoreditch and in April at Reading and doubtless accounted for the small rise observed in each case. In the early months of 1944 many more oranges came on the market and consequently the low levels of vitamin C observed in previous years were not repeated. Shoreditch values did not differ very greatly from those for Reading despite the fact that many Reading people grow their own vegetables.

SUMMARY OF RESULTS

Table I gives a summary of our results for the composition of human milk. Values for the fat content are shown separately for Reading and Shoreditch because of the difference already mentioned. No general mean can be given for total nitrogen on account of the well-known change with stage of lactation. Values given are for the 5th to 8th, and 21st to 24th weeks. On the whole our results for the major constituents, which were obtained in collaboration with Dr. S. J. Rowland, agree well with those of other workers.

The value given for vitamin A has been corrected for the stage of lactation to represent that in the 17th week. No chemical method is available for vitamin D and the values given were obtained by Dr. K. M. Henry by biological tests. No general mean for vitamin B_1 can be given because of the change during our investigation but combined yearly means for Reading and Shoreditch are quoted instead. The riboflavin values used in obtaining the means were for morning samples as already described. The mean for vitamin C is based on a much larger number of samples as no special sampling precautions were needed.

An estimate of the amount of vitamins which a baby is likely to obtain from breast milk or from cow's milk shows that the breast-fed baby will get more vitamin A and vitamin C but much less vitamin B_1 and riboflavin.

DIETARY SURVEYS

It was of course of great interest to have information about the nutrient content of the diets of the women whose milk we examined. This was not possible on a large scale but three surveys were made for us at Shoreditch by Dr. H. M. Sinclair, by Dr. E. R. Bransby and by The Social Survey. All three gave very similar results. The diets of many of these women contained fewer calories and less calcium and vitamin A than is usually considered desirable for lactating women. The intake of calcium may have been higher than shown by the Surveys since it was not possible to take into account that obtained in the drinking water. Examination of the actual amounts of food consumed showed that full advantage was not taken of the extra allowances of foodstuffs for lactating women. Thus few women took more than one pint of milk daily whereas they could have had two pints if they had wished. It is clear therefore that our results for Shoreditch are representative of women consuming diets poorer in quality and quantity than wartime conditions warranted. Unfortunately dietary surveys were not possible at Reading so we have no data for comparison.

Our grateful thanks are due to all those people whose help made this investigation possible.

Dr. S. J. Folley (*National Institute for Research in Dairying, University of Reading*): *Recent researches on the physiology of mammary development and function.*—The first requisite for successful lactation is the existence of adequately developed mammary glands. This, in the last analysis, presupposes the presence of a sufficiency of histologically normal alveolar tissue, comprising the structural elements which synthesize milk constituents, in a functional condition. The presence of an adequate system of milk ducts, and, in animals such as the ruminants, gland cisterns, is also assumed. It is thus pertinent to begin a brief survey of recent work on the physiology of milk secretion with a consideration of mammary growth.

As is now well known, mammary growth is under the control of the ovarian hormones, œstrogen and progesterone. For the present purpose there is no need to consider the question whether these sex hormones act directly on the mammary tissues, or whether the ultimate effective agents are specific mammogenic hormones secreted by the anterior pituitary in response to stimulation by sex hormones, as claimed by Turner and his school. Unfortunately it is not possible to make any satisfactory generalization regarding the respective roles of œstrogen and progesterone in mammary growth, since experiments on various species have revealed quite striking species differences. We may, however, briefly summarize the main experimental findings as follows:

In some species, such as the mouse, rat, and rabbit, œstrogen alone, at any rate in physiological doses, evokes growth of the duct system but little or no alveolar development. In order to produce the latter, combined treatment with œstrogen and progesterone is necessary. In other species, of which a notable example which has long been familiar is the guinea-pig, œstrogen alone is capable of evoking the growth of duct and alveolar tissue alike. In short, it can develop a gland which, under suitable conditions, is able to produce considerable quantities of milk, as evidenced by the fact that male guinea-pigs, in which mammary growth has been brought about by treatment with œstrogen, will rear young. It has been claimed that the same is true for the monkey, though in this case all workers are not unanimous as to whether or not the amount of alveolar growth produced by œstrogen treatment, particularly in the male, is very extensive. The gland of the female monkey seems to be more responsive as far as alveolar growth is concerned.

content of Reading milk samples. Unfortunately there were no Shoreditch results for the period in which white bread was consumed but the mean values for subsequent years were similar to those from Reading.

RIBOFLAVIN

The riboflavin content of milk, like the fat content, is subject to sampling errors. This is because the ingestion of riboflavin by the mother is rapidly followed by a rise in the riboflavin content of the milk. Samples taken at 6 a.m. give a low result because they are little influenced by meals and higher results are found for samples taken later in the day. Collection of all milk secreted during twenty-four hours, if possible, would be most suitable for the measurement of riboflavin but even then it would be important to ensure that on the day of the test no food rich in riboflavin and not normally consumed is included in the diet. As samples taken at 10 a.m. from breasts used four hours earlier give results which are roughly the same as the mean for the whole day we have used this procedure as the only possible one for making our comparisons.

The riboflavin content of milk from Reading and Shoreditch women remained almost constant during three years. The Reading values were consistently higher than the Shoreditch ones but the difference, although statistically significant, was not very marked. We prefer not to lay too much stress on it since the possibility cannot be excluded that the riboflavin content of breakfasts at Reading was higher than at Shoreditch and that Shoreditch women may have made up for this later in the day.

VITAMIN C

Before our investigation was begun there was already a considerable amount of published information about the vitamin C of human milk—almost all of it from other countries. We have confirmed previous findings that a high proportion of a mother's intake of vitamin C is secreted into her milk and that consequently lactation makes a considerable drain on her reserves. Just how seriously this should be regarded depends on one's views concerning the requirement of adults for vitamin C. At any rate Nature has made ample provision for the child and there seems to be little need for giving extra vitamin C to the breast-fed infant unless the mother is very poorly supplied with it, and even then the need of the mother will probably be greater than that of the child.

In July 1941 the vitamin-C content of milk from Reading was low but it rose rapidly and remained more or less at the higher level until December after which a marked fall occurred. The same trends were repeated at both Reading and Shoreditch in the following year. During these two years the country was largely dependent on native fruits and vegetables for vitamin C and the low values (2 to 3 mg./100 ml.) in January, February and March can be explained by a shortage of green vegetables and the seasonal decline in the vitamin-C content of potatoes. Oranges became available in March 1943 at Shoreditch and in April at Reading and doubtless accounted for the small rise observed in each case. In the early months of 1944 many more oranges came on the market and consequently the low levels of vitamin C observed in previous years were not repeated. Shoreditch values did not differ very greatly from those for Reading despite the fact that many Reading people grow their own vegetables.

recent experimental findings on galactopoiesis are thus presented as likely to be of interest to clinicians.

The discovery of the anterior-pituitary lactogenic hormone, by Stricker and Grueter (1928) and its subsequent characterization by Riddle and his collaborators as a pituitary hormone distinct from other pituitary hormones then known, and specific in its capability of causing growth and secretion of the pigeon crop-gland (a response now used for its biological assay), aroused interest in the possibility of stimulating lactation, particularly in cows and women, by anterior-pituitary extracts. With the development of methods for the partial purification of prolactin, methods which have been perfected to the point at which they now yield prolactin as a pure protein, there was some tendency to assume that purified prolactin preparations would prove more efficient as galactopoietic agents than unfractionated anterior-pituitary extracts. Extensive experiments on cows (*see* Folley and Young, 1940, 1945) have, however, shown that far from this being the case, unfractionated ox anterior-lobe extracts give considerably greater galactopoietic responses in cows in declining lactation, for a given unitage of prolactin as measured by the pigeon crop test, than partially purified prolactin preparations. Indeed, investigations on lactating cows with a series of anterior-pituitary extracts with various combinations of biological properties have revealed very little correlation between their respective prolactin (pigeon crop stimulating) and galactopoietic activities, though there was an interesting and fairly close relationship between the latter and the influence of these extracts on carbohydrate metabolism. In fact, the galactopoietic activity of anterior-pituitary extracts appears to be due to a complex of anterior-pituitary hormones, of which two important and essential members seem to be prolactin and adrenotrophin. With crude saline extracts of ox anterior pituitary, substantial, though temporary, increases in the milk yield of cows in declining lactation could be obtained, even in response to single subcutaneous injections. With repeated injections a more sustained, but still temporary, response is obtained.

In view of the fact that purified prolactin preparations have been and are being used for the treatment of hypogalactia in women, it may be of interest to consider the bearing of these experiments on cows on the clinical use of prolactin. Such clinical experiments with prolactin as have been reported have given variable and sometimes quite disappointing results. When it is remembered, however, that prolactin preparations for clinical use are standardized solely in terms of prolactin activity by means of the pigeon crop-gland response, the lack of unanimity on the efficacy of prolactin for the correction of hypogalactia is perhaps not surprising in view of the above-mentioned results in cows. This is quite apart from the fact that many cases of deficient lactation may not be due to under-secretion of pituitary hormones. It therefore seems logical to suggest that clinical trials should be carried out with crude saline extracts of ox anterior pituitary, similar to those which have been uniformly found (*see* Folley and Young, 1945) to give galactopoietic responses in cows, prepared under conditions which should ensure the presence in the extracts of all members of the galactopoietic complex of hormones. As has been pointed out, the lactating woman is surely more analogous physiologically to the cow in declining lactation than to the pigeon, and it would seem desirable that anterior-pituitary preparations intended for treatment of hypogalactia in woman should be assayed for galactopoietic activity by a mammalian test.

Finally, we may consider a further endocrine relationship, the study of which has resulted in the development of a galactopoietic agent which, on account of its cheapness and ease of preparation, will no doubt prove to be of considerable practical importance in the dairy industry. It should therefore be of interest to the clinician.

The thyroid gland by virtue of its well-established role as a regulator of body metabolism, might be expected to influence lactation in so far as the rate of milk synthesis by the mammary gland cells must tend, within limits, to increase as the metabolic rate increases.

Experiments on the effects of thyroidectomy on lactation have for various reasons given results which are difficult to interpret. Consideration of the relevant literature indicates that while lactation is possible in the absence of the thyroid, the milk yield is subnormal and the lactation period tends to be shortened.

The effects on lactation of administration of thyroid hormone are, on the other hand, less unequivocal. As long ago as 1896 Hertoghe, a Belgian clinician, observed a galactopoietic effect in a lactating cow as a result of thyroid feeding. Modern work on the subject dates from the experiments of Graham (1934) and since then numerous workers have confirmed the fact that feeding dried thyroid gland or injection of crystalline thyroxine causes a marked but temporary increase in the milk yield of lactating cows, which subsides after the treatment is discontinued. The main features of the galactopoietic effect resulting from thyroid treatment may be summarized as follows:

The increase in milk yield during the period of treatment is considerable and may (e.g. *see* Folley and White, 1936) amount to almost as much as 30% above the basal level. Over-

The most spectacular results coming under this category, however, have been obtained in ruminants. As far back as 1938, de Fremery showed that treatment with natural œstrogens would produce considerable udder development in virgin goats, and later experiments with synthetic œstrogens in our laboratory (e.g. *see* Folley and Malpress, 1944) and elsewhere have shown that not only in the virgin goat, but in the virgin heifer as well, suitable œstrogen treatment will cause the growth of udders capable in many cases of secreting economically important yields of milk. Most of these experiments were performed on goats and cows with intact ovaries, the possibility of the intervention of ovarian progesterone thus not being excluded. Sufficient experiments have now been done on ovariectomized ruminants to indicate, however, that successful results do not depend on the presence of the ovary, and we may therefore take it as an established fact that in the ruminant, œstrogen will bring about the development of both duct and alveolar tissues. The question whether the alveolar tissue so developed is normal in structure and amount is of course of prime importance, and will be dealt with in a moment. No satisfactory data exist for man, but if it is possible to argue by analogy with the monkey, it might be expected that in man also œstrogen alone would be capable of producing some alveolar development in addition to duct development.

As regards growth-promoting action on the mammary gland it was generally believed that progesterone alone was without effect. Recently, however, it has been shown that, provided large daily doses are given, growth of both ducts and alveoli can be obtained in the rat and mouse.

It is necessary at this point to turn to the consideration of functional aspects, since the lactational performance of an experimentally developed gland may depend, to a considerable extent, on the normality or otherwise of its histological structure. The main findings in extensive experiments on maiden heifers do indeed indicate the need for further morphological studies. The lactational responses, as measured by maximum daily and by total lactation yields of milk, varied widely among similar animals receiving identical or nearly identical treatment. Moreover, though the animals which responded best gave yields which can be considered as being of the same order as those which would have been expected from these animals had they become pregnant in the normal way, such responses were exceptional, and in general the response was not quantitatively comparable to a normal lactation. This at once raises the question of whether such experimentally developed glands are normal in structure, and it seems possible that some additional endocrine stimulus, the most obvious possibility being of course progesterone, acting in conjunction with the administered œstrogen, is necessary for the artificial development of glands capable of yielding amounts of milk such as would be obtained in a normal lactation.

And indeed, studies by Mixner and Turner (1943) on virgin goats indicated that the structure of the glands developed in response to œstrogen alone was abnormal in that the alveoli were excessively large in diameter, perhaps even cystic, and exhibited a tendency to papillomatous folding or puckering of the alveolar epithelium. On the other hand, in goats which received progesterone in addition to œstrogen, the mammæ were more normal histologically and the alveoli smaller in diameter. However, the histological technique used by these authors was hardly adequate for a critical study of the structure of large mammary glands. This question is now being investigated in our laboratory, in collaboration with Mr. K. C. Richardson, on a much more extensive scale with specially devised histological techniques involving, in particular, fixation by intravascular perfusion and collodion embedding and sectioning of the whole gland, the object being to probe more searchingly than hitherto the endocrine mechanisms involved in udder development in the goat. This investigation, which will utilize many expensive, specially bred goats, and very large quantities of progesterone, is as yet only in its preliminary stages, and all that can be said at present is that our findings confirm and considerably extend those of previous workers to the effect that the gland developed under the influence of œstrogen alone exhibits alveoli with excessively wide lumina, while combined treatment with œstrogen and progesterone in a ratio found to give optimal alveolar growth in experiments on small animals, gives a more nearly normal histological picture but sometimes a smaller gland.

So far in dealing with the function of the mammary gland, consideration has been confined to the phenomenon which we may describe as *lactogenesis*—the initiation of lactation. In the present state of knowledge and for clarity of discussion, it has been suggested (Folley and Young, 1940) that an allied but not necessarily identical phenomenon, the stimulation or augmentation of lactation already established, shall be described as *galactopoicsis*. It seems probable that the treatment of deficient lactation in women falls under this latter heading, since in most of such cases lactation has been initiated but the milk yield has failed to reach a level necessary for the adequate suckling of the infant. Some

JOINT DISCUSSION No. 3

DISCUSSION ON SOME ASPECTS OF SURGICAL AND RADIOLOGICAL TREATMENT OF CARCINOMA OF THE CERVIX

The Evaluation of the Results of Carcinoma of the Cervix Uteri Treated by Radical Vaginal Operation. [*Abridged.*]

By Professor SUBODH MITRA, F.R.C.S.Ed., F.R.C.O.G. (*Calcutta*)

During the Third International Radiological Congress in Paris (1931), when I submitted my five-year statistical end-results of carcinoma of the cervix uteri treated with radiation therapy, I found that Continental surgeons performing the radical vaginal operation in similar cases, and Adler of Vienna, by combining this operation with post-operative radiation, had obtained very satisfactory results. Although the general trend of opinion is in favour of radiation therapy for carcinoma of the cervix, the surgical treatment still occupies a definite place. Moreover, some workers who were previously converts of radiation therapy are coming back to surgery supplemented by post-operative radiation. An analysis of world statistics shows that whatever method be followed (operation or radiation), the end-results are, for all practical purposes, the same in the hands of experts. It has been proved beyond doubt by proper classification of cancer cases, and by obtaining data for operability rate, relative cure rate, absolute cure rate as well as by five-year and ten-year salvages that whatever method be applied, practically identical results are obtained with a small percentage of variation which may be a chance variation. It is the general belief that radiation therapy is much easier than surgery, but it is very difficult to check and control whether radiation therapy has been properly executed or not. Experts are of opinion that "properly performed radium therapy is as difficult to learn as the operation itself" (Adler).

In 1932 I started the radical vaginal operation supplemented by post-operative radiation.

Radical vaginal operation.—I have taken up the radical vaginal operation instead of the radical abdominal for the following reasons:

(1) The primary mortality is much less. Out of 151 patients operated on, 6 died, i.e. a primary mortality of 3·97% as against an average of 14% by the radical abdominal method.

(2) Stocky, plump and adipose patients can be more effectively tackled by the vaginal route.

(3) Complications of the nature of uretero-vaginal fistulæ are much less frequent after vaginal operation than after the abdominal. Even in the hands of some experts, this complication may occur to the extent of 12·3% after Wertheim's operation.

(4) The end-results after Wertheim's radical abdominal operation and Schauta's radical vaginal operation are practically the same. In my series there is 37·6% relative cure rate as against 39% of Bonney's series.

(5) The percentage of recurrence does not differ greatly after the two methods of operation, abdominal and vaginal. Kamniker, after making an extensive analysis of the materials of the 1st and 2nd Universitaets-Frauen Klinik in Vienna, has found 55% local and 30% glandular recurrences in Schauta's operation against 69% local and 26% glandular in Wertheim's operation.

(6) The greatest handicap to the radical vaginal operation is that cancer-affected lymph glands cannot be removed. It has been authoritatively worked out by Bonney, Taussig and others that there is glandular involvement in from 35–40% of all patients presenting themselves for carcinoma of cervix. Bonney claims that 23% of cases with gland involvement have passed through a five-year salvage, although the total relative cure-rate is 39%. Almost the same relative cure-rate has been found in my series of radical vaginal operation without removal of glands. Heyman's series give still better results (absolute cure rate

dosage with thyroid preparations leading to a condition of marked hypermetabolism may on the other hand decrease the yield. *Pari passu* with the enhancement of the milk yield, increases in both the percentages of fatty and non-fatty fractions of the milk solids have been observed. The increase in the non-fatty solids content is at the best slight and has not been uniformly reported; the fat content undergoes a more marked increase, however, sometimes to such a degree as to result in a 50% increase in the daily fat yield (Folley and White, 1936). These galactopoietic responses are slight or absent in cows treated during early lactation, and are most in evidence during the lengthy period of slow decline from the peak yield.

This work assumed importance from the point of view of wide-scale practical application in the dairy industry, when Ludwig and von Mutzenbecher (1939), following up the scattered observations of many earlier workers, showed that treatment of certain proteins, such as casein, with iodine under mildly alkaline conditions, produced iodoproteins which exhibited thyroid activity by the oral route, and from which thyroxine could be isolated after hydrolysis.

Since iodocasein can be made relatively easily from materials readily available it is evident

compensation.

Clinical reports on hormones for the stimulation of lactation in women have not always been favourable. In fact, some clinicians have advocated thyroid treatment for the suppression of unwanted milk secretion! Nevertheless, in view of the large amount of information we now possess regarding the galactopoietic effect of thyroid preparations in cows, further clinical trials, keeping the necessity for careful control of dosage in mind, would appear to be justified.

Relative 5-year cure rate ..	37·6%	40·0%	36·0%
Relative 10-year cure rate ..	—	—	24·5%

TABLE VI.—COMPARATIVE 5-YEAR CURE RATE DURING THE SAME PERIOD, 1932-1940

	Operation %	Radiation %
Stage I	61·5	66·0
Stage II ..	44·0	31·5
Stage III ..	15·6	12·6
Stage IV ..		2·3

	%
Absolute 5-year cure rate ..	12·9
Absolute 10-year cure rate ..	9·4

Unfortunately I cannot give an absolute cure rate of my cases from 1932 as the patients cannot be grouped under one particular method of treatment. Result will certainly be vitiated if an attempt be made to find out an absolute cure rate of operation cases against the bulk of remaining cases treated by radiotherapy.

My results from radiation therapy from 1926 to 1932 are as follows: the relative five-year cure rates are at 53·4% of Stage I, 37·5% of Stage II, 9·4% of Stage III, 1·7% of Stage IV. The absolute cure rate is at 12·9% after five years and 9·4% after ten years.

It is evident that the results of radiation are not so striking as those of operation. My hospital cannot afford to give free treatment to all cases thereby losing many early cases. The patients are mostly poor and irresponsible. 18·3% did not take the complete course of treatment either because they could not afford it or because they thought they were cured in spite of repeated warnings to the contrary. Moreover there being no arrangement for registration system, patients once changing their residence could hardly be traced. Follow-up is difficult as war, famine, flood and communal disturbances have dislocated civil life. If I take a relative cure rate of only those cases who have taken a complete course of treatment, the results will be 14·9%, which stands comparable with the results of other workers.

CONCLUSION

We have, as yet, got no remedy for advanced cases. Operable cases yield satisfactory results up to a certain limit whatever method is followed provided treatment be given efficiently and with meticulous precision. It is only by the detection of early cases and centralization of patients in special cancer clinics that we can markedly improve our end-results.

Mr. Charles D. Read (*London*): In any discussion on the subject of the treatment of carcinoma of the cervix, division of opinion invariably centres around the relative merits of radiation and radical surgery. This generally applies only to those cases coming within the category of stages one and two. There is agreement that almost all cases in stages three and four are unsuitable for treatment by radical surgery, though even in these cases it is possible to treat some by a combination of surgery and radiation.

We have various forms of treatment for carcinoma of the cervix by irradiation and surgery, and I submit that the correct method of treatment of any particular case is dependent upon the clinical features presented by the actual patient under consideration. Apart from the degree of advancement of the growth, its clinical type, the age of the patient, the presence of a cardiac or renal lesion, adiposity, and the general clinical condition of the patient, all constitute factors for careful consideration.

I have had no experience of the radical vaginal operation, having early dismissed it because of its neglect of attack on the gland-bearing area. Bonney has proved that in 40% of cases the glands are involved, so the Schauta operation cannot hope to benefit these cases. In addition gland involvement is irregular and does not depend on the degree of advancement of growth. However, I have had some experience with radiotherapy and with Wertheim's radical abdominal operation. My late chief, Mr. Victor Bonney, has, to date, operated upon over 500 cases, and can show a five-year survival rate of 40–43% following the Wertheim operation. With few exceptions he operated on all cases where removal of the growth was technically possible and of course this included many Stage 3 growths. His operative mortality was 14% over this series, and he did not combine radiotherapy with his operative measures.

On careful scrutiny of the results of any large series of cases treated either by irradiation or by radical surgical procedures, one is forced to ask "Could any of the unsuccessful irradiation cases have been saved by surgery?" and likewise, "Could any of the unsuccessful surgical

33·1%) without any surgical removal of glands. Schauta is of opinion that radical removal of glands is possible only in occasional cases; because when the iliac glands, which may be removed, are involved, the aortic group of glands, which are not surgically approachable are already carcinomatous. Some of the carcinomatous glands are bound to be overlooked because of their small size. Wertheim's opinion is that extirpation of the lymph glands can contribute nothing towards the improvement of end-results. According to Doederlein: "It is certainly more important in improving the operation for carcinoma, to extend the excision so as to take away the parametrial and paravaginal tissue with the uterus than to place too much hope for betterment in the extirpation of glands". The greater part of the lymphatic vessels infiltrated in a cervical carcinoma run with the uterine veins in the transverse cervical ligaments of Mackenrodt lying at the base of the broad ligament and extending from the uppermost part of the vagina and from the cervix to the lateral pelvic wall. When these lymphatic channels are infiltrated with carcinoma, cancer cells are well isolated from the rest of the body by the connective tissue sheath of the ligament. The spread of carcinoma is slow in this location because of the marked tissue-pressure. Once the cancer cells pass beyond the connective tissue bundle of Mackenrodt, they extend into loose subserous connective tissue: the prospects are no longer good, even if the lesion may be found operable from the technical point of view. But fortunately cancer cells remain shut up in Mackenrodt's ligaments for a considerable time and then spread slowly. This slow permeation is the reason why cervical cancer is a relatively favourable type of tumour for operation.

The logical conclusion naturally follows that in operations of cervical carcinoma, the most radical possible excision of the parametrial and paravaginal tissue should be made including also a wide cuff of vagina.

The abdominal route was preferred originally because great hopes were placed in the removal of the glands: the excision of parametrial tissue was never considered as important as the removal of lymphatic glands.

The surgeon, expert in vaginal technique and thoroughly conversant with the surgical anatomy of the pelvis, can remove a greater amount of parametrial, paravaginal, paravesical and pararectal connective tissue by the vaginal route with Schuchardt's incision than by the abdominal route. In my series, parametrium has been removed to the extent of about 2½ in. from each side.

(7) Lastly, the radical vaginal operation facilitates the introduction of radium in the parametrial tissue immediately or shortly after operation.

Professor Mitra next described the details of the technique of the extended vaginal operation. He then went on:

Post-operative complications.—Six patients died, the primary mortality being 3·97%; 3 patients died of shock, one of pulmonary embolism on the fourteenth day, one of pneumonia, and one of staphylococcal septicæmia.

The bladder was injured in 6 patients, of whom two required an operation for perfect recovery, whereas the fistula healed up spontaneously in 4 other cases. In 1 case the ureteric wall was so thinned out during dissection that it was almost on the point of bursting, but by careful stitching of the outer coat nothing untoward happened. In 3 cases there was injury to the rectal wall, due to a Schuchardt's incision, but it healed spontaneously. In 23% of the patients the perineal incision did not unite by first intention but later on healed by granulation.

B. coli infection occurs in about 54% of cases during the post-operative period. In 4 of my cases pyometra was present.

TABLE I

RECURRENCES AFTER OPERATION

After	Local	Glandular
Schauta's (vaginal) ..	55%	30%
Wertheim's (abdominal)	69%	26%

TABLE II

Operability rate	57·7%
Total No.	151
Primary mortality	3·97%
Relative 5-year cure	37·6%
Relative 10-year cure	24·5%

Statistical analysis.—For the assessment of statistical results three things are essential, viz. operability rate, relative cure rate and absolute cure rate. For the last twenty years I have been classifying my cases according to the League of Nation's formula and since 1932 operation has been undertaken as a side-chain to radiotherapy. Materials for operation were taken not only from Stages I and II but also from Stage III. Thus 42·6% of Stage I, 28% of Stage II and 5% of Stage III cases were operated upon and the rest were treated with radiation therapy. Patients were given a free choice and operation was performed only on willing patients although I have found out by careful scrutiny that 57·7% of all cases could have been operated on (*see* Tables II, III, IV, V, VI).

Results of Wertheim's Operation at the Chelsea Hospital for Women for the Years 1936-1941 Inclusive

	Stage 1	Stage 2	Stages 1 and 2
Number of cases treated..	34	20	54
Number alive at end of five years	14 — 41%	10 — 50%	24 — 44%
Lost in follow up	5	1	6
Number alive after five years excluding lost cases	14 — 48%	10 — 53%	24 — 50%
Operative deaths			3
Operative mortality			5·5%

Admittedly this is a very small series, but it does show that 54 consecutive Wertheim operations can be performed on Stages 1 and 2 cases by the various members of the staff with only three operative deaths. During the years 1936–1941 the cases for surgical treatment were not selected so conservatively as they are now, and in only relatively few cases was radiotherapy combined with surgery.

My own results of the combined approach are as yet too small in numbers and too recent in time to allow of useful analysis, but it is hoped at some later date to be able to show an improvement in the figures already shown.

I feel I must refer to the combined use of surgery and radiation in selected Stage 3 cases. On a number of occasions, after preliminary irradiation with the full Stockholm technique locally to the cervix, I have opened the abdomen, removed the appendages, and then performed a careful dissection of the iliac and obturator glands as in the Wertheim operation, but of course leaving the uterus in situ. This is followed by a full course of deep therapy. Time alone will assess the results, but to date the operative mortality has been nil.

The Radiological Treatment of Carcinoma of the Cervix Uteri

By G. E. Richards, M.D.
(*Director, Ontario Institute of Radiotherapy;
Professor of Radiology, the University of Toronto*).

Recently a number of writers on the subject of the treatment of cancer of the cervix have disparaged the use of radiotherapy and in the United States a number of surgeons have advocated a return to surgical methods. J. V. Meigs [1] has made the statement that "the treatment of cancer of the cervix by radiation is at a standstill". It may, therefore, be profitable to inquire how the best results obtainable by surgery compare with the best results obtainable by radiotherapy and whether the available evidence supports the statement that radiotherapy is static.

I. Comparison with Surgery

As has frequently been pointed out the work of Bonney in England and of Taussig in America provides, at least up to the present, the best results which have been attained by surgery. New methods of combating the post-operative complications of shock and infection may result in lowering the immediate death-rate following operation, but since the female pelvis does not lend itself to a true block dissection it will remain to be seen whether an improvement can be effected in end-results.

If a comparison is to be made of the results capable of being achieved by the two methods it is essential to compare the best results being secured by each. That this is not always done is evident from Meigs' paper already quoted in which, speaking of Taussig's operative results, the following statement is made: "Of 70 patients in Class II of the League of Nations Classification, 37% were living and well after five years. In a parallel group of 118 patients treated by radiation alone the five-year salvage was only 23%." The latter figure certainly does not represent the best results which may be secured by radiation, as will be shown presently. Bonney is reported to have operated upon 500 patients out of a total of approximately 900 diagnosed as cancer of the cervix. His five-year cure rate is stated to have been 40% for those in whom no glandular extension had occurred and 22% for those in whom lymph-node involvement was present—in other words, 40% for Stages I and II; 22% for operable Stage III cases. All Stage IV and a majority of Stage III were excluded from consideration, since they were not operated upon and therefore do not appear in the statistical report. The figures quoted for surgery in both cases represent the work of expert surgeons. It is important if a fair comparison is to be made that radiotherapy of an equally high standard be considered. For this purpose the figures from the recently published report from Manchester [2] may be used where it is reported that the five-year net survivals of cases treated in 1938 were as follows: Stage I 71%; Stage II 52%; Stage III 37%. Thus the average of Stages I and II which may be compared with Bonney's cases without lymph-node invasion is 54% against Bonney's 40%; and those in Stage III 37% against Bonney's 22%. Taussig's figure of 37% would have to be compared with the Manchester figure for Stage II of 52%.

cases have been saved by irradiation?'' Recurrences after either irradiation or radical surgery are notoriously disappointing in their treatment, and it is true to state that the time to treat a recurrence is before it has appeared!

Irradiation in the form of radium application and deep X-rays is applicable to the great majority of cases, but experience has shown that in some the growth appears to be radio-resistant, and after a preliminary healing, a breakdown occurs even after full irradiation. Koller's work on repeated biopsy during irradiation has shown that the radiosensitive and the radio-resistant growths can be fairly well distinguished during the comparatively early stages of radiotherapy. In like manner, it is accepted that the iliac and obturator glands vary in their reaction to the effects of deep therapy, and I can show specimens from patients on whom a Wertheim operation has been performed, following a full course of radium after the Stockholm method and succeeded by a full course of deep therapy, in which the cervix has healed perfectly, but in which the glands show active growth. The endocervical growth, whether columnar or squamous, appears to be particularly radio-resistant, and the presence of large fibroids or ovarian tumours, and especially of inflammatory disease of the appendages, contra-indicates radiation.

In the case of radical surgery, one is always up against the primary operative mortality, which of course cannot compare with the almost negligible risk of radiation. However, in a series of 500 cases, Bonney in his pioneer work had a primary operative mortality of only 14%—a truly remarkable tribute to his skill when it is recalled that he literally taught himself the operation and himself overcame all the difficulties which he has taught us to avoid, and he operated on practically every case that was technically possible. Recently we have had the advantages of routine blood and plasma transfusions, penicillin and the sulpha drugs, together with great advances in anæsthesia. These, together with the careful selection of patients for surgical treatment, can undoubtedly reduce the operative mortality to under 5%. In a series of over 200 consecutive Wertheim operations performed by my colleague Frank Cook or myself on Stage 1 and 2 cases only five patients failed to leave hospital or nursing home alive—mortality rate of 2·5%. It is not suggested that this figure is a tribute to exceptional operative skill. Indeed it is a tribute to the careful selection of cases for surgery, the judicious use of transfusion, the advance of anæsthesia and the care and co-operation of the nursing staff.

All my own cases had preliminary radiation in the form of at least one Stockholm dose of radium either seven days, or more, before operation, and the vast majority, about six weeks after operation, were subjected to a full course of deep therapy. In a few cases I have performed Wertheim's operation up to six months after full radiation by the Stockholm technique, and here again I can state that in the majority of such cases the operation had been made only slightly more difficult as a result of the preliminary irradiation. Pelvic sepsis is invariably the cause of the major difficulties.

The operation undoubtedly demands a reasonable degree of surgical competence, and should be completed within one and a quarter hours. After this time the condition of the patient deteriorates. Most of the cases selected are capable of completion in one hour, and many in under this time. The operator, I feel sure, should have served an apprenticeship with one who has had experience of the operation. Many appear to believe that the mortality rate is in the region of 25%—a completely fallacious figure in reasonably competent hands.

I submit that in our present state of knowledge, it is not in the best interest of the patient to embark on a fixed line of treatment by radiation or by surgery alone. Circumstances, in any case, may cause an alteration in the mode of attack. Generally speaking I feel that irradiation is the procedure of choice in the average case belonging to stages one and two. The following cases in these groups are, however, better treated by the Wertheim operation: (1) All endocervical growths. (2) Those in which biopsy shows radio-resistance. (3) Those in which ulceration recurs early after preliminary healing under irradiation. (4) Those in which the growth is complicated by the presence of large fibroids or ovarian tumours. (5) Those in which the growth is associated with pelvic inflammatory disease. (6) Where the patient refuses treatment by radiation. (7) Where the growth is in association with some congenital or acquired vaginal lesion making adequate irradiation impossible, e.g. vaginal stricture or double vagina.

Results of treatment.—In assessing the results of treatment, there is little doubt that a percentage of the patients who survive five years after irradiation are still literally dying of the disease due to the attenuated activity of the growth. A palpable mass or thickening in the pelvis of these patients is called ''fibrosis'' by the radiotherapy enthusiast, and ''growth'' by the surgical enthusiast. So often it is impossible to state dogmatically the true nature of this, and time alone makes the diagnosis certain one way or the other. I always feel that this tends to favour the figures showing the results of irradiation alone. After the radical surgical removal of a growth. the presence of a mass always signifies recurrence.

RESULTS OF WERTHEIM'S OPERATION AT THE CHELSEA HOSPITAL FOR WOMEN FOR THE YEARS 1936-1941 INCLUSIVE

	Stage 1	Stage 2	Stages 1 and 2
Number of cases treated..	34	20	54
Number alive at end of five years	14 — 41%	10 — 50%	24 — 44%
Lost in follow up	5	1	6
Number alive after five years excluding lost cases	14 — 48%	10 — 53%	24 — 50%
Operative deaths			3
Operative mortality			5·5%

Admittedly this is a very small series, but it does show that 54 consecutive Wertheim operations can be performed on Stages 1 and 2 cases by the various members of the staff with only three operative deaths. During the years 1936–1941 the cases for surgical treatment were not selected so conservatively as they are now, and in only relatively few cases was radiotherapy combined with surgery.

My own results of the combined approach are as yet too small in numbers and too recent in time to allow of useful analysis, but it is hoped at some later date to be able to show an improvement in the figures already shown.

I feel I must refer to the combined use of surgery and radiation in selected Stage 3 cases. On a number of occasions, after preliminary irradiation with the full Stockholm technique locally to the cervix, I have opened the abdomen, removed the appendages, and then performed a careful dissection of the iliac and obturator glands as in the Wertheim operation, but of course leaving the uterus in situ. This is followed by a full course of deep therapy. Time alone will assess the results, but to date the operative mortality has been nil.

The Radiological Treatment of Carcinoma of the Cervix Uteri

By G. E. RICHARDS, M.D.

(*Director, Ontario Institute of Radiotherapy;*
Professor of Radiology, the University of Toronto).

Recently a number of writers on the subject of the treatment of cancer of the cervix have disparaged the use of radiotherapy and in the United States a number of surgeons have advocated a return to surgical methods. J. V. Meigs [1] has made the statement that "the treatment of cancer of the cervix by radiation is at a standstill". It may, therefore, be profitable to inquire how the best results obtainable by surgery compare with the best results obtainable by radiotherapy and whether the available evidence supports the statement that radiotherapy is static.

I. COMPARISON WITH SURGERY

As has frequently been pointed out the work of Bonney in England and of Taussig in America provides, at least up to the present, the best results which have been attained by surgery. New methods of combating the post-operative complications of shock and infection may result in lowering the immediate death-rate following operation, but since the female pelvis does not lend itself to a true block dissection it will remain to be seen whether an improvement can be effected in end-results.

If a comparison is to be made of the results capable of being achieved by the two methods it is essential to compare the best results being secured by each. That this is not always done is evident from Meigs' paper already quoted in which, speaking of Taussig's operative results, the following statement is made: "Of 70 patients in Class II of the League of Nations Classification, 37% were living and well after five years. In a parallel group of 118 patients treated by radiation alone the five-year salvage was only 23%." The latter figure certainly does not represent the best results which may be secured by radiation, as will be shown presently. Bonney is reported to have operated upon 500 patients out of a total of approximately 900 diagnosed as cancer of the cervix. His five-year cure rate is stated to have been 40% for those in whom no glandular extension had occurred and 22% for those in whom lymph-node involvement was present—in other words, 40% for Stages I and II; 22% for operable Stage III cases. All Stage IV and a majority of Stage III were excluded from consideration, since they were not operated upon and therefore do not appear in the statistical report. The figures quoted for surgery in both cases represent the work of expert surgeons. It is important if a fair comparison is to be made that radiotherapy of an equally high standard be considered. For this purpose the figures from the recently published report from Manchester [2] may be used where it is reported that the five-year net survivals of cases treated in 1938 were as follows: Stage I 71%; Stage II 52%; Stage III 37%. Thus the average of Stages I and II which may be compared with Bonney's cases without lymph-node invasion is 54% against Bonney's 40%; and those in Stage III 37% against Bonney's 22%. Taussig's figure of 37% would have to be compared with the Manchester figure for Stage II of 52%.

Results in this institute.—Since 1929 there have been treated in this Institute 1,261 cases of cancer of the cervix, of which five-year figures are available in 756 cases. These results are shown in Table I indicating results similar to those quoted from Manchester. No doubt such figures are being obtained in most well-organized radiotherapy centres and provide a much more accurate figure for comparison than that quoted by Meigs.

TABLE I.—CARCINOMA OF THE CERVIX UTERI, 1929–1941

(*Net Survivals*)

		Living at end of					
Stage	No. cases	3 years		5 years		10 years	
I	80	67	83·8%	64	80·0%	29	72·5%
II	246	156	63·41%	132	53·66%	45	36·29%
III	289	105	36·33%	92	31·83%	23	20·90%
I, II and III	615	328	53·3%	288	46·83%	97	31·38%
IV	141	21	14·89%	13	9·22%	0	0%
Total All stages	756	349	46·2%	301	39·8%	97	29·1%

Average all cases:		
3-year survivals	349 of 756	46·2%
5-year survivals	301 of 756	39·8%
10-year survivals	97 of 333	29·1%
5-year survivals:		
Stages I and II	196 of 326	60·12%
Stage III	92 of 289	31·83%

In order to avoid misunderstanding the figures are given in the form of *net* survivals as in the Manchester report in Table I and also as gross survivals in Table II in which no deductions of any kind have been made.

TABLE II.—CARCINOMA OF THE CERVIX UTERI, 1929–1941

(*Gross Survivals—No Deductions*)

		Living at end of					
Stage	No. cases	3 years		5 years		10 years	
I	80	63	78·75%	57	71·25%	22	50·5%
II	246	150	60·98%	120	48·78%	36	29·03%
III	289	102	35·29%	84	29·06%	15	13·6%
I, II and III	615	315	51·22%	261	42·44%	73	26·25%
IV	141	17	12·06%	9	6·38%	0	0%
Total All stages	756	332	43·9%	270	35·71%	73	21·9%

Average all cases:		
3-year survivals	332 of 756	43·9%
5-year survivals	270 of 756	35·71%
10-year survivals	73 of 333	21·9%
5-year survivals:		
Stages I and II	177 of 326	54·29%
Stage III	84 of 289	29·06%

TABLE III.—CARCINOMA OF THE CERVIX UTERI

(*Comparison of Results by Surgery and Radiotherapy*)

	Stages I and II		Stage III	
	No cases	5-year percentage	No. cases	5-year percentage
Surgery:				
Bonney	500	40%	—	22%
Taussig	70	37%	—	—
Radiotherapy:				
Average of 9 clinics	2,233	41·4%	2,417	21·2%
Manchester 1934–38	340	45·2%	241	27·0%
Toronto 1929–41	326	60·12%	289	31·83%

It therefore seems a reasonable conclusion that radiotherapy is still superior to surgery by a substantial margin in those cases in which surgery is possible and has a very useful place in many cases in which surgery is quite impossible.

II

The second question in which we are interested is whether "the treatment of cancer of the cervix by radiation is at a standstill". A correct answer to this question should be equally interesting to gynæcological surgeons and to radiotherapists.

Table IV includes a tabulation quoted in full from Meigs' article, partly because it is an excellent compilation of figures from nine large clinics, both in Europe and America, but also because most readers will recognize the figures as being about fifteen years old and therefore as forming a suitable group for comparison with work of more recent vintage. Below have been added more recent figures from several centres representing present methods and results. On this basis it is apparent that quite substantial progress has been made in all groups except Stage IV. That an equally substantial improvement in the general average has not occurred may be explained by the fact that there is a widespread tendency to refer late cases to radiotherapy centres for the purpose of receiving palliative treatment and nursing care and the statistical tables are heavily and unfavourably weighted with such cases as a result. It is apparent in spite of this that definitely favourable progress has been made. The figures quoted would indicate an improvement up to 1938–40, of the order of 20% in Stage I; 15% in Stage II; 5–6% in Stage III and little or no change in Stage IV.

TABLE IV.—ANALYSIS OF RESULTS OF TREATMENT FOR CARCINOMA OF THE CERVIX

III

The next question is: "Can further improvements be looked for in the future?" We believe the answer is in the affirmative and that such improvements are to be found: (1) By an intensive campaign directed toward securing earlier diagnosis; (2) by improvements in the technical details of applying radium and its more skilful combination with roentgen therapy.

(1) *Earlier Diagnosis*

In most centres in which large numbers of cases are being treated it is still a discouraging fact that a majority of the cases being received for treatment are in the late stage when first seen. This in spite of fairly intensive educational campaigns designed to acquaint women with the symptoms of uterine cancer. We must, therefore, however reluctantly, conclude that this type of propaganda has failed up to the present and some new approach is urgently called for if we are to see more patients during Stages I and II when up to 75% of cures, or higher, may be expected. An effort to solve this problem has been under way in the United States for some years, where so-called "cancer prevention clinics" have been operated in New York and Philadelphia by Dr. Catherine MacFarlane. In these clinics patients having no reason to suspect the presence of cancer come for a physical examination at stated intervals. In her first 4,000 examinations Dr. MacFarlane is reported to have discovered two cases of cervical cancer, which low percentage would scarcely warrant the expense of setting up such clinics on a large scale.

The introduction of the Papincolaou smear method of cytological examination offers a method which can be carried out by the family doctor as a part of every physical examination, exactly as a urine and blood examination is now carried out.

Working under a grant from the Ontario Cancer Treatment and Research Foundation, Professor Edwin M. Robertson of Queen's University, Kingston, has conducted a trial of this procedure. Doctors throughout the district were provided with the necessary equipment and mailing tubes for containers. These containers hold a test tube with 95% alcohol, into which the discharge or fluid is injected by a special pipette. Sheets of instructions are supplied to each doctor and the containers are mailed in to the central laboratory. During the year 1946 Professor Robertson reports: "822 specimens of vaginal discharge were thus examined, and of this number two were found by this simple office procedure to be cancer, although the lesion was not visible to the naked eye on vaginal examination. The diagnosis was later confirmed by biopsy of the cervix. In 33 other cases of suspected or known cancer of the cervix (29) and uterus (4) the diagnosis was correctly made from the specimens sent in. In only one case was the diagnosis incorrect, but this specimen consisted almost entirely of blood and it was considered that the doctor had failed to observe careful technique in taking the specimen".

Here then is a simple office procedure no more difficult for the practising physician than a routine urinalysis and this test, as now carried out, has been proved to be 92% accurate, with the possibility of further improvement as experience is gained.

(2) *Improvements in Technical Details of Applying Radium and its More Effective Combination with Roentgen Therapy*

Several years ago we adopted the general principles described by Tod and Meredith in 1938 of calculating dosage with respect to those somewhat controversial Points A, B and S. We have modified the method slightly for our own use, but the chief difference has been in the routine use of roentgen therapy as a preliminary to the radium series. Since most of the lymph nodes in the pelvis lie close to the pelvic wall it is essential that a lethal dose for carcinoma be delivered at this point. Such a dose must be as close as possible to 5,000 r, which is not usually possible by means of radium alone in the form commonly employed, and not possible by roentgen therapy alone, short of excessive skin doses. Since 1938 the method used by us has included an intensive course of external irradiation by means of roentgen rays, followed by the radium series in three weeks' time. We believe there are advantages to be derived from the use of roentgen rays generated at 400 kV. as compared to 200 kV. in all cases except patients weighing not more than 120 pounds. A fuller discussion of this part of the subject has been published elsewhere (*Amer. J. Roentgenol.* In press). Table V gives the dosage which may be delivered at each of the important points within the pelvis. (Point C represents the side wall of the pelvis.)

TABLE V.—DOSAGE DELIVERED BY ROENTGEN THERAPY

No. of portals	Dosage in "r" (in air) per portal	Point A	Point B	Point C	Point S
6	1,800	2,970	2,970	3,150	1,870
6	2,100	3,460	3,460	3,660	2,180
6	2,400	3,960	3,960	4,190	2,490

Radium therapy.—In the past there have been several objections to the type of applicators available for the treatment of cervical carcinoma.

(1) *Inflexibility:* This criticism would be applied to metal applicators in which the intra-uterine and vaginal radium are combined, i.e. most T-shaped metal applicators.

(2) *Insecurity:* This is a very serious criticism and applies to corks, colpostats, boxes and almost all multiple applicators held in place by packing. A radiograph taken a few hours after the insertion of such applicators is usually very disillusioning if one is greatly concerned about accuracy.

(3) *Danger to personnel in handling:* Very few applicators at present in use have been so designed that all handling during loading and most of the manipulation in placing the applicator in position during treatment may be done by means of forceps.

Description of New Type Radium Applicator.—In an attempt to overcome some or all of these objections we have designed an applicator which we believe has certain advantages. It consists of two end-pieces in which the radium is loaded, which are separated from each other by a bridge or spacer. The end-pieces follow the design originally described by Paterson and Parker and conform to the shape of the field of intensity around any radium source. Originally, these were in the form of hollow shells of spun brass, chromium plated, and in the centre of each is a platinum-iridium tube of 0·5 mm. wall thickness. This tube may be made of any size of thickness to carry any radium loading which may be decided upon. A cover is provided which is so designed that in loading it can be raised and lowered entirely by instruments. The most recent model of this applicator is made of nylon which entirely eliminates all metal parts, is strong and rugged in use and may be sterilized by boiling. Nylon has a molecule composed of carbon, hydrogen and nitrogen, all elements having the same atomic numbers as tissue, and has the further advantage of being free from impurities of high atomic numbers such as frequently occur in rubber (i.e. sulphur, &c.).

The bridge or spacer is provided with apertures into which a "fork" is fitted during the manipulation of placing the applicator in position against the cervix. Once in place the applicator is locked and is under complete control of the operator and may be placed and held in any position desired. Light packing is inserted merely for the purpose of keeping the tissues out of contact with the instrument. The distal end of the controlling "fork" protrudes from the vaginal orifice and is fastened to a belt which the patient wears throughout the treatment. (A self-retaining catheter is inserted before the belt is finally adjusted, and suitable pads are used for protection.) (Shown in figs. 1, 2 and 3.)

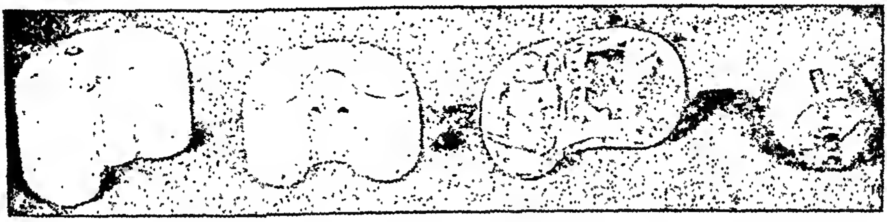

FIG. 1.—Photograph showing the four sizes of vaginal applicators described.

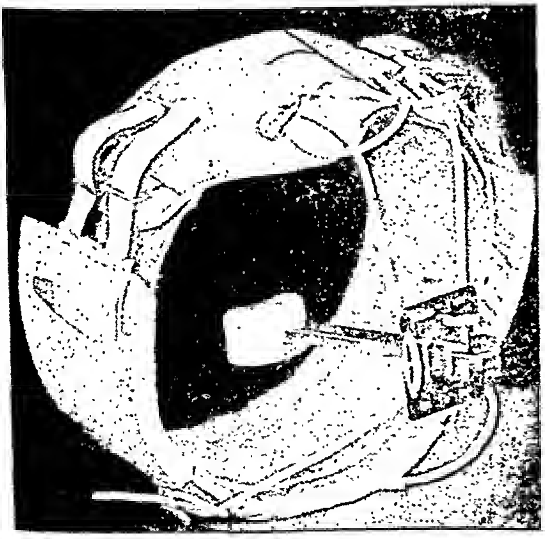

FIG. 2.—Applicator and belt as used, showing fork and method of fixation.

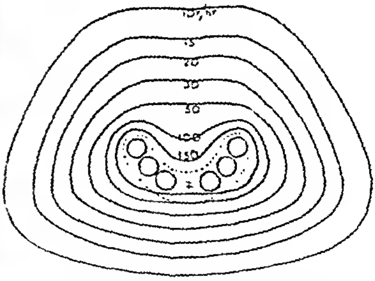

FIG. 3.—Curves showing distribution around the vaginal applicator described.

1–10 mg. tube with 1 mm. Pt filtration in each pocket. Total radium in applicator – 60 mg. Total filtration of each 10 mg. source – 1·5 mm. Pt.

Note the flattening of the intensity posteriorly, although in this case no added filter is used.

Once in place this applicator cannot slip from the position in which it is placed in any direction whatever, either towards either side or, perhaps even more important, cannot either tip over, facing the bladder and rectum (which is without doubt the most common cause of cystitis, proctitis and recto-vaginal complications), or be partially expelled. Four sizes of the applicator are available and provide amply for the requirements of individual selection and make provision for radium sources ranging from 10 mg. in each end of the applicator to as high as 90 mg. in each end. This could be increased (by altering the filter and making use of some of the new radio-active substances) up to ½ gramme of radium in each end of the applicator, if such a change in method can be shown to have any advantages.

Protection of the rectum.—In the past one of the most troublesome complications in the treatment of cervical carcinoma has been due to proctitis, either during or following the completion of therapy. Measurements made with conventional applicators show that in most cases in which adequate dosage has been delivered the dosage reaching the recto-vaginal septum has usually been above 5,000 r, which is about the tolerance limit of the rectal mucosa. In the applicator here described the rectum is protected by means of a special built-in filter. In the present applicator the material used for this filter is either gold, platinum or lead, but in the future and as soon as it becomes available metallic uranium will be used for this purpose, as suggested by Professor W. V. Mayneord. Owing to its very high atomic weight this metal is especially suitable for the purpose. By this means the intensity of radiation reaching the rectum can be reduced 25–30%, or even more if desired, thus permitting the use of as high dosages in the parametrium as these tissues will tolerate.

The intra-uterine applicator is a simple tandem in rubber tubing as, in our experience, this, by reason of its greater flexibility, tends to ease of insertion.

Dosage.—The dosage in each individual case is determined by a calculation (with apologies to all physicists) which takes into consideration the dose which has already been delivered by means of roentgen therapy.

If the plan of treatment has all been charted prior to the commencement of the roentgen series the dosage of radium required will be known and will be the amount required to build up the total to that which is lethal for cancer, or to the tolerance limit of the pelvic tissues.

Some indication as to the degree to which the individual tumour may be expected to respond will have been gained during the roentgen series, or at least prior to the administration of the radium, and this will influence the loading of the radium applicators as well as the total dose delivered. In an average case the intra-uterine tandem would carry 40 mg. enclosed in 1 mm. platinum filter, while the vaginal applicator already described would be loaded with 30 mg. in each end filtered by 1·5 mm. platinum. Under these conditions 3,500 mg.hrs. will be delivered in 87½ hours. Thus the decision to be made is whether this is sufficient or whether either the roentgen dose should be increased or that of the radium. Having reached this decision it would be modified in actual practice only in case the patient fails to tolerate the roentgen therapy well.

TABLE VI.—DOSAGE DELIVERED BY RADIUM THERAPY (IN ROENTGENS)

Type of applicator	No. of mg.hrs.	Point A	Point B	Point C	Point S
Intra-uterine tandem (40 mg.)	3,000	3,690r	780r	420r	250r
”	4,000	4,920	1,040	560	320
”	4,200	5,170	1,100	590	350
”	5,000	6,150	1,300	700	400
Intravaginal (2 × 30 mg.)	3,000	1,050	570	360	1,800
”	4,000	1,400	760	480	2,400
” . .	4,200	1,470	800	500	2,500
”	5,000	1,750	950	600	3,000

Final total dosage.—The final totals are added and recorded on a form, and while it is recognized that from the physicist's point of view there are objections to such additions, yet in practice the advantages are very great and permit a degree of dosage control not otherwise possible. In a busy department, with constantly changing personnel. such control is absolutely essential in order to reach and maintain a high technical standard and avoid serious injuries.

Intravaginal roentgen therapy.—Several writers, notably Merritt of Washington, have advocated the use of intravaginal roentgen therapy as a substitute for radium. Having tested this procedure out very thoroughly over the past six or eight years, we are convinced that although it has a useful place in the treatment of cervix carcinoma, it is not a "substitute" for radium. Merritt's most recent figures show a considerably lower five-year cure rate than may be obtained either by radium alone or by the combination of roentgen therapy and radium as described in this paper.

If our experience is an accurate guide it would indicate that the proper field for intravaginal roentgen therapy is in the advanced case with complete occlusion of the cervical canal or actual destruction of the cervix where the intracervical or intra-uterine application of radium will be impossible. Our present routine calls for this procedure in most Stage IV cases and selected cases in Stage III, where it is combined with external roentgen therapy and carried to a total vaginal dose of 3,000 r, using X-rays at 200 kV., filtration 0·2 mm. Sn., H.V.L. 1·9 mm.Cu. As will be evident from the statistics here reported the five-year survivals have not been improved to any very marked degree, although many cases have shown very gratifying degrees of healing by this method.

SUMMARY

(1) The results of treatment of cervix cancer by surgery and by radiotherapy have been compared. Radiotherapy is still producing substantially better five-year results and is applicable to a much higher percentage of the total cases.

(2) Results by radiotherapy in 1,261 cases here reviewed, of which 756 are over five years, were:

Net Survivals		Gross Survivals (no deductions)	
Stage I	80·0%	Stage I	71·25%
Stage II	53·66%	Stage II	48·78%
Stage III	31·83%	Stage III	29·06%
Stage IV	9·22%	Stage IV	6·38%
Average for all cases	39·8% 5 years 29·1% 10 years	Average for all cases	35·71% 5 years 21·9% 10 years

(3) The evidence indicates that definite progress has been made during the past ten years and means are available by which further improvement should be achieved in the future. Some suggestions by which this may be brought about are offered.

(4) A new type radium applicator is described which appears to have certain advantages in the technical application of radium to the cervix.

This paper includes quotations from an article on the same subject, accepted for publication by the *American Journal of Roentgenology*, to which acknowledgment is made.

Mr. G. W. Blomfield, (*Medical Director, Sheffield Radium Centre*): In the treatment of carcinoma of the cervix uteri the average figures for five-year cures of all cases seen in large centres range around 25% for radiotherapy, and for surgery it is less. The failures and the complications from radiotherapy result mainly from: (1) Recurrence or persistence of growth. (2) Radiation damage.

Recurrence.—A true recurrence may take place in a precancerous lesion which may persist after the growth is cured. Most "recurrences" are examples of persistence of growth. The site of the recurrence may be local or distal.

Local "recurrence" almost invariably occurs if patients default treatment after receiving only one-third or one-half of the planned therapy. If full dosage is given local cure may result, provided local spread is not too extensive, in which case it is, of course, difficult to get a homogeneous dosage high enough to be lethal to the primary growth.

Distal "recurrences" are likely to occur whenever there are distal metastases or metastases outside the area treated to high dosage. Remote "recurrences" are at present avoidable only by getting patients under treatment before remote metastases arise.

Anatomically the problem is different for different stages of growth. The Stage I case with growth limited to the cervix is a comparatively simple problem. Provided the whole of the cervix is treated adequately, and the cervix will certainly take a very high radiotherapeutic dose, a cure should result. It is the Stage II and Stage III cases which present the difficult problems and Stage IV cases which present problems at present insuperable.

Briefly, the treatment problem resolves itself into the following parts: (*a*) What to treat. (*b*) What doses should be given to these areas. (*c*) By what technique we may best achieve these dosages to these areas.

Factors such as dosage rate, fractionation and overall time all have a bearing on biological effect.

In the more advanced stages of the disease there is usually an irregular area involved from the cervix into the parametrium and over the vaginal vault, and the dosage of all areas likely to be involved is liable to be insufficient by ordinary techniques without exceeding tolerance dosage in some important adjacent organ such as bladder, bowel or ureter.

The reasons for these insufficiencies are as follows: (*a*) It is difficult to assess the exact spread of the growth. (*b*) The possible areas affected are in close relation to important structures such as rectum, bladder and ureters and dosage to these structures must be safe. (*c*) Anatomical variations and the alterations consequent upon disease make standard distribution of radium and constancy of dosage impossible.

Possible Sites of Damage

Vaginal mucosa.—The vagina tolerates very high dosage itself. Ordinary techniques commonly used give 15,000 r locally without causing much more than adhesions and contractions. High dosage associated with sepsis or with damage to bowel or bladder is dangerous.

Rectum.—This is exposed to danger in two places: (1) High up—near pelvi-rectal junction, where it may be in close relation to the pouch of Douglas or cervix. (2) In its relation to the posterior vaginal wall.

Bladder.—This is exposed to maximal dosage at the base and may undergo late necrosis with fistula formation. More commonly a telangiectasis arises visible on cystoscopy, usually harmless, but sometimes causing recurrent hæmaturia.

Ureters.—These are further out than commonly supposed. They are about 3 cm. from the mid-line and approximately 1 cm. lateral to the point A (defined below), as they pass the cervix to sweep forwards and inwards towards the trigone. They are seldom damaged by the irradiation itself and rather by growth or fibrosis and sepsis than by radio-necrosis.

Small intestine and pelvic colon.—These viscera come in close relation to the fundus uteri, the posterior uterine wall and occasionally to the pouch of Douglas and cervix uteri, with consequent high dosage at times.

Bearing in mind possible damage to these areas cases have been collected at Sheffield for data regarding the incidence of consequent complications, and then dosage was assessed in roentgen units at the sites where damage was known to occur.

Using three treatments over two or three weeks the safe tolerance doses would appear to be in accordance with the following table:

Structure	Tolerance locally in roentgens
Rectum	4,000
Base of bladder	5,000
Bowel in contact with posterior uterine wall or fundus	5,000
Vaginal vault	12,000 to 15,000

Careful analysis of the cases for dosage where radiation damage resulted showed that these tolerances had been exceeded in such cases. Damage attributable to radiation did not occur otherwise.

Physical problem.—Once the ideal dose distribution has been decided on clinical and biological lines, it is then possible to work on the technique with a view to obtaining this. The classical Stockholm and Paris techniques each represent such an attempt. The Manchester technique [1] is a modification of the Paris one, using different timing and modified colpostats, and the dosage system adopted there aims at giving a fixed limit to the point A in the pelvis, defined in position as 2 cm. lateral to the mid-cervical line and 2 cm. above the vaginal vault. The point B at the same level and 5 cm. from the mid-line is taken as an outlying point to which as high a dose as possible should be given without exceeding the fixed limit at A. Neary [2] in 1943, showed that the system of pushing the radium as far out laterally as possible did not necessarily give the highest ratio of dosage B to A. Additional screenage of one sort or another has been employed on and off since the early days when bismuth packing was tried. In 1944 I used a lead applicator with two radon sources placed centrally. By this means it was possible to give relatively large dosage as measured in milligramme hours without causing rectal damage, the lead being mostly situated between the radon sources and the rectum. Neary has designed a two-source platinum applicator to which the uterine radium can be fixed in position and this delivers a fairly constant dose across the pelvis. It has been tried clinically by Mr. Malcolm Donaldson.

Single-source vaginal applicator.—This is a single vaginal source placed centrally in the mid-line and shielded by platinum to diminish dosage to bladder, rectum and the pouch of Douglas. The first applicator designed consisted of a central sphere of platinum, 3 cm. in diameter, hollowed out so that there was 1 cm. screenage of the rectum and ½ cm. screenage of the bladder, the radium being placed centrally. Ports cut through the sphere allowed free radiation to the fornices and out to the parametria on each side. At Mr. Donaldson's suggestion the radium was loaded on the end of a rod to be inserted after positioning of the applicator. The applicator is held in position by a handle and special belt fixed to the patient. Perspex spaces of different sizes are used to pack off the vaginal wall and diminish the dosage immediately over the ports where screenage is minimal, and this takes the place of the packing ordinarily used with standard techniques. The shielding of the pouch of Douglas was found to be important in the earlier work using two radon sources and this was arranged for. The ideal direction for the beams issuing through the ports was determined by taking a number of measurements on cadavers, to determine the direction from the radium source at the centre of the sphere to the parametrium and adjacent pelvic wall so as to include likely extensions of growth.

A second and more versatile appliance was designed later to give the same essential protection to the rectum and bladder but allow movement of the sphere which could be rotated through 45 degrees in the sagittal plane to enable adjustment of the beams to meet varying clinical requirements. It also allowed for replacement of platinum screenage in the direction of the cervix by brass or aluminium, a detachable cap being used. This enabled good dosage to be delivered to the cervix and uterus when no uterine radium could be inserted and it has proved of great value, the 45 degree adjustment enabling the cervix and uterus to be effectively irradiated in these cases even when there is anteversion or retroversion.

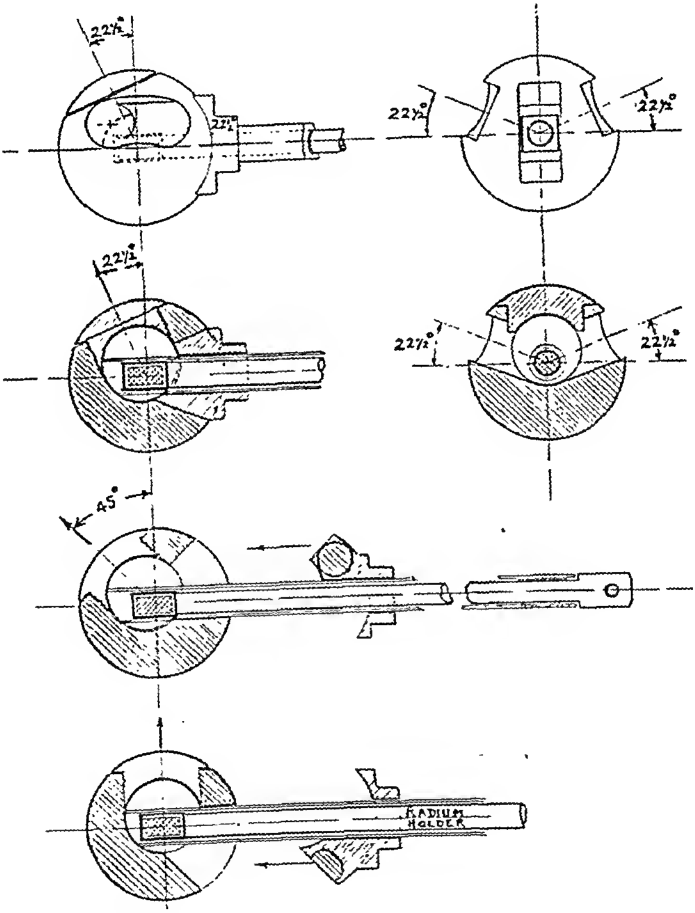

Fig. 1 illustrates the mechanism of the applicator in elevation and cross section. The radium, when inserted, lies in the centre of the sphere and the lateral beams are directed slightly upwards and backwards as shown. The platinum cap when replaced by aluminium permits the use of a vertical beam which can be rotated through 45 degrees in the sagittal plane and directed to the uterus, as shown in the diagram.

Fig. 2 illustrates how the applicator is assembled. The spacers shown can be of different sizes, the largest size which can be easily inserted is used, and the treatment time should be adjusted to give approximately uniform dosage on the outer surface. The wedges fix the sphere in position and allow adjustment of the beams. The instrument is precision made and will only assemble with the handle the right way up so as to ensure correct alignment. When the radium holder is screwed home the radium is exactly central.

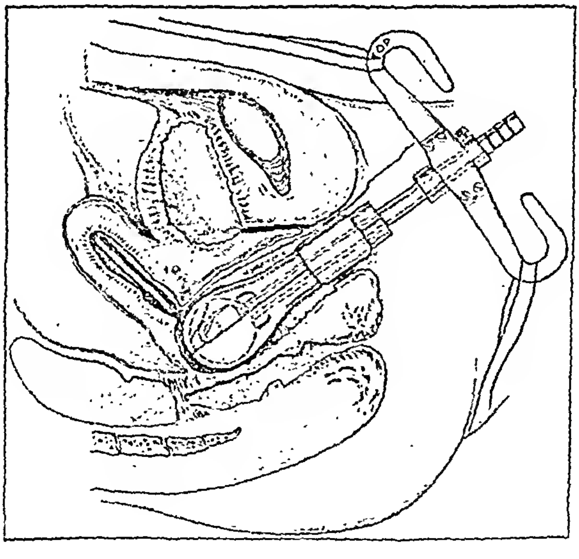

Fig. 3 shows the applicator and uterine radium in position and the anatomical relationships as viewed in sagittal section.

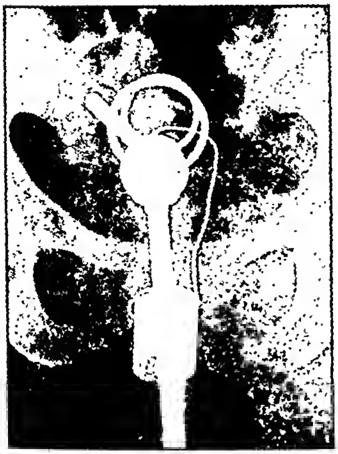

FIG. 4.

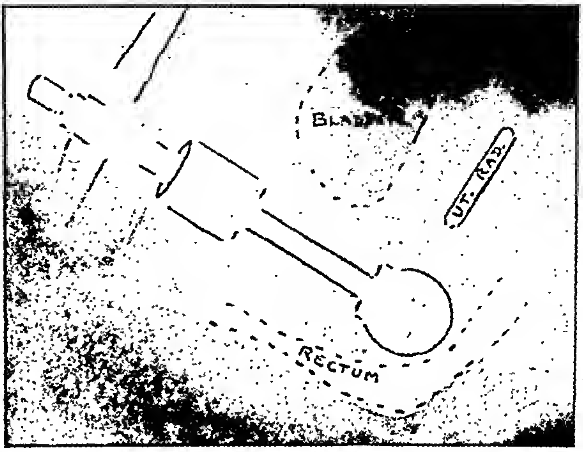

FIG. 5.

Figs. 4 and 5 show radiographs of the applicator in position. In fig. 5 the rectum has been injected with opaque medium and the bladder with air; the rectum showing in white and the bladder as a dark shadow. In fig. 4 the rings are outside the patient and are there to facilitate accurate analysis of stereoscopic radiographs.

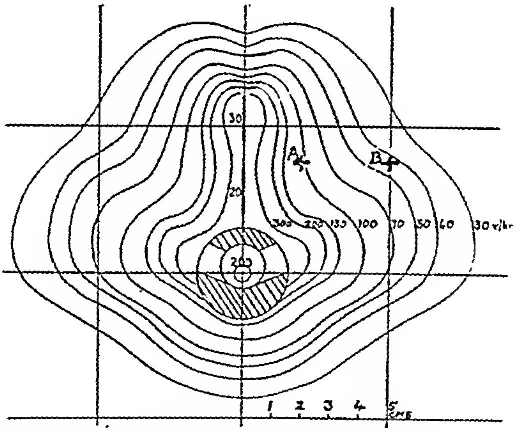

Fig. 6 shows isodose curves calculated for the applicator in conjunction with a 50 mg. uterine source, and illustrates well the slow falling off in radiation towards the parametrium and pelvic wall. Point A shown on the diagram is 2 cm. above the vaginal vault and 2 cm. lateral to the mid-line of the uterus. Point B is on the same level but 5 cm. out from the centre of the uterus towards the pelvic wall. Full physical data showing isodose curves for comparison with other techniques would require numerous illustrations. These and other details can be supplied on request.

The dosage system at present adopted aims at keeping within tolerance to vagina, bladder, rectum, pouch of Douglas and uterine surface, and generally speaking this allows vaginal radiation to 10,000 mg.hrs. using a 200 mg. source of pure radium in addition to uterine radiation of approximately 2,400 mg.hrs. Graphic methods are used for the rapid calculation of dosages to rectum, bladder and other important structures. The vaginal radium can be inserted and removed without disturbing the appliance or moving the patient but the actual dosage given should depend upon the size of the spacers used and the relative position of uterine radium and vaginal applicator as shown on the antero-posterior and lateral radiographs taken with vaginal radium out to avoid fogging.

[*October* 6, 1947]

DISCUSSION ON ANTERIOR POLIOMYELITIS

Mr. K. I. Nissen: *Poliomyelitis on St. Helena*, 1945-6.

Towards the end of 1945, the remote community on St. Helena suffered a severe outbreak of poliomyelitis, a disease unknown on the island within the memory of its oldest inhabitants. In 1836, however, Sir Charles Bell mentioned an epidemic fever among the young children on St. Helena, followed in all cases by "a want of growth in some part of their body or limbs". This may be the earliest reference to epidemic infantile paralysis in the English literature [1].

The following brief account of the epidemiological features of the recent outbreak is given with the kind permission of Dr. Wilson Rae of the Colonial Medical Service. In October 1945 I had spent a few hours on the island *en route* from South Africa by transport. When the epidemic was at its height, Dr. Rae, on Professor H. J. Seddon's suggestion, secured my immediate release from naval service and a quick return to St. Helena for a stay of six weeks.

THE ISLAND AND ITS POPULATION.—St. Helena is situated in the South Atlantic Ocean roughly 16° South and 6° West (*see* Map). It has an area of 47 square miles and is of volcanic formation. The principal feature is a semicircular ridge of mountains rising to 2,700 feet, part of the weathered rim of a great crater. From this ridge steep valleys stretch in all directions; many contain small streams, and springs of good water are abundant. The island is everywhere mountainous, the sea-face being generally formed by cliffs several hundred feet in height. The only practicable landing place is on the leeward side from an open roadstead at St. James' Bay, where in normal times one Union Castle vessel anchors each month.

Climate, vegetation and supplies.—The climate is healthy and temperate owing to the constant south-east trade wind. The rainfall reaches 40 inches in the hills, but on the lower slopes it is derived from light drizzles and is of little value.

The coastal zone is mainly rocky and barren except for prickly pears. The middle zone is partly under grass, with some small areas under afforestation. The central zone is largely under flax, which affords the main industry. Agriculture is on a small scale, with less than 5 acres under irrigation. All grain and flour are imported. The main foodstuffs of local origin are potatoes, bananas, yams, fresh vegetables and plums. During the war there was rationing of meat, rice, fats, sugar and latterly flour. The small fishing industry provides an important source of protein mainly from the albacore or tunny, but catches are variable and distribution is uneven. Half the small supply of cow's milk is consumed by Europeans. Bread, potatoes and fish are the staple articles of diet among the islanders, with sweet tea as a beverage.

The population.—A recent estimate was 4,000. Of these the British in the garrison numbered less than 200, with a similar number in Government service and commerce. The remainder, here called "islanders", are of mixed extraction, mainly from the East Indies, West Africa and Great Britain. In peacetime there is a steady exodus to domestic service and industry in South Africa, while recruiting into the British Army abroad has begun. The proportion of children therefore tends to be high.

The wartime garrison, housed in barracks at the top of Ladder Hill, included about 70 island recruits. Local enlistment ceased in the middle of 1944, and a number of men had returned to civilian work on the island.

Towns, roads and housing.—The capital, Jamestown, is situated at sea-level in the length of a narrow valley, and has 1,500 inhabitants in its crowded houses. Apart from villages at Half-tree Hollow, Longwood, and round the cable station at The Briars, the island homes are widely scattered. The

This form of applicator has now been in use for sufficient time to assess its clinical possibilities and used on these lines it is safe. It gives known dosage which can be accurately calculated, and it presents the advantages mentioned, including the possibility of giving effective cervical dosage when uterine radium cannot be inserted. It appears likely that this form of technique or something similar using heavy metal screenage will eventually replace the more classical techniques employing boxes, colpostats or pessaries.

For the clinical trials 200 mg. beam unit tubes were used for convenience. It is now proposed to use a 125 mg. vaginal source for routine work in conjunction with uterine sources of 20 mg. in the upper uterine tube, and 10 mg. in the lower uterine tube for the average-sized uterus. The treatment is given in two applications.

My thanks are due to Dr. H. Miller, M.A., Ph. D., F.Inst.P., Senior Physicist to the Sheffield National Centre for Radiotherapy, for his invaluable help and his patience in calculating and measuring isodose surfaces, and to Messrs. Johnson Matthey & Co. Ltd., who manufactured these applicators, for which they have had to make special jigs and templates. I am also indebted to the Medical Research Council for meeting the cost of the applicators and to the National Radium Commission and the National Radium Trust for the radon and the pure radium, without which this work could not have been carried out.

Mr. Frank Cock (*London*): Every case of carcinoma of the cervix should be treated by a combination of methods. Each case should be assessed in accordance with its merits and with the local and general condition of the individual patient.

With regard to surgical treatment, I do hope Mr. Read has proved to your satisfaction that the danger to life of Wertheim's operation has been grossly over-stated. The post-operative mortality in skilled hands and in selected cases, with modern accessories, should be inconsiderable.

I have long been convinced that, pending future discoveries and developments, the best treatment for carcinoma of the cervix consists of (*a*) radical hysterectomy plus deep X-ray therapy or of (*b*) radium plus deep X-ray therapy, in accordance with the features of the individual case. (I cannot see the point of combining the vaginal and intra-uterine application of *radium* with radical hysterectomy, as it seems to me that they cover more or less the same field.) In the former group I suggest that a preliminary course of deep X-ray therapy should be followed by a radical hysterectomy ten days or a fortnight later. The operation should be followed by a full course or courses of deep X-ray therapy as soon as the patient is fit to undergo such treatment. This implies that surgical and radiological facilities ought to be available in the same institution or in immediately adjacent hospitals. The patient must not have to wait in a queue for admission from one hospital to another at a distance. My second main group, involving a combination of radium and X-ray therapy, I leave of course to the expert radio-therapists. This group consists, in my view, of cases that are inoperable, and possibly of some *very* early cases.

I have been most highly impressed by Professor Subodh Mitra's exposition, by his amazing dexterity, by his honesty of statement and by his good results. But I do submit that it is impossible to extirpate by the vaginal route the obturator glands and those glands which are so closely attached to the great iliac veins. Those of us who perform Wertheim's operation are well aware how frequently these glands are affected.

In radio-therapeutic technique the excellence of the results of Dr. Gordon Richards and Dr. Blomfield, and their promise of still further progress in this direction, are most encouraging and inspiring.

Let us beware of too much de-centralization in future planning. The essence of the whole matter lies in co-operation. Sooner or later it is inevitable that large radio-therapy centres will be established in the various regions—possibly at a considerable distance from the main centres of population and from the large general and gynæcological hospitals. One cannot but feel that the surgeon, and perhaps even clinicians in general, will play a very subsidiary part in these highly specialized institutions. I do therefore recommend most strongly that *every* form of relevant therapy should be represented at or very near to the general or gynæcological hospital, where the exponents of each and every method may confer and combine in the treatment of all cases of cancer before these cases are finally transferred. I would further dare to suggest that a clinician, not necessarily a surgeon, should control the situation throughout: we are treating a patient, not merely a neoplasm.

who developed symptoms thirty-one days later and died. This young woman continued on friendly terms with members of the garrison after his visit of some two hours.

The transport embarked a mixed contingent of British and St. Helena troops. Among the former was an artillery sergeant who reached his family in Ealing on October 29. Eleven days later his daughter developed severe poliomyelitis and when admitted to Clayponds Isolation Hospital was the first patient from the district for over a year. The father could not recall any personal illness like an abortive attack.

It is unlikely that the garrison provided the source of infection. Just before and during the epidemic the garrison was free from cases of obscure pyrexia, and in any case ample opportunity for any transmission of infection had occurred since the last overseas reinforcements three months previously.

It does appear significant that the first case, a fulminating one, was visited by a person less than a week out from South Africa, an endemic area. Though the suggested incubation period of thirty-one days is remarkably long, it is still less than the thirty-five days considered to be the upper limit by American workers [2]. In crowded Jamestown, however, the visit mentioned could not be regarded as an "only possible exposure". The Ealing infection was also compatible with the presence of carriers on board the transport.

Spread of the epidemic (Table I).—After the first death a few apparently trivial cases of illness were not recognized at first as poliomyelitis. A boy of 5 with fever and generalized spasm and twitchings was thought to be suffering from the common Ascaris infection, but developed a temporary facial palsy. A boy of 10 had obscure pain in the left axilla, and the lower half of the pectoral muscle was later found paralysed. A labourer, the only case admitted to hospital with a diagnosis of influenza, had paresis of the deltoids which was not recorded for a few days. But on November 29, eleven days after the first death, a second patient gravely ill was admitted and died on December 1, a day on which a number of obvious cases reported. The first phase, lasting a fortnight, was now over. The epidemic reached a peak in the next two weeks, and then subsided to spend itself gradually over a period of six weeks. I arrived by H.M.S. *Shiel* from Capetown on December 23 and sailed again on February 1.

TABLE I.—TO SHOW INCIDENCE OF CASES BY WEEKS

		Nov.		Dec. 1945				Jan. 1946					Feb.
Week ending		21	28	5	12	19	26	2	9	16	23	30	6
Fatal ..	(11)	1	1	4	2	1	1	0	1	0	0	0	0
Paralytic	(66)	3	6	22	14	7	6	2	1	2	2	0	1
Abortive	(140)	0	3	48	52	14	9	6	2	3	2	1	0
Totals	(217)	4	10	74	68	22	16	8	4	5	4	1	1

The epidemic list in order of onset showed intervals of nine and twelve days between the first Jamestown case and the first cases in the neighbouring areas of Half Tree Hollow and The Briars. The intervals for first infections in the distant Longwood and Sandy Bay areas were thirteen and seventeen days. Graphs for the three main districts showed a marked time lag in the Sandy Bay area, from whence came, as expected, the majority of late cases.

Method of spread.—The living traffic between Jamestown and the outlying districts is almost confined to adults and donkeys. There are long stretches of barren road, so that flies and rats are unlikely vectors. The only fresh foodstuffs distributed to the periphery are bread and fish. The latter may be carried exposed for long distances, but the epidemic lacked the explosive character associated with contamination of food. Water supplies are from numerous fresh sources. Milk is brought always into Jamestown. There was in fact no evidence to conflict with the opinion that the spread was commonly by contact with adult carriers.

CLINICAL FEATURES.—The symptoms and course of the illness were fairly typical and it is not proposed to make detailed comments. There were two noteworthy signs however.

The colour of the tongue was noticed to be characteristic by Dr. Lee and his colleagues early in the epidemic. Despite the pyrexia the tongue was moist and not furred. Its general

60 miles of roads passable to motor traffic are mainly steep and stony. Traffic goes mostly by foot or donkey, and to a small extent by motor vehicle.

The typical island house consists of a row of two to four small rooms, each with an outside door. The walls are of stone with mud plaster and the woodwork suffers badly from the ravages of ants. Overcrowding is common and frequently gross. A Government building scheme is in progress but has not advanced enough to affect the acute shortage of houses. Water is obtained by hand from the nearest water tank or spring. Night-soil is collected in buckets, but the stony ground makes disposal difficult. Conditions in Jamestown, however, are much better with regard to water supply and drainage. The common pests are the house-fly and the rat. Domestic gardens are either absent or small.

Conditions preceding the epidemic.—The conditions on the island at the time of the epidemic were unusual. Drought was affecting all areas, with failure of the potato and vegetable crops. Low stocks of flour had made strict bread rationing necessary. There was clinical evidence of vitamin-B deficiency and little doubt that the average intake of vitamin C was below normal. A small epidemic of anthrax in cattle had subsided, though recently enough for many islanders to use the same word for cases of poliomyelitis.

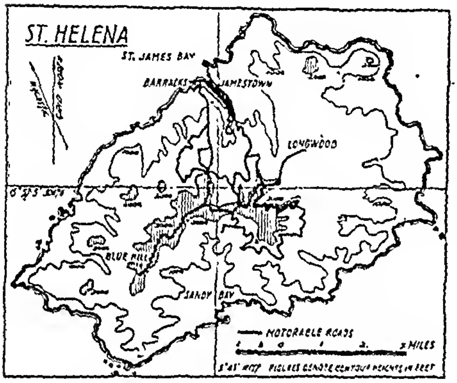

FIG. 1.—Contour map of St. Helena, showing geographical features and main roads in heavy lines.

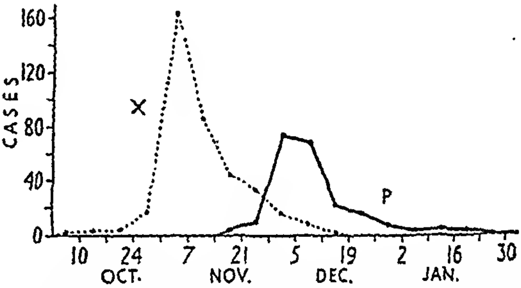

FIG. 2.—Graph to show incidence by weeks of "Influenza" (X) and of Poliomyelitis (P), abortive cases included.

Two weeks previous to the first case what was regarded as the annual outbreak of influenza had reached a very high peak (*see* Graph). Most of the 385 cases had fever with headache, general aches and pains and a sense of weakness in the limbs; only one was admitted to hospital with this diagnosis. The outbreak had not subsided when the epidemic began, and it is probable that there were some cases of cross diagnosis between "influenza" and abortive cases of poliomyelitis. Apart from the single case mentioned above, no case labelled influenza attended later with a specific muscular paralysis. This and the interval of three weeks between the peaks of the two infections suggest that the earlier outbreak was not a carrier wave, though it may in some way have prepared the ground for the coming epidemic.

THE COURSE OF THE EPIDEMIC.—On the evening of November 14, 1945, the first patient, a woman of 25, was taken ill in Jamestown with malaise and vomiting. This continued the next day, but the added fever, headache, backache, irritability and drowsiness were thought to be no more than symptoms of influenza. When seen first by a medical officer on the 16th, signs at the right base and a respiratory rate of 40 led to a provisional diagnosis of pneumonia with septicæmia. Typical paralysis of the legs and respiration developed, however, and the correct diagnosis was made before death.

Possible sources of infection.—To anticipate, there is no doubt that the strain of virus was one to which the islanders were highly susceptible and the European population almost immune. The last ship to call before the onset of the first case was H.M.T. *Reina del Pacifico* bound for Liverpool from Durban and Capetown with 2,800 persons on board. The passengers were mainly Service personnel, together with 350 women and children, for whose medical care I was chiefly responsible. Poliomyelitis was common in South Africa at this time. Apart from a few cases of measles the voyage was uneventful and no fresh invalids were transferred to hospital at Liverpool on October 28.

The transport lay off Jamestown on October 14. Several small parties of officers went ashore, myself included, but only one of the other ranks, a corporal who had previously been stationed in St. Helena. He obtained permission to visit his fiancée, the first patient, *Incubation periods.*—A few cases of value from this aspect occurred early in the epidemic.

(*a*) Short and (?) only possible exposure. The long period of thirty-one days for the first case has already been discussed.

(*b*) Maximum exposure. The Ealing case developed after eleven days. A patient and a clerk in the Civil Hospital developed severe infections twelve and eighteen days respectively after the admission of the first case.

(*c*) Minimum exposure. The second fatal case developed after the whole family had been isolated for four days.

METHODS OF CONTROL.—As soon as succeeding cases of obvious poliomyelitis were diagnosed, the disease was made notifiable, hospital treatment was made free, and measures restricting congregations of people were adopted. The schools being already closed from "influenza", church services and cinemas were discontinued, and gatherings of more than four persons, whether in shops, public houses or vehicles, were forbidden. The garrison was confined to barracks, a measure which many of the soldiers had already adopted. A review of the restrictions suggests that in view of the probable high susceptibility of the islanders, the stern warning of the first fatal case would have justified immediate action. All restrictions were lifted on January 26, by which time the epidemic had subsided. Certificates of fitness were required of all children returning to school, and this gave an opportunity to detect unreported cases of paralysis.

SUMMARY

The St. Helena epidemic of poliomyelitis affected a virgin island population. It commenced in Jamestown in November 1945 and after some delay spread to the outlying districts. There was some evidence that the virus was introduced from South Africa, an endemic area. The incubation period of the first case may have been thirty-one days. The highest incidence occurred in the three age-groups between 5 and 19. Abortive cases numbered two-thirds of the total and, when included, gave an all-over rate of recorded infection of 5·4%. Seventy-seven cases were paralysed, giving an attack rate of 19·2 per thousand. Eleven fatal cases gave a death-rate of 14·3% of all paralytic cases.

3 AGIUS, T., BARTOLO, A. E., COLEIRO, C., and SEDDON, H. J. (1945) *Brit. med. J.* (i), 759.

Dr. L. J. Maurice Laurent: *Acute meningo-encephalitis of undetermined virus ætiology.*—During a short period of seven weeks in the summer of 1946, 13 cases of an acute infection of the nervous system of an unusual type were admitted to the Park Hospital with the diagnosis of cerebrospinal fever. Judging from the clinical picture and the pathological findings, they were apparently instances of one and the same disease. All but one recovered, the fatal case died in coma on the sixth day of the illness.

History of sudden onset with headache and fever. The symptoms became worse during the next few days and admission to hospital occurred usually between the fourth and sixth days. *On admission*, the clinical signs of meningitis were evident in all. 7 were alert, 4 listless or drowsy and 2 unconscious. No rash of any kind. *Cranial nerves:* Fundi and ears normal in all. There was strabismus in 2, nystagmus in 2, transient deafness in 1, facial paralysis of supranuclear type in 6. *Plantar reflexes* flexor in 6, unilateral extensor in 5, bilateral extensor in 2. *Tendon-jerks*: Lost in 2, otherwise normal or exaggerated. Never any weakness or flaccid paralysis of any muscles of trunk or extremities on admission and afterwards. All abnormal neurological signs disappeared in fourteen days or less. No sequelæ have been observed. Pyrexial course variable, from six to twelve days.

Pathological findings and investigations.—Cerebrospinal fluid: clear or faintly opalescent, often with a fine clot on standing. Cells 40 to 800, 80 to 100% mononuclears. Protein 60 to 160 mg%. Chlorides always normal. Always bacteriologically sterile. X-rays of chest and nasal sinuses and also serum and blood tests revealed nothing abnormal. Specimens of the cerebrospinal fluid from 9 patients were examined by Dr. Findlay by animal inoculation and culture for the presence of a virus and all results were negative. Specimens colour was a cold bluish-grey, the shade obtained by pouring milk into blackcurrant juice. But round the margins small macules like flea-bites appeared and sometimes became confluent. These findings persisted for some two weeks, and were constant in all cases with paralysis. During the course of the epidemic very few "positive tongues" were seen in persons with no symptoms of infection. But at Longwood on January 29, Dr. Duncan examined 49 school children, all of whom were house contacts, and found that 27 had the type of tongue described.

The odour of the fæces was also characteristic. Several patients volunteered that the odour was offensive, like rotting vegetables, or like flax waste. The nursing staff in particular noticed the change from normal as many patients required enemata. The odour was independent of consistency and persisted for several days after the fall in temperature.

Age, sex and race (Table II).—Reference to Table II shows the very low incidence in children up to 5 years. No case was detected under one year, and there was only one case of severe paralysis in the whole of the first five-year period. The brunt of the infection fell on the three next five-year periods, with most deaths in the 15-19 age-group.

TABLE II.—TO SHOW AGE-INCIDENCE BY FIVE-YEAR PERIODS, AND SEX INCIDENCE

Age-Groups		0–4	–9	–14	–19	–24	–29	–34	–39	–44	–49	M.	F.
Fatal	(11)	0	1	2	5	0	2	0	1	0	0	3	8
Paralytic	(66)	5	19	13	15	8	2	1	3	0	0	38	28
Abortive	(140)	16	33	34	31	12	6	4	3	0	1	60	80
Totals	(217)	21	53	49	51	20	10	5	7	0	1	101	116

A striking contrast is afforded with the civilian epidemic in Malta, when 397 cases of paralysis occurred under 5 years and only 29 above that age [3]. Corresponding figures here are 5 and 61.

The only European patient was a girl of 10 living at the cable station who had an abortive infection. All others were islanders.

Abortive cases.—Abortive cases were numerous and well defined clinically. The epidemic list totalled 217. This included 11 deaths and 66 cases of paralysis. The remainder, 140, or roughly two-thirds of the total number, were cases with the criteria of infection but no definite paralysis. Many showed general weakness and inability to sit up for two or three days. Those cases admitted to hospital were quite indistinguishable from pre-paralytic cases. Two typical patients had lumbar puncture performed and cell counts of the order of 20 and 70 were found.

By no means all the abortive cases reported, as a number were treated in their homes with island remedies. The current out-patient organization, however, kept down the number of patients so missed. Cases presenting insufficient criteria to warrant inclusion in the epidemic list were fairly numerous.

The profusion of abortive cases became a serious problem. Thus an expectant mother, thought to have a mild infection, was sent home where she died. On the other hand many patients who proved abortive had to be admitted, especially from outlying districts, and retained in the crowded Civil Hospital till the risk of paralysis was over.

Deaths.—Fatal cases numbered 11, i.e. 14·3% of the total paralytic cases. The average time of death from the onset was 4·3 days, with limits of one and eight days.

Paralytic cases.—These totalled 66. With fatal cases included, the attack rate for paralysis was the high one of 19·2 per 1,000. By January 31, 28 cases remained paralysed and requiring orthopædic attention. The distribution of paralysis was a common one, with arms affected rather more than trunk muscles, and paralysis in the legs exceeding the total of other regions. Unilateral facial paralysis was observed in 5 cases, but was either transient or partial.

An estimate of the final extent of paralysis is as follows, counting severe paralysis of one limb or of the trunk muscles as a unit:—

3 to 4 units—2 cases; 2 to 3 units—6 cases; 1 to 2 units—5 cases; less than 1 unit—15 cases.

Incubation periods.—A few cases of value from this aspect occurred early in the epidemic.

(*a*) Short and (?) only possible exposure. The long period of thirty-one days for the first case has already been discussed.

(*b*) Maximum exposure. The Ealing case developed after eleven days. A patient and a clerk in the Civil Hospital developed severe infections twelve and eighteen days respectively after the admission of the first case.

(*c*) Minimum exposure. The second fatal case developed after the whole family had been isolated for four days.

METHODS OF CONTROL.—As soon as succeeding cases of obvious poliomyelitis were diagnosed, the disease was made notifiable, hospital treatment was made free, and measures restricting congregations of people were adopted. The schools being already closed from "influenza", church services and cinemas were discontinued, and gatherings of more than four persons, whether in shops, public houses or vehicles, were forbidden. The garrison was confined to barracks, a measure which many of the soldiers had already adopted. A review of the restrictions suggests that in view of the probable high susceptibility of the islanders, the stern warning of the first fatal case would have justified immediate action. All restrictions were lifted on January 26, by which time the epidemic had subsided. Certificates of fitness were required of all children returning to school, and this gave an opportunity to detect unreported cases of paralysis.

Dr. L. J. Maurice Laurent: *Acute meningo-encephalitis of undetermined virus ætiology.*—During a short period of seven weeks in the summer of 1946, 13 cases of an acute infection of the nervous system of an unusual type were admitted to the Park Hospital with the diagnosis of cerebrospinal fever. Judging from the clinical picture and the pathological findings, they were apparently instances of one and the same disease. All but one recovered, the fatal case died in coma on the sixth day of the illness.

History of sudden onset with headache and fever. The symptoms became worse during the next few days and admission to hospital occurred usually between the fourth and sixth days. *On admission,* the clinical signs of meningitis were evident in all. 7 were alert, 4 listless or drowsy and 2 unconscious. No rash of any kind. *Cranial nerves*: Fundi and ears normal in all. There was strabismus in 2, nystagmus in 2, transient deafness in 1, facial paralysis of supranuclear type in 6. *Plantar reflexes* flexor in 6, unilateral extensor in 5, bilateral extensor in 2. *Tendon-jerks*: Lost in 2, otherwise normal or exaggerated. Never any weakness or flaccid paralysis of any muscles of trunk or extremities on admission and afterwards. All abnormal neurological signs disappeared in fourteen days or less. No sequelæ have been observed. Pyrexial course variable, from six to twelve days.

Pathological findings and investigations.—Cerebrospinal fluid: clear or faintly opalescent, often with a fine clot on standing. Cells 40 to 800, 80 to 100% mononuclears. Protein 60 to 160 mg%. Chlorides always normal. Always bacteriologically sterile. X-rays of chest and nasal sinuses and also serum and blood tests revealed nothing abnormal. Specimens of the cerebrospinal fluid from 9 patients were examined by Dr. Findlay by animal inoculation and culture for the presence of a virus and all results were negative. Specimens of serum at different stages of the illness were also examined for the development of antibodies against the virus of choriomeningitis and all results were negative.

Some of the clinical features of the two comatose cases are worthy of special mention.

The first was a boy of 4 years, admitted on the fourth day in a semiconscious condition. The next day his temperature was 105°, he could swallow a little reflexly but could not be roused, there were no convulsions, no cyanosis. The pupils were moderately dilated and reacted sluggishly to light. The tendon-jerks were all brisk, the left plantar response was extensor and remained so for three weeks. He regained consciousness four days after admission, remained irritable for a week, and was discharged after forty-five days without any sequelæ.

The fatal case was a girl of 15. While home on the third day of illness she had a generalized convulsion lasting twenty minutes. She recovered consciousness, could speak and swallow but remained dazed. On the fourth day she had another generalized convulsion lasting one hour and did not regain consciousness. She was admitted in coma with jerky movements of all four limbs, she could swallow reflexly slowly. T. 104·8°. Pupils equal, dilated, reacting sluggishly to light. Right facial paralysis, of the lower part of the face only. Abd. reflexes and tendon-jerks absent. Right plantar response extensor; left not obtained. Heart, lungs, urine, blood chemistry, nil abnormal found. Blood culture sterile. Twelve hours later coma deeper, pupils fixed, respirations shallow and rapid, colour dusky, P. 140. Continuous O_2 administered and 50% glucose I.V., the colour improved but the coma was unchanged. She died sixteen hours after admission.

In neither case was there evidence of anoxæmia previous to the onset of the coma or of the convulsions. The changes in the cerebrospinal fluid were similar to those of the other eleven cases.

Post-mortem examination of the fatal case showed intense congestion of the pia mater over the convexity of the brain and cerebellum, some generalized œdema of the brain, no purulent exudate, no hæmorrhage.

Microscopical examination showed intense infiltration of the leptomeninges over the whole of the nervous system by large mononuclear cells especially over the parietal cortex and the cerebellum, small areas of perivascular cuffing with the same type of cells in the pons, mid-brain bulb and region of the basal ganglia and similar but less marked changes in the spinal cord.

Dr. Findlay carried out exhaustive investigations with specimens of this case. Serum, cerebrospinal fluid during life and selected parts of the nervous system after death were inoculated into mice, guinea-pigs, rabbits, and rhesus monkeys. All animals remained normal.

The 13 patients came from scattered areas all over London. The youngest was 2 years old, the others between 4 and 39. No two cases came from the same household, but Dr. Conybeare in his field investigations found instances of undiagnosed febrile illness in two of the contacts of one of our patients. Not one of the 13 had been in contact with a recognized case of poliomyelitis. The clinical and pathological findings amount to this: acute sterile lymphocytic meningitis in all, symptoms of encephalitis in some, confirmed post mortem in one.

Ætiology.—I think one can safely exclude a bacterial infection and assume that a neurotropic virus was in operation. Since Wallgren's [6] publication in 1924, the existence of "aseptic" (meaning thereby non-bacterial) lymphocytic meningitis has been well recognized. Numerous examples of this condition, mostly benign, have been described, but it is evident that it never constituted one ætiological entity. The viruses of mumps, of herpes zoster, of poliomyelitis, of encephalitis lethargica, of vaccinia, of measles, &c., and, since 1934, that of Armstrong and Lillie's [1] choriomeningitis of murine origin, more recently that of glandular fever, that (or should I say those) of atypical pneumonia have all been shown to give rise at times to meningitic manifestations with lymphocytosis of the cerebrospinal fluid. One is therefore forced to the conclusion that "aseptic lymphocytic meningitis" is only the common pathological denominator of a large number of virus infections of the nervous system, and in every instance the exact ætiology has to be determined by either (1) the isolation and identification of the virus, or (2) the assessment of the clinical features and the epidemiological associations.

Dr. Findlay's totally negative findings excluded choriomeningitis in view of the facility of infecting mice with the cerebrospinal fluid, and in the one fatal case made poliomyelitis improbable. On clinical grounds: post-infectious encephalitis, encephalitis lethargica (owing to the absence of sequelæ), also glandular fever and atypical pneumonia were all most unlikely. Poliomyelitis did not suggest itself to us at the time as not one of the 13 cases had been a contact of the disease and only one case of poliomyelitis had been admitted during the same period.

In the summer of 1945 an outbreak of febrile illness associated with lymphocytic meningitis in the South-east of France was reported by Sohier and Gaubert [5] and by Brunel [2]. Recently Jennings [4] has described a number of cases of a similar illness which occurred in North-West Middlesex about the same time as ours. Not one of these authors could incriminate any specific virus with certainty.

During the present epidemic of poliomyelitis in the months of June, July and August 1947, at the same time as 24 paralytic cases, 18 patients with lymphocytic meningitis presenting no clinical evidence of lower motor neurone involvement either in brain stem or cord, were admitted. Of these 18 cases, one was unconscious four days; another, alert and conscious, had myoclonus and acute cerebellar ataxia. They all recovered without paralysis or sequelæ, and I must admit that clinically they were indistinguishable from the cases seen in the summer of 1946. Rather than postulate two viruses, it is generally assumed, and probably correctly, that these unusual cases are also due to the poliomyelitis virus with clinical manifestations at different levels of the nervous system, or alternatively, that the present virus is a new strain with a different method of attack.

Diagnosis based on epidemiological prevalence is often unsatisfactory. Between 1910 and 1913, cases of lymphocytic meningitis in Paris were credited to the virus of poliomyelitis which was then prevalent. In 1922, in Stockholm, however, they were attributed to the virus of encephalitis lethargica. Looking back on our cases of 1946, the only way that poliomyelitis could have been recognized as the offending virus would have been a systematic search for it in the fæces of the patients. The short supply of monkeys, however, precluded such a large-scale investigation. Systematic search for the virus in the stools of poliomyelitis patients, of subclinical cases with or without lymphocytic meningitis and even of their contacts has been carried out in America and has shown a very high proportion of positive results [3].

The need for some rapid and easy method of identifying viruses is becoming every day a pressing problem. In the absence of help from the virus expert, the clinician faced with an isolated case or a series of cases of primary lymphocytic meningitis or meningo-encephalitis must base his diagnosis on a fine calculation of probabilities.

Dr. Douglas McAlpine: *Some observations on the* 1947 *outbreak of acute poliomyelitis.*—As a result of the outbreak of poliomyelitis this year we must anticipate a higher annual incidence of the disease than heretofore, with the probability of epidemics from time to time. The total number of cases of poliomyelitis and polio-encephalitis notified this year up to the present time exceeds 6,500; the corrected figure is probably less than two-thirds of this total. It has become increasingly clear that cases occur all the year round, an important epidemiological point. A preliminary estimate from the Ministry of Health suggests that at least 20% of all notifications have been over the age of 15, a fact which confirms the upward trend in the age-incidence in other countries. The mortality figure has been a low one, probably below 10%. There is a close similarity between the constitutional symptoms of the abortive case and the prodromata that usually precede the non-paralytic and paralytic forms. This fact suggests that in the majority of individuals symptoms subside without any evidence of invasion of the nervous system. The cerebrospinal fluid is normal. The virus may be isolated from the throat and stools of such cases. This constitutes the *abortive* form. The same remark applies to carriers, but they remain symptomless. Less frequently meningeal symptoms and signs develop and the cerebrospinal fluid shows changes; this is the non-paralytic form. Lastly, in a comparatively few individuals paralysis ensues. The symptoms which should suggest an abortive attack in contacts are headache, shivering, malaise, vague body pains and fever. To all or some of these may be added catarrhal symptoms (sore throat, coryza) or gastro-intestinal symptoms (nausea, vomiting, diarrhœa).

Non-paralytic form.—As far as I can judge this form of the disease has been common, but there has been much variation in the intensity of meningeal signs. I would include under this heading those cases which, in addition to signs of meningitis, also show nystagmus but no evidence of paresis. Despite the typical picture of meningitis, the cerebrospinal fluid may be normal; such cases should during an outbreak be labelled "abortive".

The paralytic form.—It is well known that the clinical picture of poliomyelitis may vary, not only from epidemic to epidemic, but also during the course of a single epidemic. Furthermore, clinical and histological data have made it clear that although the virus shows a high degree of neurotropism for the motor cells of the cranial nerves and spinal cord, other constituents of the nervous system may not be spared. These facts go far to explain the somewhat varied clinical picture which may be met with in this disease. The present epidemic has shown no clinical features that have not been encountered in previous outbreaks in other countries, so that a description of the various types of spinal paralysis need not detain us. Rarely pyramidal signs in one or both lower limbs are associated with wasting in upper limb muscles or of intercostals and abdominal muscles, or more rarely of a muscle group in a lower limb. Sensory symptoms such as numbness or tingling may be prominent at the onset but sensory loss is transitory. Pyramidal signs and temporary sensory phenomena, though definitely uncommon, may occasionally occur in the spinal form of the disease.

Polio-encephalitis.—The signs are mainly those of a brain-stem encephalitis, but clinically and histologically higher levels of the nervous system may be affected. A somewhat unusual feature of the cases that have occurred during the past year has been a marked degree of drowsiness and mental confusion during the first few days of the illness. In my experience the commonest sign of polio-encephalitis is nystagmus. All types may be seen. It may be the only sign signifying invasion of the central nervous system; however, other signs of polio-encephalitis or spinal paralysis are usually present. During this epidemic the presence of nystagmus, photophobia and neck rigidity in a patient who has been ill for a few days with headache and fever was considered sufficient evidence for the diagnosis of polio-encephalitis although, as I have indicated earlier, in the absence of other signs, the diagnosis of "non-paralytic poliomyelitis" might be preferable. I have seen some cases with a rare form of ocular disorder which may occur alone or may be associated with emotional instability, marked tremor of the head and mild cerebellar signs.

I owe to Dr. MacKenzie, Superintendent of Groby Road Fever Hospital, Leicester, the opportunity of seeing this condition for the first time. The following is a brief résumé of the case:

M. T., female aged 13, was taken ill on September 12 with headache, low back pain and fever. During the next four days she was feverish, sleepless and delirious. September 17: Admitted to hospital. The most striking feature of the case was a gross rotatory nystagmus-like movement of the eyes accompanied by a tremor of the head. The upper limbs were tremulous, but other cerebellar signs were not conspicuous. C.S.F., 17 lymphocytes per c.mm. Protein 0·15 gm.%. On September 22 she was mentally alert, not obviously emotional and complained only of the tremor of her head. The pupils were dilated but reacted normally. There were no ocular pareses. On looking straight forward no abnormality was evident, but on the slightest movement of her eyes laterally or upwards to fix an object, the following signs appeared: (1) A coarse side-to-side tremor of both eyeballs which was maximal at first and then after a few seconds suddenly ceased even though the eyes remained fixed on the object, a feature which distinguished the condition from true nystagmus. (2) Synchronous with the eye movements and occurring simultaneously with them was a coarse side-to-side tremor of the head; this ceased at the same moment as the eye movements. Speech was normal as were the remaining cranial nerves. Except for a mild tremor of the hands on voluntary movement and slight ataxia of the left lower limb, cerebellar signs in the limbs were not conspicuous; however, gait was not examined as the patient was in bed. The deep reflexes were normal and the plantar responses were flexor.

I have seen further examples of this condition limited to the eyes. Dr. Strickland in a recent letter to the *Lancet* has described three cases showing a minor degree of the same disturbance and suggests the term "prefixation nystagmus". A case similar to the one to which I have referred was described by Marmion and Sandilands. It may signify an unusual strain of virus.

Pyramidal signs are not unusual in polio-encephalitis, an exaggerated jaw-jerk being sometimes the first sign of their presence. Associated with nystagmus and pyramidal signs, or occurring independently of them, may be found paresis of one or more of the motor cranial nerves of which the seventh is the most vulnerable. Every variety of cranial nerve palsy from an ophthalmoplegia to mild or severe bulbar paresis has been noted in the present epidemic.

Cerebrospinal fluid.—I wish to refer to two features of the cerebrospinal fluid which have not been uncommon during this outbreak: (1) A relatively normal or normal cell count; (2) a marked increase in the protein content of the fluid. In paralytic cases which I saw overseas during the war I estimated that in approximately 5% there was a normal cell count during the active stage of the disease. The combination of a low cell count and a high protein in poliomyelitis has been reported on many previous occasions.

Differential diagnosis.—The number of neurotropic viruses which attack man appear to be on the increase, but we have no knowledge of the extent to which they have invaded this country. From the continuous presence of fresh cases of post-encephalitic Parkinsonism we can assume that epidemic encephalitis is endemic in this country. However, with the virus of poliomyelitis well established a brain-stem encephalitis is much more likely to be due to this virus than that to endemic encephalitis. The majority of the cases of virus encephalomeningitis which Jennings reported from North-West Middlesex last year, had features identical with the cases of polio-encephalitis which have appeared in the London area this summer. Dr. Laurent's series of cases would also appear to fall into the same category. Unless there is good proof to the contrary, a diagnosis of polio-encephalitis should be made in any case of brain-stem encephalitis if accompanied by meningeal signs. Similarly, the commonest cause of an acute benign lymphocytic meningitis is likely to be the virus of poliomyelitis. However, it is obvious that the complexity of the subject calls for the placing of adequate facilities at the disposal of those who are working on virus research in this country.

In conclusion, I would submit that if we are to progress in our knowledge of poliomyelitis up to and beyond the point already reached by American workers, the following steps amongst others should be taken: (1) The provision of a liberal supply of animals suitable for experimental work on poliomyelitis and encephalitis. (2) The training of teams of field workers who should be at the disposal of the Ministry of Health for the purpose of investigating each fresh outbreak of the disease.

Dr. F. O. MacCallum stated that suspensions of the brain and cord from 8 fatal cases of poliomyelitis and polio-encephalitis from various parts of the country had each been inoculated intracerebrally into a single rhesus monkey. Four monkeys inoculated with material from Belfast, Manchester, Carlisle and London had developed typical poliomyelitis and four had shown no sign of illness. A small number of specimens of acute and convalescent sera from recent cases of poliomyelitis had been examined for neutralizing antibody to the Lansing mouse-adapted human strain of poliomyelitis. No antibody had been detected in these sera.

Dr. H. Stanley Banks discussed the number and character of the 1946 cases of "benign lymphocytic meningitis" at the Park Hospital. In view of the 1946 experience, he could not exclude the possibility of an unknown virus being responsible for at least some of this year's non-paralytic cases with meningeal reactions, and suggested that "*primary* lymphocytic meningitis" should be made notifiable by hospital medical staff.

Dr. W. H. Kelleher: The Western Hospital received a high proportion of bulbar types of poliomyelitis (30%) in the earlier weeks of the epidemic and in a few of these there was some drowsiness. In one case, with marked cranial nerve disturbances and mid-brain and cerebellar involvement, there developed deep unconsciousness for a comparatively brief period—less than twenty-four hours. There was no doubt left in the minds of those who observed our cases that they were poliomyelitis and that in no case could a suspicion of meningo-encephalitis of other virus ætiology be sustained.

In only one-half of the 170 cases admitted to the Western Hospital this year could the diagnosis of poliomyelitis be confirmed. Of the first 66 genuine cases only 33% were under 5 years, 40% were between 5 and 15 years and 27% were over 15 years. Those with paresis or paralysis of a limb or limbs amounted to 63%, which compares favourably with the 91% of this type of case admitted in 1938—the previous highest incidence year. More significantly, only 19% had an upper and lower limb or limbs affected as compared with 56% in 1938. 30% of our cases showed disturbance of cranial nerves. Facial paralysis was noted in 8% (1% in 1938). Considering the number with bulbar lesions we were fortunate in meeting with not more than two patients with involvement of the vital centres, both of whom died. The number of cases with paralysis of diaphragm and/or intercostals was appreciably less than in 1938, which was in conformity with the lessened incidence of spinal lesions in general.

Dr. M. Mitman: Mr. Nissen mentioned the outbreak of influenza which preceded his epidemic of poliomyelitis. The close association of one virus disease with another or of one virus disease with a bacterial one might have profound epidemiological significance. Surveying well-known associations, Dr. Mitman mentioned the pneumococcal, streptococcal and other bacterial infections complicating such virus diseases as the common cold, measles, influenza and smallpox, and contributing materially to their fatality; the activation of febrile herpes by pneumonia, meningococcal meningitis and other diseases; but his chief interest lay in the epidemiological importance of the common cold as a precursor of epidemics of bacterial and virus diseases. A "cold" was a recognized antecedent of a number of diseases and, in trying to assess its importance, it was essential to distinguish 3 similar syndromes: First, a common cold of virus ætiology; secondly, the prodromal coryzal symptoms of the disease proper; and, thirdly, the illness of infection. Is there an illness of infection due to the specific organism of the disease or does this preliminary febrile disorder represent a different infection? Could it, for example, be a "common cold" capable of influencing the invasion of the individual and the herd with the specific organism? In the individual there is evidence that a "cold" can prepare the soil for invasion by the specific organism. In the herd it could allow the more ready dissemination of the specific organism through a large number of hosts, and in this way allow an epidemic variant to appear and to spread. It is likely that such a variant is a necessary preliminary to many epidemics. In poliomyelitis interest in this connexion devolves upon the dromedary type of temperature and the significance of the upper respiratory symptoms associated with the first pyrexial hump. Are they due to an illness of infection (and therefore possibly due to a different infection), or are they prodromal symptoms of the disease proper? He accepted the latter view, but felt that outbreaks of respiratory infection, like the influenza reported by Mr. Nissen, preceding epidemics of nervous disease, were worth close study.

Dr. Jan Jaworski said that in Poland he had treated 2 cases of poliomyelitis by injecting 3-6 c.c. of the patient's own blood subcutaneously over the region of C. 3 and 4 and again over L. 3 and 4.

Both patients were cured by six injections.

This treatment was similar to that which he had employed with success in the treatment of herpes zoster.

A paper on Acute Anterior Poliomyelitis by Sir ALLEN DALEY (Section of Medicine, November 25, 1947) will appear in the January *Proceedings*.
